Dr Newell received his degree from Harvard Medical School in 1896. He was professor of clinical obstetrics emeritus, Harvard Medical School and Massachusetts General Hospital, a member of the American Gynecological Society and a fellow of the American Medical Association.

A sister survives.

PATTERSON — William F Patterson, M.D., of Medford, died on February 23. He was in his eighty-third year.

Dr Patterson received his degree from Tufts College Medical School in 1895. He was a fellow of the American Medical Association.

PEASE — Lewis W Pease, M.D., of Weymouth, died on March 17. He was in his seventy-fourth year.

Dr Pease received his degree from Tufts College Medical School in 1902.

His widow survives.

SEWALL — Edgar F Sewall, M.D., of Somerville, died on March 22. He was in his sixty-fourth year.

Dr Sewall received his degree from Tufts College Medical School in 1913. He was a fellow of the American Medical Association.

His widow, a son, a daughter, six grandchildren and a brother survive.

BOSTON MEDICAL LIBRARY

PORTRAIT OF SAMUEL DANFORTH

The portrait of Dr Samuel Danforth (Harvard College, 1758), Paul Revere's physician, by Gilbert Stuart, owned by the Boston Medical Library, has been placed on exhibit in the Colonial Gallery of the Museum of Fine Arts through the courtesy of Mr G H Edgell, director of the Museum. The portrait is on a temporary loan to the Museum. It is considered one of the better examples of the work of Gilbert Stuart.

MISCELLANY

MEDICAL DIRECTOR OF RED CROSS NATIONAL BLOOD PROGRAM

Dr Louis K Diamond, of Boston, has been appointed full-time medical director of the Red Cross National Blood Program. While discharging his new duties he will be on temporary leave of absence from the Children's Medical Center and the Harvard Medical School.

WATER POLLUTION CONTROL BOARD

Water-pollution control, for which an Act was passed by the Eightyeth Congress, is gradually reaching the stage where definite action may be anticipated. The six non-Government members of the Water Pollution Control Advisory Board

have recently been appointed by the President, and in March the five Government members were selected by Federal Security Administrator Oscar R. Ewing.

The Board will assist in planning a program to support and promote technical research in water-pollution problems, "to provide federal technical services to State and inter-State agencies and to industries and to provide financial aid in the formulation and execution of projects for abatement of stream pollution."

CORRESPONDENCE

STUDY OF MATERNAL MORTALITY

To the Editor: Will you be so kind as to publish the following letter in a forthcoming issue of the *Journal*?

To the Hospital Administrator

The Committee on Maternal Welfare of the Massachusetts Medical Society under the chairmanship of Dr. Duncan E. Reid, obstetrician-in-chief of the Boston Lying-in Hospital and professor of obstetrics at the Harvard Medical School together with the Division of Maternal and Child Health of the Massachusetts Department of Public Health, is initiating a five-year program for the study of all maternal deaths in Massachusetts as of January 1, 1949.

The Department of Public Health is financing this project through funds made available by the Children's Bureau and is vitally interested in obtaining the wholehearted support of this program from hospital administrators, all staff members of hospitals, and all practicing physicians in the Commonwealth.

For Worcester and all hospitals west of Worcester, the obstetrician in charge of this program will be Dr. Arthur F. G. Edgelow, 76 Maple Street, Springfield. His telephone number is Springfield 4-3926. For the eastern part of the state, which includes all cities and towns east of Worcester, Dr. Luke Gillespie, 1180 Beacon Street, Brookline, telephone Longwood 6-7773, will be in charge of the program.

Doctors Edgelow and Gillespie will assign an obstetrician to investigate promptly all maternal deaths which occur in the hospital or at home during pregnancy, delivery, or postpartum. These maternal deaths should be reported by telephone to either Doctor Edgelow or Doctor Gillespie immediately and should include the name and address of the patient, date of delivery, date of death, place of death, and the name, address, and telephone number of the physician who cared for the patient.

It is suggested that any physician who is in doubt as to the procedure should contact either Dr. Edgelow or Dr. Gillespie.

We would appreciate it very much if this letter could be read at your next regular staff meeting and then posted on your bulletin board. Enclosed duplicate is for your personal files.

Should there have been a maternal death in your institution since January 1 which has not been reported, would you please report it to either of the two obstetricians named above.

By direction of the Commissioner,
RICHARD P. MACKNIGHT, M.D., Director
Division of Hospitals

Commonwealth of Massachusetts
Division of Hospitals

LUKE GILLESPIE, M.D.

1180 Beacon Street
Brookline 46, Massachusetts

REGARDING MORAL PROBLEMS

To the Editor: I agree with Dean Sperry in his article in the *Journal* of December 23 when he says that life is sacred.

Why, may I ask, is life sacred? The answer must be that it is created by God—otherwise our premise does not hold. There, I think, we have the answer to the problems of both birth control and euthanasia.

Who are we to say when God shall give His gift or when He shall take it away? We boast of our scientific advances,

which have resulted in a tremendous decline in maternal morbidity and mortality and also in a greatly increased life expectancy, and yet we find groups of physicians and clergymen advocating both birth control and euthanasia. To me it is not logical.

I believe that in matters of morals and ethics we should see things as black and white and not in shades of gray. In such matters we ought to be guided by the Ten Commandments rather than by the passing custom of the day.

MARGARET C. McMANAMY, M.D.

Orange, Massachusetts

LOWER-NEPHRON NEPHROSIS VS EXTRARENAL AZOTEMIA

To the Editor: Dr. James H. Townsend, in his reply to the letter of Walter Hollander, Jr., in the February 10 issue of the *Journal*, states that the distinction between extrarenal azotemia and lower-nephron nephrosis is largely an academic one. "We chose to call the disease extrarenal azotemia. If Mr. Hollander chooses to call it lower-nephron nephrosis, I should not object."

It appears to me that there are clinical and pathological differences between the two conditions.

Clinically, edema is an infrequent finding in extrarenal azotemia. In a review entitled "So-Called Extrarenal Uremia. A study of twenty cases," in the *American Journal of Medicine* (5:574-585, 1948), Murphy et al., eliminating cases in which vomiting was one of the major complaints, disclosed that in spite of more than an adequate fluid intake, orally and parenterally, edema occurred in only 2 cases. One patient had a + ankle edema due to heart disease, and the other had portal cirrhosis as demonstrated at autopsy. In lower-nephron nephrosis, edema generally develops, its severity depending upon the extent to which fluids had been pushed, as pointed out by Strauss in his study "Acute Renal Insufficiency due to Lower-Nephron Nephrosis," which appeared in the *New England Journal of Medicine* (239:693-700, 1948). In extrarenal azotemia low blood pressure is practically always found. In Murphy's series only 1 patient had hypertension, and at autopsy he was found to have a chromophobe adenoma of the pituitary body. In lower-nephron nephrosis, after renal shutdown, the blood pressure rises, according to Strauss.

Any serious illness or injury may be the cause of extrarenal azotemia. In its pathogenesis the common denominator appears to be diminished blood flow through the kidneys. Lower-nephron nephrosis is produced by a wide variety of traumatizing conditions that have in common the main feature of shock.

Pathologically, in lower-nephron nephrosis, the lesions occur in a similar region in all the cases, with selective tubular damage to the ascending loop of Henle and the distal convoluted tubules. The glomeruli and the proximal tubules are only indirectly affected, as demonstrated by Hall and Luetscher in their review entitled "Renal Disease" in the *New England Journal of Medicine* (239:621-631, 1948). In a study of "Extrarenal Azotemia and Tubular Disease," which appeared in the *Journal of the American Medical Association* (134:441-446, 1947), Bell and Knutson found mild to severe hydropic degeneration of the proximal convoluted tubules in 20 of 84 cases. They suggested that the tubular injury was in part or entirely responsible for the uremia. In the remaining 64 cases there were no structural changes.

In the case cited by Appel and Townsend in their article "Extrarenal Azotemia: Report of a severe case with recovery," in the *New England Journal of Medicine* (240:95-97, 1949), the patient was not in shock. He did not develop edema after the severe oliguria had begun, and the degree of hypertension (blood pressure of 144 systolic, 90 diastolic) was slight.

Like Drs. Appel and Townsend I choose to call the case one of extrarenal azotemia. However, I believe that the difference between lower-nephron nephrosis and extrarenal azotemia is more than an academic one.

JOSEPH G. WEINER, M.D.

Philadelphia, Pennsylvania

BRITISH VIEWPOINT ON BRITISH MEDICINE

To the Editor If I have been somewhat tardy in writing this letter, it is because I am naturally hesitant to enter what is exclusively an American field. Medicine, however, knows no national boundaries, and I therefore feel constrained to present to my American colleagues my own interpretation of the situation in Britain, so vividly depicted by Dr Sweet in his article in the February 3 issue of the *Journal*. Although I can quarrel with only a few of his facts, I find it difficult to believe that these have been viewed with the objectivity called for in Dr Sweet's article.

Dr Sweet considers the British National Health Service from the points of view of the specialist and the general practitioner, but he completely ignores that of the patient, who, I should have thought, would also have been interested. From all reports reaching me, the lay public in general is liking the Health Service very much indeed, and this is obviously a very important fact.

Great play is made by Dr Sweet about the amount of form filling that a doctor has to carry out. There is a large amount, and nobody objects more than the doctor, but little of the increase is due to the Health Service, the main bulk arising from the shortages resulting from the war and from our subsequent dire economic situation. There is very little in the way of a black market in Britain, and the public at large prefers that necessities in short supply should be obtained by those most in need, rather than by those who can pay inflated or illegal prices. There are black sheep in every walk of life, and doubtless some doctors issue certificates on rather flimsy grounds, but it is a measure of the high esteem in which the medical profession is held by the public that doctors are asked to undertake so important if so irksome a duty.

I cannot agree that the doctor under the National Health Service is regarded by the patient, veteran or other, as being in some sort of sinister plot against him, in general, he is regarded as being impartial and fair-minded. As for the idea, advocated by Dr Sweet, of a patient touting doctors until he finds one whose opinion can be bought, I can imagine nothing more damaging to the integrity and good name of the profession, Judas had his price.

A great deal of space is devoted by Dr Sweet to describing the delay in providing a new building for a certain professional department. These facts are only too true, — all such building in Britain is difficult to obtain, — but it is also true that a certain number of dwelling houses and other buildings were destroyed by bombs. Nothing undermines domestic morale more than sharing a house with another family, and I think it is reasonable that the highest priority should be given to domestic building.

Dr Sweet also speculates about the amount of malingering that will be encouraged by a state health service. In fact all reports reaching me state that malingering is not a major factor. Almost all the new patients should have been seen long before, and most are very considerate and even rather embarrassed at either having to visit the doctor or having him to visit them — they know only too well how busy he is. Dr Sweet's implication that doctors should only see those who think that their complaint might be trivial, provided such patients can pay suitable fees, falls right outside my conception of medical ethics, what is more important, it falls outside that of a large number of laymen and politicians. A properly trained doctor, however busy, is obviously better able to judge whether or not a complaint is trivial than a layman who is influenced by the size of his bankroll.

It is unquestionably true that panel practice in Britain is often very dreary, and a busy practitioner has to transfer to specialists many cases that in this country he might first attempt to deal with himself. A better system should undoubtedly be developed if it were possible, but against the discomfort of the overburdened general practitioner, one must weigh the advantage to the average patient of at least having an expert to decide whether he is seriously ill or not. Perhaps we are attempting to give the public a better service than the facilities and number of doctors permit, this is a matter on which the profession in this country might well ponder.

Please do not think that I necessarily endorse in full the National Health Service in Britain. There will obviously be very many teething troubles, but we shall ultimately make it work, though many heads may fall in the process, and

though many aspects may have to be changed. I merely plead that these things be viewed as objectively as possible in their true context, since it is only by this means that you in America can derive benefit rather than harm from our experiment in Britain.

G. A. SMART

Massachusetts General Hospital, Boston

Dr Smart's letter has been referred to Dr William H. Sweet, who offers the following reply.

To the Editor I am chagrined to learn that Dr Smart interprets my statements to mean that patients should be encouraged to search out a doctor whose opinions can be bought or to consult one for trivial complaints if they can pay a fee. This is remote from the idea intended.

Dr Smart's observation that the British people like their new health service is hardly astounding when one considers that it purports to relieve them of all responsibility in connection with illness and that only a tiny fraction of the expense of this service is borne by the direct health-insurance contributions of the person himself. The tentative conclusion to which I came however was that the doctor's colossal load under these conditions precluded efficient action by him — nor does Dr Smart appear to challenge this.

He does condone grievous delays in vitally needed hospital construction even though patients on long waiting lists for admission to hospitals die in their homes before a hospital bed is available. He states "that the highest priority should be given to domestic building," because "nothing undermines domestic morale more than sharing a house with another family." For some time we in my family have been sharing our house with another couple and their children. Dr Smart will perhaps be relieved to learn that the morale of the entire ménage remains excellent, and if this arrangement has by any chance hastened the completion of the new buildings of the Massachusetts General Hospital and the New England Center Hospital we are that much happier.

WILLIAM H. SWEET

Boston

REGARDING THE FARREN HOSPITAL EPISODE

To the Editor With the summary administrative dismissal of 4 members of the Franklin District Medical Society from the medical staff of the Farren Memorial Hospital in Montague City, Massachusetts, in the three days before the election in November, 1948, a total of 20 doctors have lost their hospital privileges in western Massachusetts for publicly approving the "Birth Control" referendum on the Massachusetts ballot. The others were 12 in the Pittsfield area in 1942, and 4 in the Springfield area in 1946.

The first amendment to the constitution of the United States seems to guarantee the right of free speech without penalty, the citizens of Massachusetts in the same election overwhelmingly voted reapproval of this guarantee, the Massachusetts Supreme Court had certified this referendum to the ballot for public discussion and vote, and no promise, either written or oral, had ever been requested of any of these doctors before in connection with this amendment. The medical-staff by-laws have no such requirements. No hearing, either before or after dismissal, has ever been granted. No doctor has ever been reinstated except by signing a new application blank, which included a promise not to exercise this right of free speech, 4 doctors in the Pittsfield area have made this promise.

As president of the Franklin District Medical Society I held several consultations with the Sister Superior, and with 2 members of the Executive Committee of the Trustees, two committees of the Society held meetings during the month of November, one of them with the hospital authorities. An energetic petition supporting reinstatement was voted by the Society and presented to the Board of Trustees. In spite of this abridgment of civil rights the petition was not even placed on the agenda for the meeting by the President. A petition by me as a twenty-year member of the Farren Memorial Hospital medical staff and simultaneously president of the District Medical Society was sent to the Most Reverend A. G. Cicognani, the Apostolic Delegate in Washington, and its receipt has been doubly verified. With the passage of several weeks, even with a follow-up letter, no answer has been received.

The situation in this district is different from that in others, in that alternate hospital facilities are limited. There is only one other hospital. Total county bed capacity is below requirements, and will remain so for several years. In addition, the Farren Memorial Hospital was built in 1900 by a private citizen, Bernard N. Farren, it was given to a Massachusetts tax-free public charitable corporation, he was so determined that it should only be used as a hospital that he had this legal restriction filed in the Registry of Deeds, he repeated this and added a further legal limitation in 1910, the Board of Trustees consisted, and still does as a continuing policy, of both Catholic and Protestant members, the Sisters of Providence act as the supervising agents, the hospital has always admitted patients of any race, creed and color, the hospital has been supported in part by all races, creeds and colors as a result of campaign for funds by the hospital, and doctors have always been selected on the basis of professional qualifications and abilities.

The dismissed doctors and a majority of the Franklin District Medical Society believe that admission to and dismissal from the staff of this hospital should still be based exclusively on professional qualifications and abilities. A large element of the community, who have supported the hospital without favoritism and whose hospital care has been jeopardized because of this further restriction of hospital medical care, support this stand. It is believed therefore that this report to the medical fraternity in Massachusetts should be made.

LAWRENCE R. DANE, M.D.

Greenfield, Massachusetts

SMOKE GETS IN ONE'S EYES

To the Editor Since the medical profession as a group seems to be on trial because of its reactionary conservatism and its adherence to the *status quo*, perhaps one more item of criticism is in order.

One wonders if the editor, because of the remunerative advertising by the cigarette interests and because perhaps the medical profession are as a group the greatest consumers of cigarettes, would venture to publish the enclosed clipping by a recognized authority, in the interests of cancer control.

Excessive smokers are four times as liable as nonsmokers to have cancer of the mouth and respiratory system, and even mild smokers are twice as vulnerable to the disease as persons who do not smoke, according to Dr. Herbert L. Lombard, director of the Cancer and Chronic Disease Division, Department of Public Health. — *Needham Chronicle*, March 16, 1949

J. WALTER SCHIRMER, M.D.

Needham, Massachusetts

DEPRIVATION OF LICENSE

To the Editor At the meeting of the Board of Registration in Medicine held March 24, it was voted to revoke the registration of Dr. Louis R. Medverd, 1210 Cambridge Street, Cambridge.

GEORGE L. SCHADT, M.D., Secretary
Board of Registration in Medicine

State House
Boston

AN OPEN LETTER

To the Editor A most critical professional manpower shortage is facing the medical departments of the armed forces. The urgency of the need for physicians and dentists can be judged from the fact that by July of this year the armed forces will have lost almost a third of their present staff of physicians and dentists. The tours of duty of these professional men will expire, and normal procurement measures cannot fill the vast number of vacancies that will arise.

By the end of July we shall be short about 1600 physicians and 1160 dentists. By next December this shortage will grow to 2200 physicians and 1400 dentists. This means that the armed forces will not have enough professional men to give minimum medical service to almost 1,700,000 men and women who are serving their country.

You and your publication have been asked many times for assistance in special drives and campaigns for the welfare of our country. You have at all times shown whole-hearted co-operation.

We have sought and received support in this campaign from the professional societies from the national to the community level. Deans of medical and dental schools and the heads of hospitals have also been asked to co-operate in this emergency.

The success of this procurement campaign will depend primarily upon public understanding and public support. The people of the United States must be made aware of the seriousness of the problem that faces us. If this shortage is allowed to develop, it could jeopardize our entire national defense program.

The medical departments of the armed forces and the Government ask your co-operation in averting a situation that could have serious effects on the security of this country. Through your editorial pages and news columns you can help us inform the people of this country of the vital needs of the medical departments of the armed forces. You can urge young men who received their medical and dental educations during the war years, and who have given no service, to volunteer their services to their country now when the need is so great.

It must be made clear that we are not asking for physicians and dentists from areas where a shortage already exists. We are only trying to replace the physicians and dentists who have completed their obligation and who will be relieved from duty with the armed forces and will return to civilian life to practice their professions.

Your co-operation in this campaign can be of inestimable value and will be greatly appreciated by the medical departments of the armed forces, the young men and women in our armed forces and the families of these young people.

Washington

BOOK REVIEWS

The Battle of the Conscience. A psychiatric study of the inner working of the conscience. By Edmund Bergler, M.D. 8°, cloth, 296 pp. Washington: Washington Institute of Medicine, 1948. \$3.75.

The title and subtitle of this work lead one to believe that here at last is a full-length study of a controversial and highly important subject. Instead, there are a number of related but, unfortunately, not fully integrated chapters — each almost complete in itself — in which the role of conscience is studied only as it pertains to the topic under discussion. Frequently, greater emphasis is placed on other studies of the author, with especial emphasis on the triad of the mechanism of oral eroticism (as the basis for neurotic symptoms), and for sublimation a five-layer structure is alleged to exist.

Granting such possible mechanisms, one remains unimpressed about the designated numbers or strata as such. Clinical experience convinces one that such categories, although convenient, rarely exist, and this is not too strange since undoubtedly neither psychiatrist nor analyst ever succeeds in learning even an infinitesimal part of the dynamics of the mind (the thought process, the conscience) at either conscious or unconscious level.

Similar criticism can be made of the author's designation of magic gestures with completely different meanings. The fact that he designated various types under the term "magic gesture" will not succeed in preventing confusion in the literature because it is reasonable to assume that the term will be frequently used and its meaning will not always be clear.

An apology is made that analytical material is scant in criminal cases because some millionaire has failed to donate funds for such a study — a candid, but disheartening admission, when one recalls that scientists in other fields have devoted years of study without thought to monetary reward. This has been true particularly in the medical world and applies not only to research but also to care of the sick. Therefore, one might suppose that despite the lack of funds for 50 experienced analysts to devote themselves exclusively

BRITISH VIEWPOINT ON BRITISH MEDICINE

To the Editor If I have been somewhat tardy in writing this letter, it is because I am naturally hesitant to enter what is exclusively an American field. Medicine, however, knows no national boundaries, and I therefore feel constrained to present to my American colleagues my own interpretation of the situation in Britain, so vividly depicted by Dr Sweet in his article in the February 3 issue of the *Journal*. Although I can quarrel with only a few of his facts, I find it difficult to believe that these have been viewed with the objectivity called for in Dr Sweet's article.

Dr Sweet considers the British National Health Service from the points of view of the specialist and the general practitioner, but he completely ignores that of the patient, who, I should have thought, would also have been interested. From all reports reaching me, the lay public in general is liking the Health Service very much indeed, and this is obviously a very important fact.

Great play is made by Dr Sweet about the amount of form filling that a doctor has to carry out. There is a large amount, and nobody objects more than the doctor, but little of the increase is due to the Health Service, the main bulk arising from the shortages resulting from the war and from our subsequent dire economic situation. There is very little in the way of a black market in Britain, and the public at large prefers that necessities in short supply should be obtained by those most in need, rather than by those who can pay inflated or illegal prices. There are black sheep in every walk of life, and doubtless some doctors issue certificates on rather flimsy grounds, but it is a measure of the high esteem in which the medical profession is held by the public that doctors are asked to undertake so important if so irksome a duty.

I cannot agree that the doctor under the National Health Service is regarded by the patient, veteran or other, as being in some sort of sinister plot against him, in general, he is regarded as being impartial and fair-minded. As for the idea, advocated by Dr Sweet, of a patient touting doctors until he finds one whose opinion can be bought, I can imagine nothing more damaging to the integrity and good name of the profession, Judas had his price.

A great deal of space is devoted by Dr Sweet to describing the delay in providing a new building for a certain professional department. These facts are only too true, — all such building in Britain is difficult to obtain, — but it is also true that a certain number of dwelling houses and other buildings were destroyed by bombs. Nothing undermines domestic morale more than sharing a house with another family, and I think it is reasonable that the highest priority should be given to domestic building.

Dr Sweet also speculates about the amount of malingering that will be encouraged by a state health service. In fact all reports reaching me state that malingering is not a major factor. Almost all the new patients should have been seen long before, and most are very considerate and even rather embarrassed at either having to visit the doctor or having him to visit them — they know only too well how busy he is. Dr Sweet's implication that doctors should only see those who think that their complaint might be trivial, provided such patients can pay suitable fees, falls right outside my conception of medical ethics, what is more important, it falls outside that of a large number of laymen and politicians. REGARDING THE FARREN HOSPITAL EPISODE

To the Editor With the summary administrative dismissal of 4 members of the Franklin District Medical Society from the medical staff of the Farren Memorial Hospital in Montague City, Massachusetts, in the three days before the election in November, 1943, a total of 20 doctors have lost their hospital privileges in western Massachusetts for publicly approving the "Birth Control" referendum on the Massachusetts ballot. The others were 12 in the Pittsfield area in 1942, and 4 in the Springfield area in 1946.

The first amendment to the constitution of the United States seems to guarantee the right of free speech without penalty, the citizens of Massachusetts in the same election overwhelmingly voted reapproval of this guarantee, the Massachusetts Supreme Court had certified this referendum to the ballot for public discussion and vote, and no promise, either written or oral, had ever been requested of any of these doctors before in connection with this amendment. The medical-staff by-laws have no such requirements. No hearing, either before or after dismissal, has ever been granted. No doctor has ever been reinstated except by signing a new application blank, which included a promise not to exercise this right of free speech, 4 doctors in the Pittsfield area have made this promise.

As president of the Franklin District Medical Society I held several consultations with the Sister Superior, and with 2 members of the Executive Committee of the Trustees, two committees of the Society held meetings during the month of November, one of them with the hospital authorities. An energetic petition supporting reinstatement was voted by the Society and presented to the Board of Trustees. In spite of this abridgment of civil rights the petition was not even placed on the agenda for the meeting by the President. A petition by me as a twenty-year member of the Farren Memorial Hospital medical staff and simultaneously president of the District Medical Society was sent to the Most Reverend A. G. Cicognani, the Apostolic Delegate in Washington, and its receipt has been doubly verified. With the passage of several weeks, even with a follow-up letter, no answer has been received.

anajes del Dispensario Antituberculoso Central y del Sanatorio Antituberculoso de Otra de Santa Cruz de Tenerife, Canarias, España. Director Dr T Cervia Volume VIII, Años 1946-47 8°, paper, 245 pp, illustrated Santa Cruz de Tenerife Imprenta Católica, 1948

This report is divided into two parts, the first comprising the statistics of the sanatorium for the years 1946 and 1947, and the second consisting of a series of clinical papers by Director Cervia and his assistants on the various aspects of tuberculosis. The text is concluded with a pneum by Dr Duran, entitled *Cantar del buen bacilo*. The volume constitutes a valuable addition to the literature of tuberculosis, and the series should be in all collections on the subject and in reference and research medical libraries.

Textbook of Surgical Treatment, including Operative Surgery Edited by C F W Illingworth, CBE, MD, ChM, FRCS, Regius Professor of Surgery, University of Glasgow. Compiled by twenty-one contributors. Third edition. 8°, cloth, 644 pp, with 289 illustrations. Baltimore Williams and Wilkins Company, 1947 \$10 00

This collected work by twenty-one contributors has been revised and brought up to date. Four contributors have been added to the authors. The chapter on wounds and wound infections has been rewritten, and sections added on penicillin in surgery, plastic surgery, rehabilitation and facio-maxillary injuries. New material has been incorporated on the use of protein in surgery, the Rh factor and the anticoagulant treatment of thrombosis. Fifty-nine illustrations have been added. The work is of British origin and is well published in every way. It is recommended as a reference text for all medical libraries and surgeons.

Recent Advances in Surgery By Harold C Edwards, CBE, MS, FRCS, surgeon and lecturer in surgery, King's College Hospital, London, surgeon to the Evelina Hospital for Sick Children, and dean of the medical school, King's College Hospital. Third edition. 12°, cloth, 457 pp, with 131 illustrations. Philadelphia Blakiston Company, 1948 \$6 50

The first edition of this reference book was published in 1928, the second edition of 1929 was translated into Spanish, and this third edition has been revised to bring the material up to date. Short lists of references are appended to the various chapters. The material is well organized and is arranged by divisions of the body. Short lists of references are appended to the various chapters. It is a British book, printed in Great Britain, and well published. The plates are separately inserted in the text. The volume should be in all medical libraries and should prove useful to surgeons.

Oral and Dental Diseases Aetiology, histopathology, clinical features and treatment. A textbook for dental students and a reference book for dental and medical practitioners By Hubert H Stnnes, MD, MDS, FDS, FRCS, Eng., professor of dental surgery and director of dental education, University of Liverpool, and consultant, E.M.S. Maxillo-facial Centre, Broad Green Hospital, Liverpool. 8°, cloth, 896 pp, with 926 illustrations. Baltimore Williams and Wilkins Company, 1948 \$18 00

This volume constitutes a comprehensive treatise on the diseases of the mouth, jaws and teeth. The material is well organized. There is a long chapter on oral tumors and one on the diseases of the salivary and oral mucous glands. Lists of references are appended to the various chapters. The text is well printed with a good legible type. Comprehensive indexes of authors and subjects conclude the volume. The treatise is British and printed in Great Britain. It is recommended for all medical libraries and should prove valuable to all dentists and to physicians interested in the subject.

Retropubic Urinary Surgery By Terence Millin, MA, MCh (Dubl), FRCS, FRCSI, surgeon, All Saints' Hospital for Genito-Urinary Diseases, London, genitourinary surgeon, Royal Masonic Hospital, London, urologist, Surrey County Council, and genitourinary surgeon, Chelsea Hospital

for Women, London, Southall-Norwood and Cray Valley hospitals. 8°, cloth, 203 pp, and 163 illustrations. Baltimore Williams and Wilkins Company, 1947 \$7 00

This monograph describes the author's methods of retro-pubic approach for prostatic surgery. Included is his hitherto unpublished operation for stress incontinence in women, first used in 1944. An appendix lists fifty consecutive one-stage retropubic prostatectomies. A good index ends the text. The book is of British origin and is well published. It should prove valuable to all surgeons interested in the subject.

A Course in Practical Therapeutics By Martin E Rehfuess, MD, professor of clinical medicine and Sutherland M Prevost Lecturer in Therapeutics, Jefferson Medical College Philadelphia, and attending physician, Jefferson Medical College Hospital, Philadelphia, F Kenneth Albrecht, MD, and Alison H Price, MD, assistant professor of medicine, Jefferson Medical College, Philadelphia, and assistant physician, Jefferson Medical College Hospital, Philadelphia. 4°, cloth \$24 pp, with 70 plates. Baltimore Williams and Wilkins Company, 1948 \$15 00

This joint work of thirteen clinicians covers the whole field of therapeutics in a practical manner. The text is divided into four large sections comprising general therapeutic principles, symptomatic therapy, treatment of specific disorders and special treatment. The symptoms discussed in the second part are arranged alphabetically. The various diseases and conditions in the third part are arranged by the systems of the body or by classes of diseases. The treatment of each disease is preceded by a concise description of the etiology, pathology and symptomatology. The treatment is extensive in scope. The material is well arranged, and the text is well printed with a good type in two columns on good paper. A comprehensive index concludes the volume. The inside front and back covers are used for valuable tables on normal values in blood constituents and metric and apothecary doses. This is a poor practice because anything printed on the covers becomes defaced and worn from usage of the volume. The book should prove valuable to physicians in their daily work, and as a reference work for medical libraries.

Human Nutrition By V H Mottram, MA (Cant.) 12°, cloth, 151 pp, with 9 illustrations. Baltimore Williams and Wilkins Company, 1948 \$2 75

This popular manual on human nutrition is written by an eminent British scientist. The material is well arranged and written in a simple, easy style. The fundamentals of dietetics, food hygiene and cooking and processing and storage of foods and proteins, minerals and the vitamins are considered in various chapters. There are also chapters on normal dietetics, digestion, absorption and metabolism of food, and on the nature of foods, comprising analyses of the common foods. The chapter on the optimal diet is gauged to present British conditions. A good index concludes the text. The volume is well published.

Treatment by Manipulation in General and Consulting Practice By A G T Fisher, MC, MB, ChB, FRCS (Eng), orthopedic surgeon to the rheumatic unit, St. Stephen's Hospital. Fifth edition of *Manipulative Surgery*. 8°, cloth, 275 pp, with 126 illustrations. New York Paul B Hoeber, Incorporated, 1948 \$5 00

This book was first published in 1925 under the title of *Manipulative Surgery*. In this fifth edition much material has been added, and forty-five new illustrations have been included. Many sections have been rewritten and expanded to incorporate the advances in knowledge made since the fourth edition of 1944. Emphasis has been placed on the treatment of crippling deformities of rheumatic disease. The objective of the work is to emphasize the value of manipulative treatment in carefully selected cases of certain sequelae of injuries and diseases affecting the joints, muscles, tendons and fasciae. The various chapters discuss the pathology of the joints, prevention and diagnosis of adhesions and manipulative treatment in general and of the upper and lower extremities, the spine and the sacroiliac joint. The concluding chapters consider the dangers of manipulation in unsuitable cases, after-treatment and osteopathy. The book is of British origin and printed in Great Britain. The publishing is well done, and the illustrations are excellent. The volume should be in all medical libraries and should prove useful to orthopedists.

to the study of criminals, perhaps each analyst might feel honored to participate in such a study by devoting a "free hour" to the purpose.

Apart from these few criticisms, the book makes good reading, the examples cited are typical, and sources of other works are clearly acknowledged. The author's style remains clear, but by now, this is taken for granted in any of Dr. Bergler's books.

The Driving Forces of Human Nature and Their Adjustment: An introduction to the psychology and psychopathology of emotional behavior and volitional control. By Thomas V. Moore, Ph.D., M.D. 8°, cloth, 461 pp., with 26 illustrations. New York: Grune and Stratton, 1948. \$6.50.

In this work the author presents a compilation of some of the more important aspects that are at present acceptable in the study of the forces concerned in human behavior. The author draws upon his obviously extensive and broad cultural background to clarify his position, and colors the entire work with a religious (Roman Catholic) texture. It is in essence a psychologic, philosophical work in which he draws upon examples both in experimental psychology and in psychiatric therapy. He touches on various theories concerned in the dynamics of human behavior and, for the most part, maintains a "middle of the road" position regarding dynamic theories, reserving as his ultimate solution that of religion. He presents numerous case studies and methods of treatment concerning these cases, choosing them carefully to illustrate his point of view. As an introduction to the problems of human nature, the book presents a wealth of material both historically and analytically.

Physiology of Exercise. By Laurence E. Morehouse, Ph.D., and Augustus T. Miller, Jr., Ph.D. 8°, cloth, 353 pp., with 51 illustrations and 10 tables. St. Louis: C. V. Mosby Company, 1948. \$4.75.

This book attempts to give the fundamental facts of physiology as they concern exercise. It is written primarily for teachers of physical education and practitioners of physical medicine. The material is presented in a simple, easily understood style. A glossary at the end of the book explains the technical terms that have been used. The chapters on physical fitness and on training should be of particular interest to physicians. This book can be recommended as a helpful volume containing the essential data on the physiology of exercise.

Psychic Energy: Its source and goal. By M. Esther Harding, M.D., M.R.C.P. With a foreword by C. G. Jung. 8°, cloth, 497 pp., with 5 illustrations and 9 plates. New York: Pantheon Books, 1947. \$4.50. The Bollingen Series X.

In this book the author, via a Jungian delving into the "unconscious," attempts to answer the query whether or not the primitive and "unconscious" side of man's nature can be tamed effectively or even altered. She believes that contemporary culture and civilization afford but a poor façade covering unconscious roots that are essentially base, vile and self-annihilating. Such a façade is superficial and vulnerable, and men must regress to primitive levels of the unconscious, as seen in the totalitarian rationalization and the world conflicts of today. The author holds out little hope of changing the "collective unconscious" of a people, but individuals may be saved and thus possess "the germ of a renaissance of the spiritual values of mankind."

The author draws freely upon the art and literature of various cultures in support of her theses, but this seems to serve only the more to leave the reader with the sensation of having viewed a séance of religious mysticism. The book is as pessimistic and ethereal as anything Jung himself might have written. One gathers that peoples, as such, are doomed, condemned even pre-partum by the "collective unconscious"; salvation there is for an accidental few who can be led, through the means of "analytical psychology," to wallow in the "unconscious" and be led therefrom again chaste and pure in heart and mind.

BOOKS RECEIVED

The receipt of the following books is acknowledged and this listing must be regarded as a sufficient receipt for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

De betekenis van de lymfklier-punctie voor de diagnostiek periferie lymfklierzwellingen. By L. B. J. Stuyt. Ar. Prof. Dr. Proefschrift, Universiteit van Amsterdam, 1 Juli, 1947. Paper, 110 pp., with 31 illustrations. Amsterdam: S. & H. H. Holkema's Boekhandel, 1947.

In this monograph, which was presented as a thesis for the degree of doctor of medicine at the University of Amsterdam in 1947, the author discusses puncture and aspiration of swollen lymph nodes for the purpose of obtaining material for cytologic diagnosis. The text is based on the experience of the author with over 300 patients and on the literature of the subject. The author indicates that the method may be used when biopsy is contradicted, that it is possible to identify cell pictures in a number of conditions and that the procedure may be used as often as desired and as a control on therapy, he recommends that the method be adopted as routine in the differential diagnosis of enlargement of the peripheral lymph nodes. The material is well organized, discussing in order the anatomy and physiology of the lymph nodes, and their pathological anatomy, the clinical diagnosis of enlargement of the peripheral lymph nodes, the technique of puncture and its diagnostic value. The text is in Dutch, with summaries in English and French. A bibliography is appended to the text. The type, printing and illustrations are excellent.

Racial Variations in Immunity to Syphilis: A study of the disease in the Chinese, white and Negro races. By Chester A. Frazier, M.D., Dr. P.H., and Li Hung-Chung, M.D. 8°, cloth, 122 pp., with 27 tables. Chicago: University of Chicago Press, 1948. \$2.50.

In this monograph the authors analyze 16,845 consecutive cases of syphilis in the Chinese, white and Negro races. The study points out that regardless of race or sex the disease was essentially the same in all people and that the differences between races lay almost entirely in the relative frequency of the development of the disease. A bibliography and a good index conclude the volume.

Advances in Pediatrics. Editorial Board: S. Z. Levine, M.D., Cornell University Medical College, New York; Allan M. Butler, M.D., Harvard Medical School, Boston; L. Emmett Holt, Jr., M.D., New York University, College of Medicine, New York; and A. Ashley Weech, M.D., University of Cincinnati, College of Medicine, Cincinnati. Volume III. 8°, cloth, 363 pp. New York: Interscience Publishers, 1948. \$7.50.

This third volume of an important series presents eight papers by different authors of interest to pediatricians and physicians concerned with the diseases of children. The papers comprise the effects of birth processes and obstetric procedures upon the newborn infant, retrolental fibroplasia, emotions and symptoms in pediatric practice, therapeutics of epileptiform seizures, viral hepatitis, abnormalities of sexual development during childhood and adolescence, psychologic considerations of puberty and adolescence, and the osteochondroses. The papers present the up-to-date knowledge on the particular subjects under consideration. Comprehensive bibliographies are appended to the various papers. There are good indexes of authors and subjects and the volume is concluded with a cumulative index of authors and subjects for volumes 1 to 3. The type and printing are good, but a heavy, coated paper is unnecessarily used, making the volume too heavy for its size. It should be remembered that when this type of paper becomes wet by accident the volume is transposed into a block as hard as concrete. The series is valuable and should be in all medical libraries and in the collections of physicians interested in pediatrics.

CARDIAC ANEURYSM*

MAX CAPLAN, M.D.,† AND PAUL M. SHERWOOD, M.D.‡

ROCKY HILL, CONNECTICUT

PRIOR to 1931, the diagnosis of acquired aneurysm of the left ventricle was made only ten times ante mortem.^{1,2} With the better appreciation of the significance of the clinical features of this condition and the increased use of modern diagnostic facilities, more and more cases have been reported in the literature, and a new evaluation of the prognosis is warranted. Thus, although in Parkinson, Bedford, and Thomson's³ cases, the longest survival was thirty months, in Dressler and Pfeiffer's⁴ cases it was seven years. Young and Schwedel⁵ have reported the case of a patient who survived for ten years after the diagnosis of cardiac aneurysm, and Penner and Peters⁶ described a patient who, up to 1946, had already survived fifteen years. Many cases have been reported in which the patients have pursued a useful and comparatively active life for two, four, five,³ seven^{4,7} and nine⁷ years after the development of the characteristic radiographic findings of ventricular aneurysm. The longest survival mentioned in the literature is a patient, followed by Robertson⁸ for eighteen years, who still engages in heavy work. Formerly a rare condition, ventricular aneurysm is now frequently suspected before death and no longer, by itself, has the dire prognosis commonly associated with it in the past.^{3,9} We report herewith 2 cases of cardiac aneurysm followed on the Medical Service of the Veterans Home and Hospital at Rocky Hill, Connecticut.

CASE REPORTS

CASE 1 W. C., a 56-year-old man, was transferred to the hospital for convalescent hospital care. He was a highway-department maintenance worker, and his duties had included pick and shovel work as well as clearing snow. From 1943 to 1946 he had noted occasional sharp stabbing nonradiating pains in the anterior portion of the chest deep behind the lower third of the sternum. The onset was sudden and usually occurred while he was at work; the pain waxed and waned and varied in duration from several hours to an entire day. On the evening of June 20, 1946 he was suddenly seized with severe substernal and precordial pain, which radiated down both arms. He was immediately sent to a hospital. Two weeks later and again 4 weeks later, while in the hospital he had a similar but much milder episode

of substernal pain. Thereafter he improved uneventfully and was transferred to this hospital.

Physical examination revealed a well developed and well nourished man who was not acutely ill. Examination of the head was not significant. The thyroid gland was not enlarged. The lungs were clear. The maximum cardiac impulse was heaving and appeared in the fourth interspace just medial to and below the left nipple and 2 cm. inside the left border of cardiac dullness. The heart sounds were distant and faint, and not in keeping with such a marked cardiac pulsation. Rhythm was regular, and no murmurs were present. The liver was not enlarged, and there was no peripheral edema.

The blood pressure was 136/84 in both arms.

Laboratory examination revealed normal urine specimens and no anemia or leukocytosis; the nonprotein nitrogen was 29, and the fasting blood sugar 103 mg. per 100 cc. and the sedimentation rate was 12 mm. per hour (Cutler method). Blood Wassermann and Mazzini tests were negative.

X-ray examination of the chest disclosed the heart to be somewhat enlarged in the transverse diameter and revealed a marked prominence and dilatation of the left border of the heart (Fig. 1). Under the fluoroscopic screen, an expanding pulsation of the hugging area that coincided with each contraction of the left ventricle was noted.

An electrocardiogram (Fig. 2) showed regular sinus rhythm, with a rate of 80, a PR interval of 0.20 second and QRS complexes of 0.08. In Lead 1 the main deflection was downward, with elevated, bowed ST segments and a shallow, inverted T wave. The R wave was notched and the T wave, low and upright in Lead 2. Lead 3 showed depressed ST segments. In the left-arm lead the main deflection was downward, with elevated bowed ST segments, and a shallow, inverted T wave. The right-arm lead had an inverted P wave, upright QRS complexes and a diaphasic T wave. In the left-leg lead the QRS complexes and T wave were upright. The R waves were low in Lead V₁ and absent in Leads V₂, V₃, V₄ and V₅, the ST segments were elevated in Leads V₂, V₃, V₄ and V₅, and the T waves were diaphasic in Lead V₂ and inverted in Leads V₃, V₄ and V₅. In Lead V₆ there were low-voltage QRS complexes, elevated ST segments and an inverted T wave. Serial electrocardiograms showed no essential change.

The patient has been fully ambulatory in the hospital and has cared for himself completely. He walks to the dining room and to the auditorium for motion-picture entertainment. He performs light work at the Department of Occupational Therapy. In addition, he voluntarily helps in small tasks about the ward. His complaints referable to the cardiovascular system are limited to palpitation after infrequent climbing of stairs. Repeated x-ray films over the two-year period while he has been in this hospital have revealed no change in the size or configuration of the heart (Fig. 1).

CASE 2 A. S., a 74-year-old man, was admitted to the hospital on July 9, 1948, because of shortness of breath nine months before admission, directly after arising from bed he had suddenly been seized with excruciating pain in the left anterior portion of the chest. There was associated sweating and marked shortness of breath. He entered another hospital, where on the following day the precordial pain was more pronounced. His pulse was stated to be rapid

Textbook of Chiropody By Margaret J M Swanson, B Litt, F Ch S, co-founder of Edinburgh Foot Clinic and School of Chiropody 8°, cloth, 212 pp, with 168 illustrations Baltimore Williams and Wilkins Company, 1948 \$5 00

This short treatise on chiropody as a specialty also considers the medical and surgical conditions met with in practice that should be referred to competent specialists. The text is well written in a scientific manner, and the material is well arranged. The publishing is excellent and was done in Great Britain. The illustrations are also excellent. A glossary of terms concludes the text. There is a good index. The book is recommended to medical libraries and to all persons interested in the subject.

Principles and Practice of the Rorschach Personality Test By W Mons, M R C S, L R C P, Lt-Col R A M C, adviser in psychiatry, South East Asia Command 8°, cloth, 164 pp Philadelphia J B Lippincott Company, 1948 \$4 00

This manual on the Rorschach ink-blot test is intended as an introduction to more advanced works and is based on ten years' experience, including examination of 1000 children, aged four to sixteen years, and divided into two equal groups of normal and subnormal children. There is a good index, and the publishing is excellent in every way.

Standards for the Diagnosis and Treatment of Cancer By the Cancer Committee of the Iowa State Medical Society 8°, paper, 160 pp Iowa City, Iowa Athens Press, 1948 \$1 00

This manual was first published in 1937. During the following eleven years over fifty thousand copies were printed and distributed to the medical profession of Iowa and nearby states. This second edition has been revised to bring the subject up to date. The text is divided into a number of short, concise chapters on the diagnosis, treatment and prognosis of cancer of the various organs and structures of the body. Under diagnosis the early and late signs and differential diagnosis are considered. Two preliminary chapters discuss general considerations and the cancer problem and the family doctor. The final chapter is on radiation therapy in general. An extensive bibliography arranged by chapters concludes the text. The manual is well published in every way and should prove valuable as a compendium for practicing physicians.

Microbiology and Pathology By Charles F Carter, M D, instructor in pathology and applied microbiology, Parkland Hospital School of Nursing, Dallas, Texas, director, Carter's Clinical Laboratory, Dallas, consulting pathologist, St. Louis Southwestern Railway Hospital, Texarkana, Arkansas, and consulting pathologist, Mother Frances Hospital, Tyler, Texas. Fourth edition 8°, cloth, 845 pp, with 216 illustrations St. Louis C V Mosby Company, 1948 \$5 00

Dr Carter, in this new edition of his standard textbook, first published in 1936, has thoroughly revised the text to bring it up to date. The section on microbiology has been entirely rewritten, incorporating the great advances in knowledge in the field since the publication of the third edition in 1944, including the use of the sulfonamides and the antibiotics. A chapter on immunization has been added. The section on pathology has been largely rearranged and rewritten. Infectious hepatitis and homologous serum jaundice have been discussed, and new chapters on the hospital pathologist and his work, and on defects of body development have been included. Lists of selected references have been appended to the various chapters. The text is concluded with a chapter on laboratory exercises and a glossary of terms. There is a good index. The book is designed for the use of schools of nursing and nurses, and the need of four editions speaks well for its soundness.

Preoperative and Postoperative Care of Surgical Patients By Hugh C Ilgenfritz, M D. With a foreword by Urban Maes, M D, D Sc. 8°, cloth, 898 pp, with 110 illustrations St. Louis C V Mosby Company, 1948 \$10 00

This treatise is comprehensive in scope. The early chapters deal with general subjects such as fluid and electrolyte balance, metabolism and nutrition, shock, transfusion sedative

medication, systemic and organic complicating factors, therapy, general measures, minor and major postoperative complications, care of the wound and burns. The latter consider the various organs and regions of the body. The comprehensive index concludes the volume. The type printing are excellent, but the use of a heavy filled page is not justified by the text. The book should prove useful to surgeons and as a reference work for medical libraries.

More Than Armies. The story of Edward H Cary, M D Booth Mooney With an introduction by Dr Morris Wein 8°, cloth, 270 pp Dallas, Texas Mathis, Van and Company, 1948 \$5 00

This biography of Dr Cary is written in a narrative by a trained journalist. Dr Cary has been interested in medical education for many years and has been closely associated with the American Medical Association for thirty years, serving as trustee for five years and as president of the Association in 1933. He is a past president of the Southern Medical Association. He served for a number of years as dean of the Medical School of Baylor University and, in 1917, founded the Southwestern Medical College. He is a distinguished ophthalmologist. The book is well published, but lack of chapter headings detracts from its reference value and the price of five dollars seems high for the volume. It is recommended for all medical-history collections.

Take Off Your Mask By Ludwig Eidelberg, M D 8°, cloth, 230 pp New York International Universities Press, 1948 \$3 25

This small volume depicts an imaginary working day of a psychoanalyst. Seven case histories are presented, dealing with different kinds of psychic disturbance. These cases are not actual but are built up to portray ideal examples of condition under discussion. One chapter is devoted to training analysis. The book is semipopular and should prove useful to persons interested in the subject.

Eskimo Doctor By Aage Gilberg, M D. Translated by Elliott 8°, cloth, 229 pp, illustrated New York W W Norton and Company, Incorporated, 1948 \$3 00

This is the story of a young Danish physician who went to be the community doctor for an isolated group of polar Eskimos in Thule, Greenland, the northernmost human settlement in the world. Dr Gilberg tells of the day-to-day life of himself and his wife, describing his adventures while he ministered to the people scattered over a large area, and the character and customs of the Eskimos. The story is well told in an easy, narrative style. The book is translated from the original Danish. It is recommended for all medical history collections and to all persons interested in the history of medicine. It is a fine piece of work.

NOTICES

MASSACHUSETTS ASSOCIATION OF MEDICAL TECHNOLOGISTS

The state conference of the Massachusetts Association of Medical Technologists will be held at Horticultural Hall, Elm and Chestnut Streets, Worcester, on Saturday, April 12.

PROGRAM

- 10 00 a m - 12 00 m Business meeting and nomination of state officers (Mrs. Eichman of the American Society of Medical Technologists, will be the speaker)
- 12 30 p m Lunch
- 2 00 - 3 00 p m Newer Serologic Technics for Isoantibodies Dr Victor Vaughan, III
- 3 00 - 4 00 p m Registry Its standards and how to establish them Dr Donald Nickerson

(Notices concluded on page xv)

were heard. The blood pressure in both arms was 150/90. The liver was enlarged and tender, and pitting edema of both ankles was present.

Laboratory examination disclosed negative urinalyses and no anemia or leukocytosis. The blood Mazzini test was negative.

X-ray examination of the chest revealed considerable cardiac enlargement. Projecting upward from the left ven-

ward) and upright T wave. The left-leg lead showed a tall R wave, deep S wave, depressed ST segments and upright T wave. Lead V_1 showed a small R wave, deep S wave and upright T wave, with U wave present. Lead V_2 showed deep QS complex and upright T wave, with U wave present. In Lead V_3 the QS complex was present, with embryonal R wave and upright T wave. In Lead V_4 the QS complex

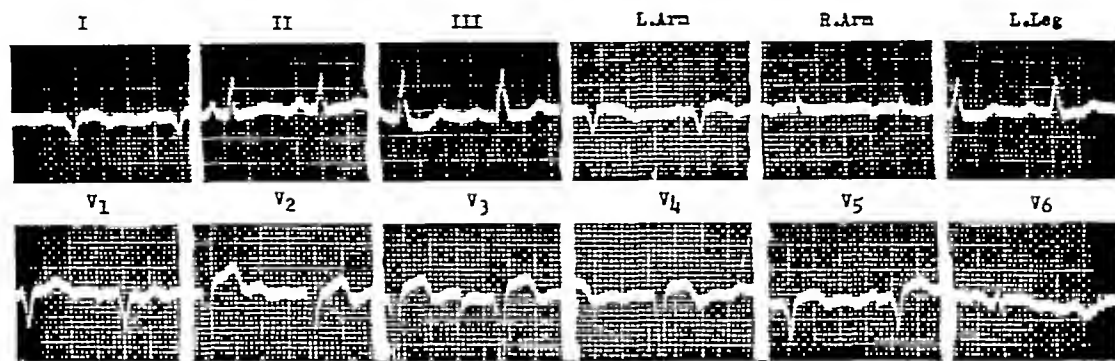

FIGURE 2 Electrocardiogram in Case 1

tricular contour there was a bulge extending for a distance of approximately 4 cm. The base of the bulge measured 8 cm in diameter (Fig. 3).

An electrocardiogram (Fig. 4) showed regular sinus rhythm, with a rate of 94, a PR interval of 0.18 second and QRS complexes of 0.10. The Q wave was deep in Lead I. The R waves were tall in Leads 1, 2 and 3. The ST segments were ele-

vated in Lead 1, slightly depressed in Lead 2 and depressed in Lead 3. The T waves were inverted in Lead 1 and upright in Leads 2 and 3. The S waves were deep in Leads 2 and 3. The left-arm lead showed a deep Q wave, tall R wave, elevated ST segments and inverted T wave, and the right-arm lead small QS complex (main deflection down-

ward) and upright T wave. In Lead V_3 the Q wave was small, the ST segments elevated, and the T wave diphasic. The ST segments were elevated and bowed in Lead V_4 , with a shallow, inverted T wave.

On a low-salt diet, digitalization, and mercurial diuretics, the patient rapidly improved and has become asymptomatic.

was rehospitalized 1 month later for congestive failure and improved on digitalization. At this time x-ray films were interpreted as showing "cardiac enlargement with a question of aneurysm." He was discharged to a convalescent home in April, 1948. In July the patient was admitted to this hospital

no distention of the neck veins. There were scattered crepitant rales at both lung bases. The point of maximal impulse was diffuse and forceful but displaced above the left nipple and inside the midclavicular line. The heart sounds were distant. The rhythm was regular, and no murmurs

Cardiac aneurysms have been described as varying from the size of a small prune,¹³ or a large duck's egg,²⁰⁻²² to an area equal to or greater than the heart itself.²⁰⁻²² Sternberg¹³ includes small, clot-containing cavities wholly within the cardiac wall as aneurysms, and states that thus many cardiac aneurysms are present that do not distort the cardiac contour. The average measurements of the cardiac aneurysm as observed in 21 cases at autopsy were 2 to 4 cm in diameter and 1.2 to 3 cm in depth.²⁻¹⁶ In the living patient, however, the apparent size of the aneurysm is greater, owing to the increased intracardiac pressure during systole. The aneurysm may be noted over a period to increase in size. Cardiac aneurysms are not infrequently multiple, and in the series of 21 cases described by Brams and Gropper¹⁶ in which the aneurysm was found at autopsy, 6 had two or more such aneurysms.

Incidence

Aneurysm of the heart is stated by Parkinson, Bedford and Thomson³ to occur in 9 per cent of patients suffering myocardial infarction. At the Massachusetts General Hospital in a series of autopsy cases examined between 1926 and 1945 Wang, Bland and White²⁴ found 52 large cardiac aneurysms in 556 patients with myocardial infarction, or an incidence of 10 per cent. An incidence of 10 per cent is also reported by Foot¹⁵ in 107 cases of old myocardial infarction. It is interesting to observe that although these three papers are based on series in three widely separated geographical areas (England, Massachusetts and California) the relative percentage is the same. Others have found the incidence even higher.²⁵ Libman²⁶ points out that cardiac aneurysm occurs fifteen times as frequently as Hodgkin's disease. With the increased diagnosis of myocardial infarction,²⁴ it is evident that cardiac aneurysm should be recognized oftener during life.

The development of the aneurysm closely follows the occurrence of myocardial infarction, many appearing within a week to several months after the acute episode.¹⁵⁻¹⁷ It is obvious, therefore, that the age incidence for cardiac aneurysm parallels that of myocardial infarction.

Since the incidence of myocardial infarction is greater in men than in women, it is likewise not surprising to note Crawford's² statement that in a summary of the literature, 66 per cent of patients with cardiac aneurysms were males. In later papers, the incidence in males appears higher. Parkinson et al.³ (1938) report 14 out of 15, Brams and Gropper¹⁶ (1940) 20 out of 21, and Crawford² (1943) 11 out of 13.

CLINICAL FEATURES

Symptoms

Practically all the symptoms in patients with cardiac aneurysms can be attributed to the underlying cardiac lesion. The aneurysm per se is asymptomatic except for occasional development of pain in the region of the apex.²³ The anginal syndrome or symptoms of left ventricular failure that may appear are not produced by the aneurysm but are related to the coronary artery or myocardial disease. Patients who have had so-called silent myocardial infarcts may develop cardiac aneurysms without any symptoms whatsoever.

Physical Signs

Some signs are described that make one suspect the existence of this lesion. On inspection a pulsation that is plainly distinguishable from that of the apical beat is seen. This is forceful and heaving and is located just lateral to the left sternal border. With palpation, one may confirm the forcefulness and heaving character of the pulsation. Crawford² considers this sign of such importance that he states that its presence permits the diagnosis to be made by physical examination alone. The area of cardiac dullness is increased and sometimes is irregular in contour.

The heart sounds are usually diminished, but more characteristic is the 'dull first heart sound with poor tone with little or no muscular quality.'²⁷ This sign together with abnormal pulsation, was described by Libman²⁶ in 1926 as being highly suggestive of the diagnosis of cardiac aneurysm. Others have concurred in the importance of these physical findings. Brams and Gropper¹⁶ found pulsation present in 57 per cent of their 21 cases. Although not of diagnostic importance, other physical findings in cardiac aneurysm are a systolic murmur in the area of abnormal pulsation, which develops after a myocardial infarction and a gallop rhythm. The mechanism of the gallop rhythm found in a case of ventricular aneurysm was studied in detail by LeRoy and Roberts²⁸ who found that during systole the aneurysm bulged outward and by traction on the papillary muscle prevented the closure of the anterior leaflet of the mitral valve, resulting in auricular reflux of blood and producing a third heart sound.

The various arrhythmias that occur in severe myocardial disease are found in patients with cardiac aneurysm, and frequent extrasystoles, auricular fibrillation, auricular flutter and paroxysmal ventricular tachycardia have been described.³

A noteworthy feature of the clinical picture of cardiac aneurysm is the normal or low blood pressure. In a series of 15 cases,³ no evidence of previous or present hypertension was found. In Crawford's² series of 13 cases, only 1 patient showed elevated

ETIOLOGY

Pathogenesis

Although a small number of cardiac aneurysms are of rheumatic,^{3, 9, 10} syphilitic,^{1, 3} congenital,^{3, 10} traumatic^{9, 10} and mycotic^{3, 9, 10} origin, the vast majority (at least 85 per cent)^{12, 14} follow coronary occlusion with subsequent myocardial infarction. The infarct is followed by necrosis, which in turn leads to connective-tissue scarring. A variable number of subendocardial elastic fibers are involved. The damaged area behaves in an abnormal manner in that for a period intracardiac pressure during systole results in its expansion. If sufficient fibrous tissue replaces the muscular elements, a localized

which cardiac aneurysm followed gumma or infective endocarditis and abscess formation

Site

Since most cardiac aneurysms follow myocardial infarction,^{12, 14} the most frequent locations for ventricular aneurysms are the areas supplied by the anterior descending branch of the left coronary artery — namely, the apex, the anterior wall of the left ventricle and the anterior half of the interventricular septum. Aneurysm of the posterior wall is rare^{3, 10} despite the frequency of posterior myocardial infarction, and to our knowledge has only been reported as diagnosed clinically by one author.¹⁷ Although aneurysm of the interventricular septum

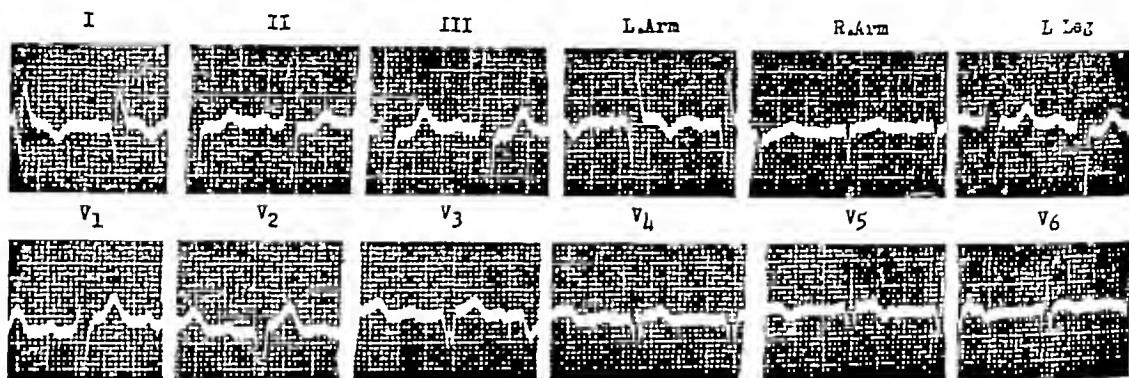

FIGURE 4 *Electrocardiogram in Case 2*

protrusion of the scar results. This protrusion, when present over a considerable length of time, becomes the chronic ventricular aneurysm. If the connective-tissue scar is not sufficiently strong to withstand the intracardiac pressures, rupture of the ventricle and death follow.

The factors that influence the integrity of the fibrous-tissue scar within the damaged area have been described as the number of attacks of myocardial infarction¹⁵ and the amount of bed rest after the acute episode.^{10, 14, 16} Other conditions, such as the presence of concomitant acute disease with increased demands on the heart, chronic pulmonary disease and lack of optimal therapy (oxygen), also affect the status of the healing cardiac musculature. The assumption that multiple attacks of myocardial infarction must occur before a cardiac aneurysm develops is unwarranted, since in 13 of 21 patients described by Brams and Gropper¹⁶ there was a history of only one acute episode.

Other etiologic mechanisms should not be overlooked. Linck¹¹ reports a case due to congenital origin of the left coronary artery from the pulmonary artery, a few cases have been described⁹ in

may cause a Bernheim syndrome⁹ and lead to its discovery by apparent right ventricular enlargement, in most cases this condition cannot be diagnosed during life.

Pathology

The shape of the aneurysm is variable. The most common type is merely a simple outpouching of the heart-muscle wall not sharply delineated from the remainder of the ventricle, occasionally, it is saccular and communicates with the ventricular cavity by means of a neck. The wall of the aneurysm is thin and occasionally transparent, and composed of replacement fibrous tissue and whatever muscular elements remain. It is covered by the firmly adherent pericardium. Within the aneurysm, thrombosis and eventually organization of the clot occur. Calcification of the wall, the clot or the pericardium occurs and may suggest the diagnosis roentgenologically. This calcification occurred in 30 per cent of 20 cases of ventricular aneurysm reported by Foord.¹⁸ It should be noted that calcification of the pericardium may occur as an independent entity, and its presence is not a specific radiographic finding of cardiac aneurysm.

Cardiac aneurysm, varying from the size of an egg,^{20, 22} to an area as large as the heart itself.^{20, 23} Sternberg²⁴ has reported that in living cavities whole aneurysms, and that aneurysms are present in the cardiac contour. The average size of a cardiac aneurysm as observed were 2 to 4 cm in diameter and 2 to 3 cm in depth.^{2, 16} In the living, the apparent size of the aneurysm is increased by the increased intracardiac pressure. The aneurysm may be noted as a bulge or increase in size. Cardiac aneurysms are frequently multiple, and in the series described by Brams and Groppe¹⁶ an aneurysm was found at autopsy, such aneurysms

Incidence

Aneurysm of the heart is stated by Bedford and Thomson³ to occur in 9 per cent of patients suffering myocardial infarction at the Massachusetts General Hospital in a series of 100 cases examined between 1926 and 1940. Bland and White²⁴ found 52 large cardiac aneurysms in 556 patients with myocardial infarction, an incidence of 10 per cent. An incidence of 10 per cent is also reported by Foord¹⁸ in 107 cases of myocardial infarction. It is interesting to observe, although these three papers are based on series from three widely separated geographical areas (England, Massachusetts and California) the relative incidence is the same. Others have found the incidence even higher.²⁵ Libman²⁶ points out that a cardiac aneurysm occurs fifteen times as frequently as Hodgkin's disease. With the increased diagnosis of myocardial infarction,²⁴ it is evident that cardiac aneurysm should be recognized oftener during life.

The development of the aneurysm closely follows the occurrence of myocardial infarction, many appearing within a week to several months after the acute episode.^{15, 17} It is obvious, therefore, that the age incidence for cardiac aneurysm parallels that of myocardial infarction.

Since the incidence of myocardial infarction is greater in men than in women, it is likewise not surprising to note Crawford's¹ statement that in a summary of the literature, 66 per cent of patients with cardiac aneurysms were males. In later papers, the incidence in males appears higher. Parkinson et al.² (1938) report 14 out of 15, Brams and Groppe¹⁶ (1940) 20 out of 21, and Crawford¹ (1943) 11 out of 13.

Pathology

The shape of the aneurysm is variable. The most common type is merely a simple outpouching of the heart-muscle wall not sharply delineated from the remainder of the ventricle, occasionally, it is saccular and communicates with the ventricular cavity by means of a neck. The wall of the aneurysm is thin and occasionally transparent, and composed of replacement fibrous tissue and whatever muscular elements remain. It is covered by the firmly adherent pericardium. Within the aneurysm, thrombosis and eventually organization of the clot occur. Calcification of the wall, the clot or the pericardium occurs and may suggest the diagnosis roentgenologically. This calcification occurred in 30 per cent of 20 cases of ventricular aneurysm reported by Foord.¹⁸ It should be noted that calcification of the pericardium may occur as an independent entity, and its presence is not a specific radiographic finding of cardiac aneurysm.

sequent involvement of the pleura or diaphragm. This systolic expansion is one of the bases for the diagnosis by roentgenkymography. Absent pulsation in this area is the other.

Secondary x-ray findings may be very valuable in the diagnosis. An intraventricular thrombus may cast a shadow of increased density, calcification within the thrombus or wall of the sac may likewise be noted. In this situation the clot is helpful in the x-ray diagnosis but by interference with the transmission of pulsation another important sign is obscured. Schwedel¹⁷ describes an incisura between the bulge and the remainder of the left ventricular contour just above the diaphragm in the anteroposterior view.

Massive aneurysms involving the entire left ventricular wall are commonly overlooked, since the x-ray appearance is then merely one of an enlarged left ventricle.

Even though the most common site for cardiac aneurysm is the apex, this location does not lend itself to easy recognition by routine x-ray study. Surrounding structures, especially the diaphragm, obscure this area. Special technic, including examination under different phases of respiration and the use of effervescent substances to inflate the stomach, may be attempted to reveal the apical aneurysm protruding into the gas bubble.

Posterior-wall aneurysms, which are less common, have been demonstrated by Schwedel¹⁷ by means of fluoroscopy and repeated radiographic examinations that showed progressive increase in size of the localized bulge. Occasionally, the barium-filled esophagus is displaced by the aneurysm of the posterior wall in the left oblique view.⁹

The aneurysm of the interventricular septum has never been diagnosed clinically to our knowledge. The presence of calcification in the septum, however, may lead to its recognition.

Angiocardiography may be of great help in the diagnosis since this method portrays the cardiac chambers and more clearly elucidates deformities of the cardiac contours. It is obvious that a clot may interfere with the deposition of the radio-opaque substance within the cardiac chamber, and hence the continuity or communication of the deformity of the cardiac shadow with the intraventricular cavity may not be demonstrated and a ventricular aneurysm may be missed.

Differential Diagnosis

Only a few conditions are encountered commonly enough to be considered in the differential diagnosis of cardiac aneurysm. Primary tumors of the heart and pericardium are exceedingly rare.³⁵ Metastatic tumors may be considered when an unusual cardiac bulge is seen in a heart that is not enlarged, and when the bulge pulsates synchronously with the remainder of the heart. Occasionally, the diagnosis may be suspected in patients with

known cancer, or in cases of unexplained heart block.³⁶

Localized pericardial fluid may be differentiated by the history of pericarditis and the nature of the pulsation.

Aneurysms of the descending aorta can usually be distinguished by fluoroscopy and possibly by angiocardiology. A diastolic murmur and a positive serologic test for syphilis will aid in the recognition of an aneurysm of the sinus of Valsalva when it projects to the left.

Diseases associated with pulmonary hypertension may enlarge the conus arteriosus so that it simulates cardiac aneurysm. Carefully performed fluoroscopy will demonstrate that the area involved consists of the entire pulmonary conus rather than a localized ventricular bulge, and the type of cardiac murmur (in cases of mitral stenosis), the presence of congenital heart disease or signs of pulmonary disease aid in this differentiation.

Extracardiac lesions that produce apparent deformities of the cardiac silhouette and may be confused with a cardiac aneurysm are tumors of the mediastinum or lung. Of these, dermoids occur at a younger age and are usually asymptomatic except for pressure symptoms, and there is no antecedent history of myocardial infarction. Sometimes the tumors contain teeth or other bony structures, which are seen on x-ray examination. Teratomas of the mediastinum may distort the cardiac configuration³⁷ but may be associated with teratomas elsewhere, as in the ovary or testis.

Other benign or malignant intrathoracic tumors are less common but may be confusing when in close proximity to the ventricular shadow.³⁸ With the development of the technic of visualization of the cardiac chambers and related structures by the injection of 70 per cent diodrast solution most of these extracardiac lesions can be delineated.

A diverticulum of the pericardium projects to the right in contrast to the usual left-sided cardiac aneurysm. Hydatid cyst of the pericardium can be differentiated by appropriate skin and serologic tests. The para-apical fat triangle is easily differentiated by x-ray examination.

Clinical Course

The presence of a cardiac aneurysm does not in itself affect the clinical course. The underlying cardiac disease, rather than the existence of the aneurysm, determines the development of anginal pains, signs or symptoms of congestive heart failure, arrhythmias or even death. Recurrent acute episodes should not be attributed to the cardiac aneurysm but to the progressive coronary-artery and myocardial disease. Fisher³⁹ has recently reported a case of cardiac aneurysm with rupture. In 1944 Beck³⁹ described a case of ventricular aneurysm in which he grafted a segment of fascia lata over the aneurysm in the hope of preventing

blood pressure The blood pressure in Hartley's¹⁰ 2 cases was reported as 110 systolic, 90 diastolic, and 150 systolic, 90 diastolic Penner's⁶ patient had a blood pressure of 140 systolic, 90 diastolic Consideration of this important feature of blood pressure within the normal range led Parkinson, Bedford and Thomson³ to raise the possibility that previous hypertension when associated with ventricular hypertrophy may exert a protective effect in preventing the development of a cardiac aneurysm The thickened muscular wall of the ventricle is less likely to be involved in its entire thickness after coronary thrombosis, whereas the wall of a heart that has not undergone hypertrophy due to hypertension may be more easily involved in greater proportion, leading to the development of a cardiac aneurysm

It must be noted, however, that in 1 of the 3 cases reviewed by Eliaser and Konigsberg²⁹ the patient had hypertension, as did 50 per cent of those in the series of Brams and Gropper¹⁶ The latter authors question the ability of the hypertrophied myocardium, which they consider abnormal muscle, to protect against the formation of cardiac aneurysms

Electrocardiogram

There is no unanimity of opinion about the electrocardiographic pattern in ventricular aneurysm The earliest papers, summarized by Eliaser and Konigsberg²⁹ in 1939, showed that 23.5 per cent of the tracings revealed a downward direction of the major deflection in Lead 1, with inversion of the T wave, whereas the ventricular complex was upright in Lead 3 On the other hand, in Crawford's⁹ analysis of 13 cases, none of the electrocardiograms showed the changes described by the above authors In 35.3 per cent of the cases reported to 1939,²⁹ a left-axis deviation was present, with major deflections directed downward in Lead 2 and Lead 3 with or without low amplitude of the ventricular complex in Lead 1 Some of the remainder showed left-bundle-branch block or equivocal records

Nordenfelt,³⁰ in his electrocardiographic study of 10 cases, showed that when the aneurysm involved the anterior wall the following pattern often persisted: relatively low R or Q wave with negative T wave in Lead 1, deep S wave with upright T wave in Lead 2, deep S wave with upright T wave in Lead 3, and absent or low R wave and deep S wave in Lead 4 In all leads the ST segment was elevated

Sigler and Schneider³¹ observed that the electrocardiogram is of no specific diagnostic value but that apical aneurysms seem to be associated with the pattern described above Gross and Schwedel³² have pointed out that there may be a progressive deviation of the electric axis to the right Goldberger³³ mentions the pattern of low R wave in Lead 1

and deep S waves in Leads 2 and 3 as occurring occasionally in cases of ventricular aneurysm In the most recent paper that we have seen in the literature on the electrocardiographic pattern of ventricular aneurysm, Goldberger and Schwartz³⁴ emphasize the value of the augmented unipolar right-arm lead In 15 cases of ventricular aneurysm in which the standard leads were variable or tended to show the pattern of low R wave in Lead 1 and deep S waves in Leads 2 and 3, the right-arm lead revealed an upward deflection of the QRS complex, regardless of the site of the infarction or rotation of the heart They regard this upward deflection of the QRS complex in the right-arm lead as so important that the diagnosis of ventricular aneurysm should not be made in its absence One of our patients showed this finding (Fig 2), whereas in Case 2 the pattern was atypical (Fig 4)

It is apparent that there is no electrocardiographic pattern that is definitely characteristic of ventricular aneurysm A low R wave in Lead 1, however, with deep S waves in Leads 2 and 3, is suggestive and, if associated with elevated ST segments in all leads, can be considered helpful Persistence of this pattern for a considerable period is also helpful since regression of the pattern to normal often occurs after uncomplicated infarction The presence of right-axis deviation with a heart obviously enlarged to the left is rare but may occur in patients with ventricular aneurysm This right-axis deviation occurred in 27.3 per cent of the cases reported by Eliaser and Konigsberg²⁹

The variation in the electrocardiographic pattern found in ventricular aneurysm must be due to many other factors besides the presence of the ventricular aneurysm It is obvious that progression of the underlying heart disease and recurrent myocardial infarcts influence the electrocardiogram Other changes may be due to rotation of the heart, or to alterations in the thrombus within the aneurysm⁵

X-ray Observations

The localized bulging of the left ventricular wall just above the apex is the most characteristic radiographic appearance of cardiac aneurysms The x-ray diagnosis of the aneurysm in this site is comparatively easy In the anteroposterior view, the bulge is most commonly seen just above the apex, and by means of fluoroscopy or lateral and oblique films, the portion of the ventricle involved is identified In the oblique view, the cardiac silhouette shows an abrupt shelving of the anterior wall⁹ Sometimes, pulsation can be seen in the aneurysmal area, but most investigators agree that it is not a necessary criterion for the diagnosis¹⁷ When this paradoxical pulsation occurs in the bulge, it is almost pathognomonic The bulge may become adherent to the pericardium, and, during systole, there may be expansion of the aneurysm with sub-

sequent involvement of the pleura or diaphragm. This systolic expansion is one of the bases for the diagnosis by roentgenkymography. Absent pulsation in this area is the other.

Secondary x-ray findings may be very valuable in the diagnosis. An intraventricular thrombus may cast a shadow of increased density, calcification within the thrombus or wall of the sac may likewise be noted. In this situation the clot is helpful in the x-ray diagnosis but by interference with the transmission of pulsation another important sign is obscured. Schwedel¹⁷ describes an incisura between the bulge and the remainder of the left ventricular contour just above the diaphragm in the anteroposterior view.

Massive aneurysms involving the entire left ventricular wall are commonly overlooked, since the x-ray appearance is then merely one of an enlarged left ventricle.

Even though the most common site for cardiac aneurysm is the apex, this location does not lend itself to easy recognition by routine x-ray study. Surrounding structures, especially the diaphragm, obscure this area. Special technic, including examination under different phases of respiration and the use of effervescent substances to inflate the stomach, may be attempted to reveal the apical aneurysm protruding into the gas bubble.

Posterior-wall aneurysms, which are less common, have been demonstrated by Schwedel¹⁷ by means of fluoroscopy and repeated radiographic examinations that showed progressive increase in size of the localized bulge. Occasionally, the barium-filled esophagus is displaced by the aneurysm of the posterior wall in the left oblique view.⁹

The aneurysm of the interventricular septum has never been diagnosed clinically to our knowledge. The presence of calcification in the septum, however, may lead to its recognition.

Angiocardiography may be of great help in the diagnosis since this method portrays the cardiac chambers and more clearly elucidates deformities of the cardiac contours. It is obvious that a clot may interfere with the deposition of the radio-opaque substance within the cardiac chamber, and hence the continuity or communication of the deformity of the cardiac shadow with the intraventricular cavity may not be demonstrated and a ventricular aneurysm may be missed.

Differential Diagnosis

Only a few conditions are encountered commonly enough to be considered in the differential diagnosis of cardiac aneurysm. Primary tumors of the heart and pericardium are exceedingly rare.²⁵ Metastatic tumors may be considered when an unusual cardiac bulge is seen in a heart that is not enlarged, and when the bulge pulsates synchronously with the remainder of the heart. Occasionally, the diagnosis may be suspected in patients with

known cancer, or in cases of unexplained heart block.²⁶

Localized pericardial fluid may be differentiated by the history of pericarditis and the nature of the pulsation.

Aneurysms of the descending aorta can usually be distinguished by fluoroscopy and possibly by angiocardiology. A diastolic murmur and a positive serologic test for syphilis will aid in the recognition of an aneurysm of the sinus of Valsalva when it projects to the left.

Diseases associated with pulmonary hypertension may enlarge the conus arteriosus so that it simulates cardiac aneurysm. Carefully performed fluoroscopy will demonstrate that the area involved consists of the entire pulmonary conus rather than a localized ventricular bulge, and the type of cardiac murmur (in cases of mitral stenosis), the presence of congenital heart disease or signs of pulmonary disease aid in this differentiation.

Extracardiac lesions that produce apparent deformities of the cardiac silhouette and may be confused with a cardiac aneurysm are tumors of the mediastinum or lung. Of these, dermoids occur at a younger age and are usually asymptomatic except for pressure symptoms, and there is no antecedent history of myocardial infarction. Sometimes the tumors contain teeth or other bony structures, which are seen on x-ray examination. Teratomas of the mediastinum may distort the cardiac configuration²⁷ but may be associated with teratomas elsewhere, as in the ovary or testis.

Other benign or malignant intrathoracic tumors are less common but may be confusing when in close proximity to the ventricular shadow.²⁸ With the development of the technic of visualization of the cardiac chambers and related structures by the injection of 70 per cent diodrast solution most of these extracardiac lesions can be delineated.

A diverticulum of the pericardium projects to the right in contrast to the usual left-sided cardiac aneurysm. Hydatid cyst of the pericardium can be differentiated by appropriate skin and serologic tests. The para-apical fat triangle is easily differentiated by x-ray examination.

Clinical Course

The presence of a cardiac aneurysm does not in itself affect the clinical course. The underlying cardiac disease, rather than the existence of the aneurysm, determines the development of anginal pains, signs or symptoms of congestive heart failure, arrhythmias or even death. Recurrent acute episodes should not be attributed to the cardiac aneurysm but to the progressive coronary-artery and myocardial disease. Fisher²⁹ has recently reported a case of cardiac aneurysm with rupture. In 1944 Beck³⁰ described a case of ventricular aneurysm in which he grafted a segment of fascia lata over the aneurysm in the hope of preventing

blood pressure The blood pressure in Hartley's¹⁰ 2 cases was reported as 110 systolic, 90 diastolic, and 150 systolic, 90 diastolic Penner's⁶ patient had a blood pressure of 140 systolic, 90 diastolic Consideration of this important feature of blood pressure within the normal range led Parkinson, Bedford and Thomson⁸ to raise the possibility that previous hypertension when associated with ventricular hypertrophy may exert a protective effect in preventing the development of a cardiac aneurysm The thickened muscular wall of the ventricle is less likely to be involved in its entire thickness after coronary thrombosis, whereas the wall of a heart that has not undergone hypertrophy due to hypertension may be more easily involved in greater proportion, leading to the development of a cardiac aneurysm

It must be noted, however, that in 1 of the 3 cases reviewed by Eliaser and Konigsberg²⁹ the patient had hypertension, as did 50 per cent of those in the series of Brams and Gropper¹⁶ The latter authors question the ability of the hypertrophied myocardium, which they consider abnormal muscle, to protect against the formation of cardiac aneurysms

Electrocardiogram

There is no unanimity of opinion about the electrocardiographic pattern in ventricular aneurysm The earliest papers, summarized by Eliaser and Konigsberg²⁹ in 1939, showed that 23.5 per cent of the tracings revealed a downward direction of the major deflection in Lead 1, with inversion of the T wave, whereas the ventricular complex was upright in Lead 3 On the other hand, in Crawford's⁹ analysis of 13 cases, none of the electrocardiograms showed the changes described by the above authors In 35.3 per cent of the cases reported to 1939,²⁹ a left-axis deviation was present, with major deflections directed downward in Lead 2 and Lead 3 with or without low amplitude of the ventricular complex in Lead 1 Some of the remainder showed left-bundle-branch block or equivocal records

Nordenfelt,³⁰ in his electrocardiographic study of 10 cases, showed that when the aneurysm involved the anterior wall the following pattern often persisted: relatively low R or Q wave with negative T wave in Lead 1, deep S wave with upright T wave in Lead 2, deep S wave with upright T wave in Lead 3, and absent or low R wave and deep S wave in Lead 4 In all leads, the ST segment was elevated

Sigler and Schneider³¹ observed that the electrocardiogram is of no specific diagnostic value but that apical aneurysms seem to be associated with the pattern described above Gross and Schwedel³² have pointed out that there may be a progressive deviation of the electric axis to the right Goldberger³³ mentions the pattern of low R wave in Lead 1

and deep S waves in Leads 2 and 3 as occurring occasionally in cases of ventricular aneurysm In the most recent paper that we have seen in the literature on the electrocardiographic pattern of ventricular aneurysm, Goldberger and Schwartz³⁴ emphasize the value of the augmented unipolar right-arm lead In 15 cases of ventricular aneurysm in which the standard leads were variable or tended to show the pattern of low R wave in Lead 1 and deep S waves in Leads 2 and 3, the right-arm lead revealed an upward deflection of the QRS complex, regardless of the site of the infarction or rotation of the heart They regard this upward deflection of the QRS complex in the right-arm lead as so important that the diagnosis of ventricular aneurysm should not be made in its absence One of our patients showed this finding (Fig 2), whereas in Case 2 the pattern was atypical (Fig 4)

It is apparent that there is no electrocardiographic pattern that is definitely characteristic of ventricular aneurysm A low R wave in Lead 1, however, with deep S waves in Leads 2 and 3, is suggestive and, if associated with elevated ST segments in all leads, can be considered helpful Persistence of this pattern for a considerable period is also helpful since regression of the pattern to normal often occurs after uncomplicated infarction The presence of right-axis deviation with a heart obviously enlarged to the left is rare but may occur in patients with ventricular aneurysm This right-axis deviation occurred in 27.3 per cent of the cases reported by Eliaser and Konigsberg²⁹

X-ray Observations

The localized bulging of the left ventricular wall just above the apex is the most characteristic radiographic appearance of cardiac aneurysms The x-ray diagnosis of the aneurysm in this site is comparatively easy In the anteroposterior view, the bulge is most commonly seen just above the apex, and by means of fluoroscopy or lateral and oblique films, the portion of the ventricle involved is identified In the oblique view, the cardiac silhouette shows an abrupt shelving of the anterior wall⁹ Sometimes, pulsation can be seen in the aneurysmal area, but most investigators agree that it is not a necessary criterion for the diagnosis¹⁷ When this paradoxical pulsation occurs in the bulge, it is almost pathognomonic The bulge may become adherent to the pericardium, and, during systole, there may be expansion of the aneurysm with sub-

sequent involvement of the pleura or diaphragm. This systolic expansion is one of the bases for the diagnosis by roentgenkymography. Absent pulsation in this area is the other.

Secondary x-ray findings may be very valuable in the diagnosis. An intraventricular thrombus may cast a shadow of increased density, calcification within the thrombus or wall of the sac may likewise be noted. In this situation the clot is helpful in the x-ray diagnosis but by interference with the transmission of pulsation another important sign is obscured. Schwedel¹⁷ describes an incisura between the bulge and the remainder of the left ventricular contour just above the diaphragm in the anteroposterior view.

Massive aneurysms involving the entire left ventricular wall are commonly overlooked, since the x-ray appearance is then merely one of an enlarged left ventricle.

Even though the most common site for cardiac aneurysm is the apex, this location does not lend itself to easy recognition by routine x-ray study. Surrounding structures, especially the diaphragm, obscure this area. Special technic, including examination under different phases of respiration and the use of effervescent substances to inflate the stomach, may be attempted to reveal the apical aneurysm protruding into the gas bubble.

Posterior-wall aneurysms, which are less common, have been demonstrated by Schwedel¹⁷ by means of fluoroscopy and repeated radiographic examinations that showed progressive increase in size of the localized bulge. Occasionally, the barium-filled esophagus is displaced by the aneurysm of the posterior wall in the left oblique view.⁹

The aneurysm of the interventricular septum has never been diagnosed clinically to our knowledge. The presence of calcification in the septum, however, may lead to its recognition.

Angiocardiography may be of great help in the diagnosis since this method portrays the cardiac chambers and more clearly elucidates deformities of the cardiac contours. It is obvious that a clot may interfere with the deposition of the radio-opaque substance within the cardiac chamber, and hence the continuity or communication of the deformity of the cardiac shadow with the intraventricular cavity may not be demonstrated and a ventricular aneurysm may be missed.

Differential Diagnosis

Only a few conditions are encountered commonly enough to be considered in the differential diagnosis of cardiac aneurysm. Primary tumors of the heart and pericardium are exceedingly rare.³³ Metastatic tumors may be considered when an unusual cardiac bulge is seen in a heart that is not enlarged, and when the bulge pulsates synchronously with the remainder of the heart. Occasionally, the diagnosis may be suspected in patients with

known cancer, or in cases of unexplained heart block.³⁶

Localized pericardial fluid may be differentiated by the history of pericarditis and the nature of the pulsation.

Aneurysms of the descending aorta can usually be distinguished by fluoroscopy and possibly by angiocardiology. A diastolic murmur and a positive serologic test for syphilis will aid in the recognition of an aneurysm of the sinus of Valsalva when it projects to the left.

Diseases associated with pulmonary hypertension may enlarge the conus arteriosus so that it simulates cardiac aneurysm. Carefully performed fluoroscopy will demonstrate that the area involved consists of the entire pulmonary conus rather than a localized ventricular bulge, and the type of cardiac murmur (in cases of mitral stenosis), the presence of congenital heart disease or signs of pulmonary disease aid in this differentiation.

Extracardiac lesions that produce apparent deformities of the cardiac silhouette and may be confused with a cardiac aneurysm are tumors of the mediastinum or lung. Of these, dermoids occur at a younger age and are usually asymptomatic except for pressure symptoms, and there is no antecedent history of myocardial infarction. Sometimes the tumors contain teeth or other bony structures, which are seen on x-ray examination. Teratomas of the mediastinum may distort the cardiac configuration³⁷ but may be associated with teratomas elsewhere, as in the ovary or testis.

Other benign or malignant intrathoracic tumors are less common but may be confusing when in close proximity to the ventricular shadow.³⁸ With the development of the technic of visualization of the cardiac chambers and related structures by the injection of 70 per cent diodrast solution most of these extracardiac lesions can be delineated.

A diverticulum of the pericardium projects to the right in contrast to the usual left-sided cardiac aneurysm. Hydatid cyst of the pericardium can be differentiated by appropriate skin and serologic tests. The para-apical fat triangle is easily differentiated by x-ray examination.

Clinical Course

The presence of a cardiac aneurysm does not in itself affect the clinical course. The underlying cardiac disease, rather than the existence of the aneurysm, determines the development of anginal pains, signs or symptoms of congestive heart failure, arrhythmias or even death. Recurrent acute episodes should not be attributed to the cardiac aneurysm but to the progressive coronary-artery and myocardial disease. Fisher³³ has recently reported a case of cardiac aneurysm with rupture. In 1944 Beck³⁹ described a case of ventricular aneurysm in which he grafted a segment of fascia lata over the aneurysm in the hope of preventing

its rupture. This patient died a few weeks later of a complicating pneumonia. This direction of surgical effort although brilliant seems unwarranted since Levine³⁵ has stated that rupture of the chronic ventricular aneurysm rarely if ever occurs. In the two largest series of cases that we have encountered,^{16, 17} no case of rupture of the cardiac aneurysm took place.

The prognosis of ventricular aneurysm, therefore, depends on the pre-existing coronary-artery disease, and since this may be static or actually improved by the development of collateral circulation there are many reports of longevity^{3, 8} in the literature. In fact, some of these patients have done and are doing manual labor, and many have carried on the normal activities of daily living without untoward incident. The presence of more than one cardiac aneurysm does not seem to alter the prognosis.¹⁶

In some aneurysms thrombosis and fibrosis do not occur, and because of progressive enlargement the wall of the sac becomes thin, its only support being that of the adherent pericardium. It is in this rare type that rupture may take place. Another of the relatively few complications of the aneurysm itself is the development of embolic phenomena. A small portion of the intra-aneurysmal clot may detach itself and result in hemiplegia, gangrene of the feet, or infarcts of the viscera, kidneys or skin.^{3, 10, 20}

DISCUSSION

If one accepts the statement of Parkinson, Bedford and Thomson³ that 1 out of every 11 patients with myocardial infarction will develop cardiac aneurysm and the autopsy figures of the Massachusetts General Hospital²⁴ showing a 10 per cent incidence of cardiac aneurysm in patients after myocardial infarction, it appears that many cases are being missed clinically. Sigler and Schneider²¹ state that only 0.5 per cent have been diagnosed during life and support our impression that the diagnosis should be made more frequently. It might be well, therefore, to review the important diagnostic features of cardiac aneurysm.

A history of previous infarction can usually be elicited although silent myocardial infarction must be kept in mind.

The presence of abnormal pulsations within the area of cardiac dullness but separate and distinct from the apical impulse may be seen.

A poor, dull first sound despite the increased pulsations may be present.

A localized bulge sometimes accompanied by increased density, calcification, pericardial adhesion or incisura (Schwedel) may be demonstrated.

There are also a number of findings that are not in themselves as definitive as those listed above, but their presence should lead to the awareness of the possibility that a ventricular aneurysm exists: an enlarged heart with distant heart sounds, an enlarged heart with the physical finding of normal

blood pressure², an enlarged heart with the electrocardiographic finding of right-axis deviation or the finding of an upward deflection of the QRS complexes in the right-arm lead³⁴, and the late occurrence of cerebral or other embolism in a patient who has had a myocardial infarction.³

In view of the recent emphasis on early ambulation after myocardial infarction, a warning note about the pathogenesis of cardiac aneurysm must be sounded. It has frequently been pointed out^{10, 14, 16, 40} that many patients who have developed ventricular aneurysms have received inadequate bed rest after the acute episode of infarction. Zimdahl and Busuego⁴⁰ considered it significant in the development of the aneurysm in one of their patients that he was sent back and forth to a diagnostic laboratory for three days after his attack. Some patients may have had the silent type of myocardial infarction, and no bed rest at all was prescribed. During the period of myomalacia every precaution must be taken to support the weakened myocardium, and undoubtedly bed rest reduces the work of the heart and allows a firmer scar to develop.

It will be interesting to note the effect on the incidence of rupture of ventricular aneurysm of the introduction in 1945⁴¹ of anticoagulant therapy for myocardial infarction. Reduction of clot formation within the aneurysm theoretically may result in a thin-walled sac that does not have the support of a firm, lamellated clot. The x-ray diagnosis may be more difficult because of the lack of increased density and calcification in the bulge. This type, having only the pericardium as its support, tends to increase its size and is more likely to rupture. On the other hand, the late embolic manifestations mentioned above may be prevented.

SUMMARY

Two cases of ventricular aneurysm diagnosed during life are reported. The patients are not incapacitated by their cardiac aneurysms, and their cardiac symptoms are referable to the underlying cardiac disease.

The increased incidence, physical and x-ray findings, and clinical course of cardiac aneurysm are reviewed. Certain criteria for the ante-mortem diagnosis, as well as the brighter outlook regarding prognosis and longevity, are stressed.

The effect on cardiac aneurysms of two recently introduced regimens in the therapy of myocardial infarction — early ambulation and anticoagulant therapy — are briefly discussed.

OSTEITIS PUBIS*

M ABRAMS, MD,* I SEDLEZKY, MD,† AND DAVID B STEARNS, MD‡

BOSTON

THE number of reported cases of osteitis pubis following suprapubic or retropubic prostatectomy^{1,11} suggests that it is a rare complication. Since this is not in accord with our own experience we herewith present 5 cases with observations relating to diagnosis and treatment. Two of them followed retropubic prostatectomy, and 2 followed suprapubic prostatectomy, the fifth case followed an abdominoperineal resection for carcinoma of the rectum.

CASE REPORTS

CASE 1 J W, a 61-year-old man, was admitted to the hospital with the chief complaint of frequency of urination during the day and night and hesitancy and diminution in the force of the urinary stream. An examination of the urine revealed 15 to 20 white cells and 3 to 5 red cells per high-power field. Urine culture grew out many colonies of hemolytic *Staphylococcus aureus*. The findings of the lower urinary tract were consistent with an obstructing prostate. Three days later a retropubic prostatectomy was done. The post-operative course was uneventful.

Thirty-eight days after the operation the patient first began to notice pain over the symphysis pubis. The pain gradually became worse, and 12 days thereafter he was readmitted to the hospital. Coughing, walking or motion of the legs in any direction increased the severity of the pain. Except for marked tenderness over the symphysis pubis, physical examination was entirely negative.

The white-cell count was 15,000, the blood acid and alkaline phosphatase as well as the phosphorus, were normal. Urine culture showed a few colonies of *Pseudomonas aeruginosa* and *Staph. albus*. A roentgenogram taken the day after admission showed some irregularity and erosion of the upper edges of the inner margins of the pubic bones. Successive films demonstrated progressive destruction of the medial margins of the pubic bones. Healing was demonstrated by the laying down of dense bone at the articular margins of the pubis.

Streptomycin, penicillin sulfadiazine and sulfamerazine failed to alter the clinical course of the disease. Diathermy and local heat were ineffective. Opiates were necessary to control the pain and discomfort. At the end of 3 weeks, an orthopedic belt which had only aggravated the symptoms in the acute phase of the disease, now gave definite relief. Improvement occurred slowly. The patient was free of all pain 9 weeks after the onset of symptoms.

CASE 2 M H, a 74-year-old man, was admitted to the hospital in acute urinary retention. For 1 year prior to admission he had complained of nocturia three to five times and of difficulty in starting the urinary stream. The prostate on rectal examination was very large. Examination of the urine revealed 3 to 5 white cells per high-power field. Culture of

*Assistant in genitourinary surgery Harvard Medical School resident in urology Beth Israel Hospital.

†Resident in radiology Beth Israel Hospital.

‡Assistant professor of urology Boston University School of Medicine visiting urologist, Massachusetts Memorial Hospitals associate visiting urologist, Beth Israel Hospital.

the urine grew out a few colonies of *Ps aeruginosa*. Five days later a retropubic prostatectomy was done. The post-operative course was uneventful. A urine culture taken the day the catheter was removed grew out many colonies of *Aerobacter aerogenes* and *Ps aeruginosa*.

Twenty-nine days after operation the patient began to complain of a constant dull pain over the symphysis pubis and along the inner aspects of both thighs. Coughing, walking or sitting aggravated the pain. There was definite localized tenderness over the symphysis pubis. On examination the white-cell count was 12,000, the acid and alkaline phosphatase levels were normal. A culture of the urine grew out *Ps aeruginosa*. A roentgenogram of the pelvis taken 7 days after the onset of symptoms revealed slight erosion of the

tional surgical procedure was necessary. Four months after operation the patient first began to complain of a dull aching pain in both groins. The pain was referred to the perineum and along the inner aspects of both thighs. Gradually these symptoms became worse, and 2 months thereafter the discomfort required hospitalization.

Physical examination revealed an elderly man in obvious pain. Coughing, sitting or any movement of the lower extremities increased the severity of the symptoms. There was definite tenderness over the symphysis pubis. On examination the urine contained 15 to 20 white cells and 5 to 10 red cells per high-power field. Culture of the urine showed many colonies of *Ps aeruginosa*, as well as a moderate number of *Escherichia coli*. The blood calcium, acid phosphatase, al-

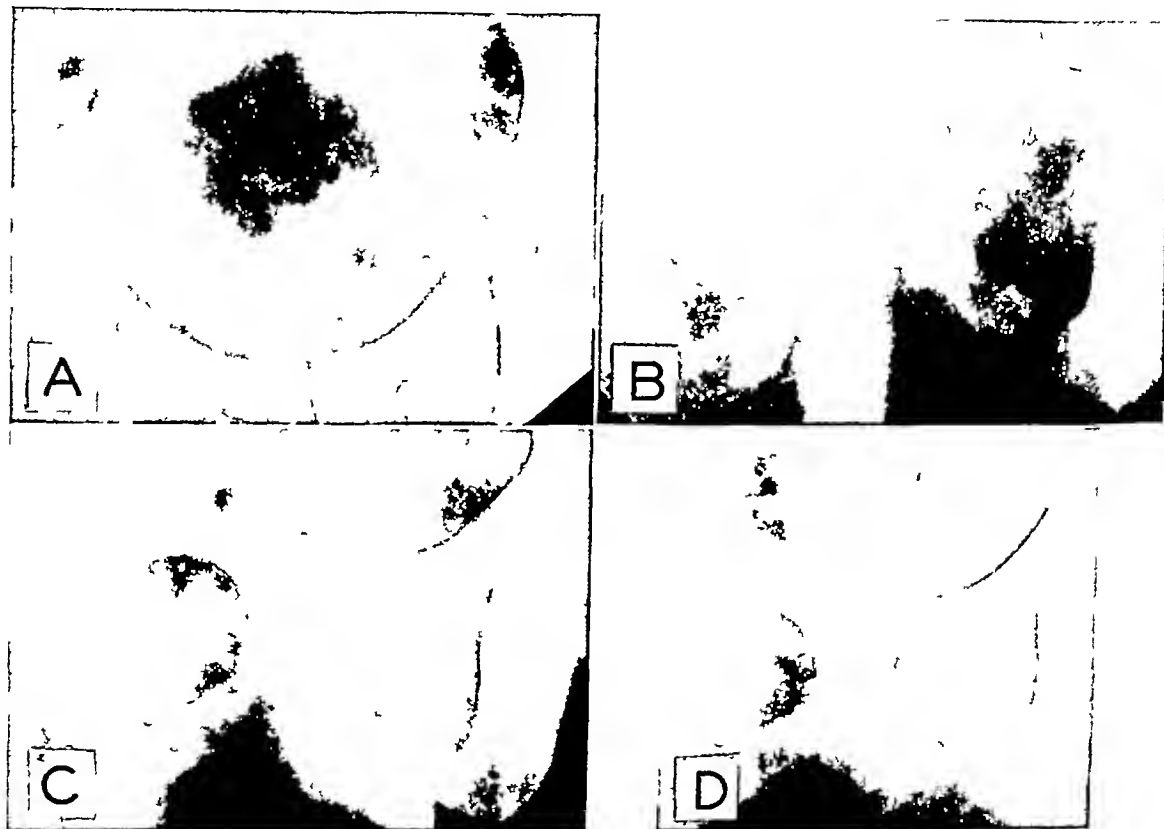

FIGURE 1 Roentgenograms in Case 3

A = preoperative film, showing normal symphysis pubis (note prostatic calculi). B and C = films taken six months after suprapubic prostatectomy, with the patient standing first on the left foot and then on the right (note the wide symphysis and considerable mobility of the pubic bones). D = film taken eighteen months after operation, showing the symphysis pubis to be irregularly widened (the bony margins are dense, and the adjacent bone sclerotic, the process is apparently healed).

right os pubis. Another roentgenogram taken 1 month later demonstrated further destruction of the upper medial corner of the left os pubis. Penicillin, streptomycin and sulfadiazine had no effect on the clinical course of the disease. Large doses of vitamin B given intravenously in conjunction with a course of deep x-ray therapy proved ineffective. An orthopedic belt, which extended from above the crest of the ilium to below the symphysis pubis, allowed the patient to become ambulatory 2 weeks after the onset of symptoms. Six weeks later he was entirely free of pain.

CASE 3 F W, a 66-year-old man, had a two-stage suprapubic prostatectomy for a benign prostatic hypertrophy. Numerous calculi were present within the prostate. After the second stage, the immediate postoperative course was complicated by the development of epididymitis. The elevated temperature returned to normal in 6 days, and no addi-

kaline phosphatase and phosphorus were normal. A roentgenogram of the pelvis demonstrated the wide symphysis pubis that is consistent with osteitis pubis. Films taken with the patient standing first on the left foot and then the right foot revealed the extreme mobility of the pubic bones at this time (Fig 1B and C). Immobilization of the pubis with a tight orthopedic belt gave the patient some relief. Eight days later he was ambulatory with the aid of a cane. Twenty days later he was discharged, very much improved, but still unable to walk without the aid of the tight belt and cane. A roentgenogram taken 1 year later showed an irregularly widened symphysis pubis. The bony margins were dense, and the adjacent bone sclerotic. This represented a healed process (Fig 1D).

CASE 4 A M, a 71-year-old man, had a two-stage suprapubic prostatectomy for a benign hypertrophy of the prostate

in another hospital. He was discharged 25 days after the second operation with a small, draining suprapubic sinus. Urinary control was excellent. Seventy-seven days after operation he was admitted for the first time to the Massachusetts Memorial Hospitals because of severe pain over the symphysis pubis and across the inner aspects of both thighs. Coughing, walking or motion of the legs in any direction aggravated the pain. These symptoms had begun 3 weeks earlier and had gradually become worse. There was tenderness on pressure over the symphysis pubis. A slight purulent discharge at the lower angle of the suprapubic wound was noted. The rest of the examination was entirely negative.

On admission, the urine contained many white cells and 2 or 3 red cells per high-power field. Culture of the urine grew out *Ps aeruginosa* and *Esch coli*. The white-cell count was 15,500. The acid and alkaline phosphatase determinations were normal. A roentgenogram of the pelvis showed a wide symphysis pubis with irregular erosion of the bone surfaces (Fig 2). A diagnosis of osteitis pubis was made. Two days

FIGURE 2 Roentgenogram Taken in Case 4 Seventy-Seven Days after a Suprapubic Prostatectomy. Note the unusually wide symphysis, with irregular erosion of the bony surfaces, the pubic bones show patchy rarefaction.

later a course of deep x-ray therapy was given. The patient received 200 r daily for 6 days over the pubis. Large doses of components of the vitamin B complex were also given. On the 4th day of therapy, definite improvement was noted. Four days later, the patient was able to move with only moderate discomfort. Seven days later he was discharged totally free from symptoms. The sinus at the lower end of the incision was healed. (No antibiotics or sulfonamides were given to this patient.)

CASE 5* E S, a 50-year-old man, was admitted to the Massachusetts Memorial Hospitals for an abdominoperineal resection for an adenocarcinoma of the rectum. He had a moderately febrile postoperative course. Two months thereafter he was readmitted to the hospital because of constant pain over the symphysis pubis. Standing, sitting, coughing or walking increased the severity of the pain. On admission the temperature was 101°F. Examination of the urine showed 5 to 6 white cells per high-power field. Urine culture grew out many colonies of *Ps aeruginosa* and hemolytic *Staph aureus*. The white-cell count was 12,000. Physical examination revealed a functioning colostomy, a small draining sinus at the lower end of the abdominal incision and tenderness to even slight palpation over the symphysis pubis. Cultures from the draining sinus grew out *Ps aeruginosa*. A roent-

genogram of the pelvis demonstrated beginning erosion of the medial surfaces of both pubic bones with widening of the symphysis.

Penicillin and sulfadiazine were started on admission. Four days later the temperature returned to normal. However, the pain over the symphysis pubis persisted for 3 weeks, when gradually it began to subside. Four weeks later the patient was free of all pain. A roentgenogram taken 7 months after the operation again demonstrated a wide symphysis pubis. Healing was clearly represented by the irregular, dense and sclerotic medial margins of the pubis.

DISCUSSION

Although the etiology of this condition remains obscure, the symptoms, physical findings, laboratory data and course are all suggestive of an inflammatory process. Wheeler,⁵ on the basis of his experimental studies, did not consider osteitis pubis as an inflammatory process. He attempted to reproduce this disease in the rabbit by introducing urine, both sterile and infected, under the periosteum of the pubis. This failed to produce any evidence of periostitis. The introduction of foreign bodies under the periosteum and even deliberate trauma to the space of Retzius failed to reproduce periostitis or osteitis. Wheeler therefore preferred to consider this syndrome as an example of acute bone atrophy of the Sudeck type. Sudeck's acute bone atrophy has been described¹² as a post-traumatic type of lesion that usually occurs in the neighborhood of multiarticular joints such as the wrist and foot and is regarded as a neurovascular disturbance. In addition to pain over the involved joint there is swelling, atrophy of the subcutaneous tissues and trophic changes in the skin. Roentgenologically, there is very marked decalcification of the bones.

We believe that osteitis pubis is of an inflammatory nature. The urine that escapes into the space of Retzius during and after operation slowly saturates and puddles in the retropubic soft tissues and sets up an inflammatory process that progresses so that the bone eventually becomes involved. At this point the clinical symptoms become evident. Although no bone biopsies were taken in any of the cases reported above, Muschat⁷ reports a curettage biopsy of the symphysis pubis in a patient suffering from osteitis pubis. The specimen showed inflammation. Chemotherapy failed to alter the clinical course of the disease in any of our cases. Trauma to the symphysis pubis — by retractors, drains or needle puncture — may be a factor in the development of this clinical entity. The fact that osteitis pubis occurs so infrequently in women after extensive gynecologic operations suggests that trauma alone is not the sole cause.

The diagnosis of osteitis pubis offers no particular problem clinically. A history of a recent prostate operation and the development of localized pain over the symphysis should immediately suggest this condition. The pain, which is at first mild, soon becomes severe and radiates to the perineum and over the inner aspects of the thighs. Any motion

*Permission to cite this case was obtained from Dr. C. Howe.

of the lower extremities increases the intensity of the pain. The pain is probably the result of muscle pull on the inflamed periosteum, in addition to increased intraosseous tension. In the 5 cases reported above, pain over the symphysis pubis appeared as early as twenty-nine days (Case 2), and as late as a hundred and twenty days after operation (Case 3). Some authors report these symptoms as early as fourteen days after the operation. Physical findings are usually entirely negative except for the localized tenderness over the symphysis pubis. A suprapubic sinus is occasionally found (Cases 4 and 5). During the early stages of the disease the patient usually has a mild fever. A white-cell count of 12,000 to 15,000 was present in all our cases. A moderate anemia was noted in Cases 4 and 5. The blood calcium, phosphorus, acid and alkaline phosphatase were normal. Examination of the urine revealed many white cells. Cultures of the urine grew out *Ps aeruginosa*, *Esch coli* and hemolytic *Staph aureus*. *Ps aeruginosa* was predominant and present in all cases.

Though this condition can be suspected on the basis of the clinical features, the final diagnosis rests on the roentgenologic findings. The technic of x-ray examination is important. The use of a fine-focus tube, a small cone and a Bucky diaphragm with the patient in the prone position are all essential factors in demonstrating the earliest bony changes. Stereoscopic films may be of help. The rectum should be free of gas and feces.

In general, roentgenographic changes have been observed two or three weeks after the onset of symptoms. However, in 1 case (Case 2) changes were noted as early as seven days. The earliest changes consist of blurring of the symphyseal contours of the pubis, with patchy osteoporosis of the contiguous bone. As the process continues bilateral, irregular and progressive destruction of the opposing articular surfaces of the symphysis pubis occurs. This is largely symmetrical, but one side may be more involved. No sequestra are produced or expected since the bone involved is predominantly spongy. It is a fact that necrotic, spongy bone is removed by resorption, and only compact bone by sequestration.¹³ The progressive widening of the symphysis pubis is predominantly the result of loss of bone substance rather than just a separation of the pubic bones. The changes in the symphysis pubis are sufficient to permit considerable vertical mobility of the pubic bones. To show this, films were taken with the patient standing first on one foot and then on the other (Fig 1B and C).

The healing period is variable, depending upon the extent of the lesion. Most authors agree that this period varies from two to six months. Roentgenologically, healing is signalled by the arrest in the progress of the bone destruction and the laying down of dense bone at the margins of the eroded symphysis pubis. Cases have been described in

which the end result is ankylosis of the symphysis pubis.

The differential diagnosis included a simple pre-vesical-space infection without bone involvement, acute and chronic hematogenous osteomyelitis of the pubic bone, a metastatic lesion from the prostate and primary bone sarcoma.

A simple infection of the space of Retzius without bone involvement should offer no problem in the differential diagnosis. The clinical course is mild, and roentgenologic changes are absent. An acute hematogenous pyogenic osteomyelitis will give a more severe, more acute systemic reaction as well as more pronounced local changes. A specific chronic infection such as tuberculosis can be less easily ruled out purely on the basis of the initial roentgenographic changes. Tuberculosis of the symphysis pubis is extremely rare. The initial destructive phase may be difficult to distinguish from a metastatic lesion from a prostatic carcinoma. The characteristic restricted localization of bone resorption to the pubis, the history of a recent prostatic operation, the low-grade febrile course and the prominence of osteolysis with little or no osteoblastic features are against a metastatic lesion from the prostate. The acid and alkaline phosphatase was normal in the 5 cases of osteitis pubis reported above. The lack of periosteal reaction and the absence of spiculation or tumor mass are all against a diagnosis of primary bone sarcoma.

There is no specific treatment for this clinical entity. In the acute phase the intense suprapubic pain forces the patient to complete bed rest. Opiates and sedatives are necessary to keep the patient comfortable. In our cases, the use of penicillin, streptomycin and sulfadiazine did not in any way alter the course of the disease. Diathermy and local heat over the symphysis had little effect. The injection of 1 per cent novocain into the painful spastic muscles of the upper thigh occasionally gave temporary relief. In 1 case the use of deep x-ray therapy appeared to be beneficial. In 2 other cases in which it was tried it was of no benefit. Large doses of components of the vitamin B complex were also ineffective. After the subsidence of the acute process, which lasted between eighteen and twenty-one days, an orthopedic belt, extending from above the crest of the ilium to below the symphysis pubis, immobilized the symphysis pubis and proved beneficial. This belt, with the aid of a cane, allowed early motion. Relief of symptoms occurred slowly.*

SUMMARY

Five cases of osteitis pubis are reported. Two of them followed retropubic prostatectomy, 2 followed suprapubic prostatectomy, and the fifth an abdominoperineal resection for carcinoma of the rectum. We do not know the specific etiology of

*Since this paper was submitted for publication 4 additional cases of osteitis pubis have been reported: 2 after retropubic surgery and 2 after transurethral resection.

osteitis pubis but consider it to be inflammatory. Trauma to the symphysis pubis, by retractors, drains or needle puncture, may be a factor in the development of this clinical entity. The fact that osteitis pubis occurs so infrequently in women after extensive gynecologic operations suggests that trauma alone is not the sole cause.

The diagnosis of osteitis pubis offers no particular problem. A history of a recent prostatic operation and the development of localized pain over the symphysis pubis should immediately suggest this entity. The roentgenologic findings are typical and definitely establish the diagnosis. The medial articular aspects of the pubic bones are predominantly involved. First there is merely blurring of the bony contours associated with osteoporosis of the adjacent bone. Then, there is slow, progressive erosion of the symphyseal aspects of the pubic bones. Healing is shown by arrest in the progress of the bone destruction and the laying down of dense sclerotic bone at the margins of the widened symphysis pubis. Urine cultures in the 5 cases reported grew out *Pseudomonas aeruginosa*. The significance of this finding is not established.

There is no specific treatment of osteitis pubis. Although deep x-ray therapy and large doses of com-

ponents of the vitamin B complex appeared to help 1 patient, they proved of no help in 2 other cases. Penicillin, streptomycin, sulfadiazine and sulfathiazole were ineffective in controlling any of the symptoms. The disease, though distressing and of long duration, is self limited and does not require surgical intervention.

WERNER'S SYNDROME*

A Report of Two Cases

JACOB SCHOTT, M.D.,† AND SIDNEY DANN, M.D.‡

BROOKLYN, NEW YORK

OCCASIONALLY the opportunity of seeing one of the rarer disease states or syndromes presents itself to most physicians. Their recognition can be made more readily possible if those who see them bring them to the attention of the profession.

Our purpose in this paper is to add 2 more cases of Werner's syndrome to the literature, to review briefly the more pertinent features of the syndrome and to outline the criteria in as simple a manner as possible, so that they can be easily remembered. Thannhauser,§ in 1945, added 5 cases to the literature and in a most excellent article summarized all that had been published on the subject.

ETIOLOGY

The etiology of the disease is not definitely known. The accepted theory at present is that it is due to a defect in the germ plasma that becomes evident in

the third or fourth decade of life. That it is a primary endocrine disturbance has been excluded. Although there is not much doubt that an endocrine element is present, this is thought to be secondary and not primary.

Heredity plays a role, there is frequently collateral occurrence in brothers and sisters of one generation.

DIAGNOSIS

Usually the first frank manifestation of the syndrome is premature graying of the hair, soon followed by thinning.

The shortness of stature dates back to the adolescent age. Birth and childhood development are normal, but in the adolescent years these patients do not maintain the expected growth increase.

Not long after the graying of the hair, which usually starts about the age of twenty, the extremities, particularly the lower ones, begin to take on a spindly appearance. Much discussion and investigation of the skin changes has resulted in the conclusion that they are not sclerodermatous in character. From the waxy, taut, atrophic appearance, at first glance one is apt to mistake them for sclero-

§Thannhauser S. J. Werner's syndrome (progeria of adult) and Rothmund's syndrome: two types of closely related hereditary atrophic dermatoses with juvenile cataracts and endocrine features: critical study with five new cases. *Ann. Int. Med.* 23:559-626, 1945

of the lower extremities increases the intensity of the pain. The pain is probably the result of muscle pull on the inflamed periosteum, in addition to increased intraosseous tension. In the 5 cases reported above, pain over the symphysis pubis appeared as early as twenty-nine days (Case 2), and as late as a hundred and twenty days after operation (Case 3). Some authors report these symptoms as early as fourteen days after the operation. Physical findings are usually entirely negative except for the localized tenderness over the symphysis pubis. A suprapubic sinus is occasionally found (Cases 4 and 5). During the early stages of the disease the patient usually has a mild fever. A white-cell count of 12,000 to 15,000 was present in all our cases. A moderate anemia was noted in Cases 4 and 5. The blood calcium, phosphorus, acid and alkaline phosphatase were normal. Examination of the urine revealed many white cells. Cultures of the urine grew out *Ps aeruginosa*, *Esch coli* and hemolytic *Staph aureus*. *Ps aeruginosa* was predominant and present in all cases.

Though this condition can be suspected on the basis of the clinical features, the final diagnosis rests on the roentgenologic findings. The technic of x-ray examination is important. The use of a fine-focus tube, a small cone and a Bucky diaphragm with the patient in the prone position are all essential factors in demonstrating the earliest bony changes. Stereoscopic films may be of help. The rectum should be free of gas and feces.

In general, roentgenographic changes have been observed two or three weeks after the onset of symptoms. However, in 1 case (Case 2) changes were noted as early as seven days. The earliest changes consist of blurring of the symphyseal contours of the pubis, with patchy osteoporosis of the contiguous bone. As the process continues bilateral, irregular and progressive destruction of the opposing articular surfaces of the symphysis pubis occurs. This is largely symmetrical, but one side may be more involved. No sequestra are produced or expected since the bone involved is predominantly spongy. It is a fact that necrotic, spongy bone is removed by resorption, and only compact bone by sequestration.¹³ The progressive widening of the symphysis pubis is predominantly the result of loss of bone substance rather than just a separation of the pubic bones. The changes in the symphysis pubis are sufficient to permit considerable vertical mobility of the pubic bones. To show this, films were taken with the patient standing first on one foot and then on the other (Fig 1B and C).

The healing period is variable, depending upon the extent of the lesion. Most authors agree that this period varies from two to six months. Roentgenologically, healing is signalled by the arrest in the progress of the bone destruction and the laying down of dense bone at the margins of the eroded symphysis pubis. Cases have been described in

which the end result is ankylosis of the symphysis pubis.

The differential diagnosis included a simple pre-vesical-space infection without bone involvement, acute and chronic hematogenous osteomyelitis of the pubic bone, a metastatic lesion from the prostate and primary bone sarcoma.

A simple infection of the space of Retzius without bone involvement should offer no problem in the differential diagnosis. The clinical course is mild, and roentgenologic changes are absent. An acute hematogenous pyogenic osteomyelitis will give a more severe, more acute systemic reaction as well as more pronounced local changes. A specific chronic infection such as tuberculosis can be less easily ruled out purely on the basis of the initial roentgenographic changes. Tuberculosis of the symphysis pubis is extremely rare. The initial destructive phase may be difficult to distinguish from a metastatic lesion from a prostatic carcinoma. The characteristic restricted localization of bone resorption to the pubis, the history of a recent prostatic operation, the low-grade febrile course and the prominence of osteolysis with little or no osteoblastic features are against a metastatic lesion from the prostate. The acid and alkaline phosphatase was normal in the 5 cases of osteitis pubis reported above. The lack of periosteal reaction and the absence of spiculation or tumor mass are all against a diagnosis of primary bone sarcoma.

There is no specific treatment for this clinical entity. In the acute phase the intense suprapubic pain forces the patient to complete bed rest. Opiates and sedatives are necessary to keep the patient comfortable. In our cases, the use of penicillin, streptomycin and sulfadiazine did not in any way alter the course of the disease. Diathermy and local heat over the symphysis had little effect. The injection of 1 per cent novocain into the painful spastic muscles of the upper thigh occasionally gave temporary relief. In 1 case the use of deep x-ray therapy appeared to be beneficial. In 2 other cases in which it was tried it was of no benefit. Large doses of components of the vitamin B complex were also ineffective. After the subsidence of the acute process, which lasted between eighteen and twenty-one days, an orthopedic belt, extending from above the crest of the ilium to below the symphysis pubis, immobilized the symphysis pubis and proved beneficial. This belt, with the aid of a cane, allowed early motion. Relief of symptoms occurred slowly.*

SUMMARY

Five cases of osteitis pubis are reported. Two of them followed retropubic prostatectomy, 2 followed suprapubic prostatectomy, and the fifth an abdominoperineal resection for carcinoma of the rectum. We do not know the specific etiology of

*Since this paper was submitted for publication 4 additional cases of osteitis pubis have been reported: 2 after retropubic surgery and 2 after transurethral resection.¹⁴

was completely normal. Three other siblings had died at birth, a fourth had died at the age of 2 weeks.

The patient weighed 102 pounds and was 4 feet, 10 inches in height. Her habitus was strikingly characteristic — spindly arms and legs, with a normally developed trunk. She had the typical bird-like facies resulting from a receding chin, tendency to beaking of the nose and the wearing of powerful lenses in her eyeglasses. Her gait was unsteady because of the atrophy of the muscles of the lower extremities and the high plantar arch, but she walked without any characteristic aberration. Her hair was diffusely sparse and was dyed black. She was of average intelligence and of rather cheerful disposition. No respiratory distress or asthenia was noted.

The right eye showed a buphthalmos (post-glaucoma), and the left a surgical coloboma. Some fibrosis of the lens bed was noted. The fundus seen through a +15 lens was slightly paler than normal, the vessels were moderately sclerotic, but there were no hemorrhages, exudates or pigmentation. The movements of the extraocular muscles were normal. There was mild circumcorneal injection of the left eye. The teeth were in good condition. The tongue was moist, with well developed papillae. The pharynx was clear. The ears were normal and did not project from the sides of the head in any unusual fashion. The eardrums were also normal. The eyelashes and eyelids were sparse. The voice appeared to be weak and somewhat high pitched (confirmed by the patient's statement), but indirect laryngoscopy did not reveal the hyperemic or keratotic changes described in this condition. The neck was supple. There was no distention of the veins, no tracheal deviation and no palpable thyroid gland.

The lungs were clear to percussion and auscultation. The heart was not enlarged, and the sounds were of fair quality. The aortic second sound was louder than the pulmonary. There was a Grade III, blowing systolic murmur over the entire precordium, maximal over the base, there were no thrills. Sinus rhythm was normal.

The left breast showed normal development, no masses or tenderness was noted. On the right side there was a healed mastectomy scar with no evidence of infiltration or tenderness in this region.

The abdomen was moderately obese and flabby. There was slight tenderness in the right upper quadrant, but no palpable masses or viscera.

Neurologic examination was entirely normal.

There was marked atrophy of the musculature of all the extremities, most pronounced in the distal segments, and this was accompanied by a moderate degree of weakness. The skin also appeared to be atrophic and over some of the terminal phalanges appeared to be tightly bound down to the underlying tissues, although true scleroderma was not present. Owing to the muscular atrophy the bony prominences of the fingers and toes were more prominent. The instep was markedly arched, and the patient used metal arches in her bathroom slippers for ambulation. There was bilateral hallux valgus. Callosities, the size of a 25-cent piece, were noted in the skin over the heads of the first and fifth metatarsals and over the calcaneus, these areas were not tender. On the right medial and the left lateral malleoli there were ulcerations about the size of a dime. These were excavations bordered by corn-like areas similar to those described above. The bases were greyish yellow, and there was no discharge. The areas were quite tender to the touch. Three scabrous callosities were also noted over the lower tibial areas. The tip of the third right toe was reddened, but no discharge was noted. There was no clubbing or edema. There were good pulsations of the posterior tibial and dorsalis pedis vessels.

The skin was dry and atrophic, with a moderate degree of fine scaling. There were no telangiectases, petechiae or jaundice. The nails were well developed but showed evidence of having been bitten. No fat pads were noted. There was a normal distribution of the female hair.

Rectal examination was negative.

Pelvic examination showed a parous introitus. There were no abnormal findings.

The temperature was 98.6°F, the pulse 80, and the respirations 20. The blood pressure was 110/70.

Examination of the blood revealed a red-cell count of 2,500,000, with a hemoglobin of 10 gm per 100 cc., and a white-cell count of 12,900, with 40 per cent neutrophils and

60 per cent lymphocytes. The sedimentation rate (Linzenmeier method) was 18 mm in 43 minutes. The urine, which had a specific gravity of 1.010, gave a negative to +++ test for sugar, a negative test for albumin and a negative test for acetone, the sediment contained an occasional white cell. The blood sugar was 103 to 225 mg, the urea nitrogen 15 mg, the calcium 9.5 to 11.0 mg, the phosphorus 3.0 to 6.5 mg, the uric acid 3.4 mg, the creatinine 1.6 mg, and the cholesterol 200 mg per 100 cc., with 25 per cent cholesterol esters. The total protein was 6.8 gm per 100 cc., with 4.7 gm of albumin and 2.1 gm of globulin, and the carbon dioxide combining power 56 to 68 vol per cent. The urea clearance was 32 per cent. The phenolsulfonephthalein test showed 45 per cent excretion of the dye in 2 hours. The galactose tolerance test showed the excretion of 3.2 gm in the urine. The alkaline phosphatase was 1.6 Bodansky units per 100 cc. The cephalin flocculation and Mazzini tests were negative. The basal metabolic rate was +1 per cent.

Oscillometric findings on the left were 2.5 at the wrist, 2 above the ankle, 4 below the knee and 4 above the knee, and on the right, 1.5 at the wrist, 4 above the ankle, 4 below the knee and 4 above the knee.

Electrocardiograms, which revealed a tendency to left-axis deviation (with a small Q wave and isoelectric T wave in Lead 3, inverted T wave in Lead CF₂ and upright but low-voltage T wave in Lead CF₄), were interpreted as showing questionable myocardial damage.

X-ray examination of the chest was negative except for evidence of removal of the right breast. Films of the feet demonstrated marked hallux valgus on the right and a moderate degree on the left. There were no apparent gross abnormalities in the bones of the upper and lower extremities. The hands disclosed normal bone texture and density. Films of the skull showed hyperostosis of the frontal and parietal bones bilaterally. The pituitary fossa was small but within normal limits. There was no evidence of increased intracranial pressure or bone erosion.

The patient was placed on partial bed rest and given 200 gm of carbohydrate, 75 gm of protein and 40 gm of fat. She was fairly well regulated on 15 units of protamine zinc insulin and 15 units of regular insulin given in separate syringes in the morning. She also received the following medications three times daily: nicotinic acid, 200 mg, vitamin C, 200 mg, and vitamin B₁₂, 20 mg. Papaverine, which had been given in doses of 0.1 gm (1½ gr) three times daily, was discontinued because of nausea. The patient claimed considerable subjective improvement on this medication, she stated that her legs felt "looser and stronger." The ulcerations healed slowly, leaving thin scabrous lesions. Of course, it is not possible to determine the relative roles played by the bed rest and the medications in the healing of these long-standing lesions. She was placed gradually on an ambulatory status and discharged as "improved" after 7 weeks in the hospital.

CASE 2. M.B., a 45-year-old woman, the sister of the patient in Case 1, was admitted to the Cumberland Hospital on February 10, 1948, complaining of chest pain of 2 days' duration. The pain was described as precordial and substernal and continuous in severity, with no radiation. She complained of weakness and had noted dyspnea only on talking. There was no cough, edema or palpitations and no previous similar episodes.

The past history included diabetes of 16 years' duration, the diagnosis had first been made during routine urine examination while the patient was undergoing treatment for a foot infection. The disease had been fairly well controlled on 10 units of regular insulin and 10 units of protamine zinc insulin taken in separate syringes in the morning. Three and a half years prior to admission a cataract developed in the right eye, and this was removed 6 months later. One year before admission a cataract extraction was done on the left eye. Vision had been poor. Glaucoma developed in the right eye postoperatively. The patient had had gray hair since the age of 40. Three years prior to admission ulcers on the legs entirely similar to those described in Case 1, as well as corns over the bony prominences on the soles of the feet, developed. The ulcers were painful, and she had great difficulty in walking. She stated that the legs felt very cold and she was bothered by cold weather.

dermatous extremities, but on more careful examination, it is found that the skin can be elevated easily from the subcutaneous structures. It is in the latter structures that the fault lies. The subcutaneous fat tissue is practically absent, and the underlying muscle is extremely thin and atrophic.

Areas of circumscribed hyperkeratoses and ulcerations are not long in appearing, superimposed on the underlying skin changes. That the ulcers are not completely trophic is shown by their readiness in successfully taking a skin graft. The ulcers appear most frequently on areas subjected to pressure—the malleoli of the ankles and over the Achilles tendon, heels and toes. They are due merely to pressure on areas where the skin is tightly drawn over the bone without any protective, subcutaneous fat padding. The hyperkeratotic areas are present chiefly on the soles and over the heels and the heads of the first and fifth metatarsals.

Cataracts fall into the class of juvenile cataracts. Werner, as a student on the ophthalmology wards, first described the occurrence of juvenile cataracts with scleroderma. Star-like opacities develop, mostly on the posterior pole and on the periphery of the lens.

Diabetes may be present in the overt or latent states. There may be only a tendency to this disorder of metabolism as evidenced by abnormal glucose tolerance curves, or the disease may be full blown. Both cases reported below were in diabetic patients, and one, particularly, is rather difficult to control with the usual measures.

Generalized arteriosclerosis is another manifestation of Werner's syndrome. It is the usual type of arteriosclerosis and may result in early complications involving the circulatory system.

Underdevelopment of the sexual organs is a constant finding. Most of the female patients menstruate for some time at least, whereas in the males, erections and the ability to have intercourse are also preserved for a period.

Osteoporosis can readily be demonstrated in roentgen-ray studies of the bones. It has been found, too, in some cases that areas of metastatic calcification exist.

THERAPY

In view of the abiotrophic nature of the disease, one cannot hope to accomplish a great deal along curative lines. However, a certain degree of symptomatic improvement can be obtained. The diabetes can be controlled by the usual methods. Generally, the diabetic state in these patients is not too severe, although occasionally they present problems in control. Thyroid should be given for the usual indications of a hypothyroid state. The cataracts may require iridectomy as in the cases reported below. For the skin changes we have been using large doses of components of the vitamin B complex, especially nicotinic acid, with satisfactory results. Some of the

tautness of the skin and the immobility of the ankles has been relieved, and the patients have expressed considerable subjective relief. The smaller ulcerations have healed. Larger skin ulcerations are said to respond to grafting.

Finally, in view of the hypogonadism, negative calcium balance, diabetes and increased urinary gonadotropins, it has been suggested that estrogenic therapy be given a trial. We have not used it in our cases.

CASE REPORTS

CASE 1 R W, a 41-year-old woman, was admitted to the hospital on January 25, 1948, complaining of pain and purulent discharge from the right third toe. About 8 months prior to admission the patient had noted pain in the right third toe, which was followed shortly by a moderate amount of purulent discharge from the ulcer at that site. At about the same time small areas of ulceration appeared over the malleoli and the lower tibial regions. The ulcers were quite painful, especially at night, and the patient experienced great difficulty in walking. For an indefinite period, moreover, she had difficulty in walking, although less severe, because of a "high arch," and she wore metal arches in her shoes. Treatment at the hospital afforded some relief, but the symptoms returned shortly after discharge.

The patient had been treated for diabetes for the past 7½ years. She took 15 units of regular insulin and 15 units of protamine zinc insulin in separate syringes in the morning. However, at the age of 23, when bilateral cataracts developed, routine examination of the urine revealed the presence of sugar. At that time she underwent a bilateral cataract extraction. Five years before entry glaucoma had developed in the right eye. Three years later this eye had become infected, and despite the use of penicillin she had lost the vision of that eye.

She had been told on numerous occasions that she had "pituitary and thyroid trouble." From about the age of 15 she had noted that the upper and lower extremities were very thin and that the skin of the extremities was "tight" and hard especially toward the distal regions. She had also noted the development of large "corns" over the bony prominences of the soles of the feet. Ulcerations developed relatively recently as noted above. She had had scattered gray hairs since the age of 32, she studiously dyed these as they appeared, and it was not possible to determine the extent of the canities. The hair had become more sparse in recent years.

In 1943 she noted a mass in the right breast and underwent a radical mastectomy for carcinoma. Since that time she had had no complaints because of the malignant growth.

The menses had begun at the age of 11. The periods occurred every 21 days and lasted for 7 days. The flow was rather profuse. For 2½ years prior to August, 1947, there had been no vaginal bleeding, but at that time she had a period. There was no further vaginal bleeding until her stay on the wards of this hospital, where she had a 3-day period of rather scanty vaginal bleeding. She had been pregnant once, with delivery after 7 months' gestation, the son was 7 years old and in good health. She believed her thinness had been aggravated during this pregnancy. She was legally separated from her husband, who was in a mental institution. She claimed normal libido. There were no symptoms referable to the cardiovascular, respiratory, genitourinary or gastrointestinal systems.

The parents of the patient were first cousins. The father had "kidney trouble" but was otherwise normal. Diabetes had developed in the mother at the time of the menopause, and she had died in diabetic coma at the age of 57, she had had asthma. The parents had no canities or any of the other signs of progeria manifested by the patient. The mother had three sisters, 2 of whom were diabetic and none of whom had gray hair, cataracts or the characteristic habitus of Werner's syndrome. The father had 3 half-sisters, all of whom were alive and well, and 2 brothers, of the latter, 1 had died during an intestinal operation, and the other of carcinoma of the throat. None of the father's siblings manifested the stigmas of the syndrome. The patient has a sister (Case 2) who suffered from similar symptoms. A brother

was completely normal. Three other siblings had died at birth, a fourth had died at the age of 2 weeks.

The patient weighed 102 pounds and was 4 feet, 10 inches in height. Her habitus was strikingly characteristic—spindly arms and legs, with a normally developed trunk. She had the typical bird-like facies resulting from a receding chin, tendency to heaving of the nose and the wearing of powerful lenses in her eyeglasses. Her gait was unsteady because of the atrophy of the muscles of the lower extremities and the high plantar arch, but she walked without any characteristic aberration. Her hair was diffusely sparse and was dyed black. She was of average intelligence and of rather cheerful disposition. No respiratory distress or asthenia was noted.

The right eye showed a buphthalmos (post-glaucoma), and the left a surgical coloboma. Some fibrosis of the lens had been noted. The fundus seen through a +15 lens was slightly paler than normal, the vessels were moderately sclerotic, but there were no hemorrhages, exudates or pigmentation. The movements of the extraocular muscles were normal. There was mild circumferential injection of the left eye. The teeth were in good condition. The tongue was moist, with well developed papillae. The pharynx was clear. The ears were normal and did not project from the sides of the head in any unusual fashion. The eardrums were also normal. The eyelashes and eyelids were sparse. The voice appeared to be weak and somewhat high pitched (confirmed by the patient's statement), but indirect laryngoscopy did not reveal the hyperemic or laryngeal changes described in this condition. The neck was supple. There was no distention of the veins, no tracheal deviation and no palpable thyroid gland.

The lungs were clear to percussion and auscultation. The heart was not enlarged, and the sounds were of fair quality. The aortic second sound was louder than the pulmonic. There was a Grade III, blowing systolic murmur over the entire precordium, maximal over the base, there were no thrills. Sinus rhythm was normal.

The left breast showed normal development, no masses or tenderness was noted. On the right side there was a healed mastectomy scar with no evidence of infiltration or tenderness in this region.

The abdomen was moderately obese and flabby. There was slight tenderness in the right upper quadrant, but no palpable masses or viscera.

Neurologic examination was entirely normal.

There was marked atrophy of the musculature of all the extremities, most pronounced in the distal segments, and this was accompanied by a moderate degree of weakness. The skin also appeared to be atrophic and over some of the terminal phalanges appeared to be tightly bound down to the underlying tissues, although true scleroderma was not present. Owing to the muscular atrophy the bony prominences of the fingers and toes were more prominent. The instep was markedly arched, and the patient used metal arches in her bathroom slippers for ambulation. There was bilateral hallux valgus. Callosities, the size of a 25-cent piece, were noted in the skin over the heads of the first and fifth metatarsals and over the calcaneus; these areas were not tender. On the right medial and the left lateral malleoli there were ulcerations about the size of a dime. These were excavations bordered by corn-like areas similar to those described above. The bases were greyish yellow, and there was no discharge. The areas were quite tender to the touch. Three scabrous callosities were also noted over the lower tibial areas. The tip of the third right toe was reddened, but no discharge was noted. There was no clubbing or edema. There were good pulsations of the posterior tibial and dorsalis pedis vessels.

The skin was dry and atrophic, with a moderate degree of fine scaling. There were no telangiectases, petechiae or jaundice. The nails were well developed but showed evidence of having been bitten. No fat pads were noted. There was a normal distribution of the female hair.

Rectal examination was negative.

Pelvic examination showed a parous introitus. There were no abnormal findings.

The temperature was 98.6°F, the pulse 80, and the respirations 20. The blood pressure was 110/70.

Examination of the blood revealed a red-cell count of 2,500,000, with a hemoglobin of 10 gm per 100 cc., and a white-cell count of 12,900, with 40 per cent neutrophils and

60 per cent lymphocytes. The sedimentation rate (Linzmeier method) was 18 mm in 45 minutes. The urine, which had a specific gravity of 1.010, gave a negative to +++ test for sugar, a negative test for albumin and a negative test for acetone, the sediment contained an occasional white cell. The blood sugar was 103 to 225 mg, the urea nitrogen 15 mg, the calcium 9.5 to 11.0 mg, the phosphorus 3.0 to 6.5 mg, the uric acid 3.4 mg, the creatinine 1.6 mg, and the cholesterol 200 mg per 100 cc., with 25 per cent cholesterol esters. X-ray examination of the chest was negative except for evidence of removal of the right breast. Films of the feet demonstrated marked hallux valgus on the right and a moderate degree on the left. There were no apparent gross abnormalities in the bones of the upper and lower extremities. The hands disclosed normal bone texture and density. Films of the skull showed hyperostosis of the frontal and parietal bones bilaterally. The pituitary fossa was small but within normal limits. There was no evidence of increased intracranial pressure or bone erosion.

The patient was placed on partial bed rest and given 200 gm of carbohydrate, 75 gm of protein and 40 gm of fat. She was fairly well regulated on 15 units of protamine zinc insulin and 15 units of regular insulin given in separate syringes in the morning. She also received the following medications three times daily: nicotinic acid, 200 mg, vitamin C, 200 mg, and vitamin B₁, 20 mg. Papaverine, which had been given in doses of 0.1 gm (1½ gr) three times daily, was discontinued because of nausea. The patient claimed considerable subjective improvement on this medication, she stated that her legs felt "looser and stronger." The ulcerations healed slowly, leaving thin scabrous lesions. Of course, it is not possible to determine the relative roles played by the bed rest and the medications in the healing of these longstanding lesions. She was placed gradually on an ambulatory status and discharged as "improved" after 7 weeks in the hospital.

CASE 2. M B, a 45-year-old woman, the sister of the patient in Case 1, was admitted to the Cumberland Hospital on February 10, 1948, complaining of chest pain of 2 days' duration. The pain was described as precordial and substernal and continuous in severity, with no radiation. She complained of weakness and had noted dyspnea only on talking. There was no cough, edema or palpitations and no previous similar episodes.

The past history included diabetes of 16 years' duration, the diagnosis had first been made during routine urine examination while the patient was undergoing treatment for a foot infection. The disease had been fairly well controlled on 10 units of regular insulin and 10 units of protamine zinc insulin taken in separate syringes in the morning. Three and a half years prior to admission a cataract developed in the right eye, and this was removed 6 months later. One year before admission a cataract extraction was done on the left eye. Vision had been poor. Glaucoma developed in the right eye postoperatively. The patient had had gray hair since the age of 40. Three years prior to admission ulcers on the legs entirely similar to those described in Case 1, as well as corns over the bony prominences on the soles of the feet, developed. The ulcers were painful, and she had great difficulty in walking. She stated that the legs felt very cold and she was bothered by cold weather.

dermatous extremities, but on more careful examination, it is found that the skin can be elevated easily from the subcutaneous structures. It is in the latter structures that the fault lies. The subcutaneous fat tissue is practically absent, and the underlying muscle is extremely thin and atrophic.

Areas of circumscribed hyperkeratoses and ulcerations are not long in appearing, superimposed on the underlying skin changes. That the ulcers are not completely trophic is shown by their readiness in successfully taking a skin graft. The ulcers appear most frequently on areas subjected to pressure—the malleoli of the ankles and over the Achilles tendon, heels and toes. They are due merely to pressure on areas where the skin is tightly drawn over the bone without any protective, subcutaneous fat padding. The hyperkeratotic areas are present chiefly on the soles and over the heels and the heads of the first and fifth metatarsals.

Cataracts fall into the class of juvenile cataracts. Werner, as a student on the ophthalmology wards, first described the occurrence of juvenile cataracts with scleroderma. Star-like opacities develop, mostly on the posterior pole and on the periphery of the lens.

Diabetes may be present in the overt or latent states. There may be only a tendency to this disorder of metabolism as evidenced by abnormal glucose tolerance curves, or the disease may be full blown. Both cases reported below were in diabetic patients, and one, particularly, is rather difficult to control with the usual measures.

Generalized arteriosclerosis is another manifestation of Werner's syndrome. It is the usual type of arteriosclerosis and may result in early complications involving the circulatory system.

Underdevelopment of the sexual organs is a constant finding. Most of the female patients menstruate for some time at least, whereas in the males, erections and the ability to have intercourse are also preserved for a period.

Osteoporosis can readily be demonstrated in roentgen-ray studies of the bones. It has been found, too, in some cases that areas of metastatic calcification exist.

THERAPY

In view of the abiotrophic nature of the disease, one cannot hope to accomplish a great deal along curative lines. However, a certain degree of symptomatic improvement can be obtained. The diabetes can be controlled by the usual methods. Generally, the diabetic state in these patients is not too severe, although occasionally they present problems in control. Thyroid should be given for the usual indications of a hypothyroid state. The cataracts may require iridectomy as in the cases reported below. For the skin changes we have been using large doses of components of the vitamin B complex, especially nicotinic acid, with satisfactory results. Some of the

tautness of the skin and the immobility of the ankles has been relieved, and the patients have expressed considerable subjective relief. The smaller ulcerations have healed. Larger skin ulcerations are said to respond to grafting.

Finally, in view of the hypogonadism, negative calcium balance, diabetes and increased urinary gonadotropins, it has been suggested that estrogenic therapy be given a trial. We have not used it in our cases.

CASE REPORTS

CASE 1 R. W., a 41-year-old woman, was admitted to the hospital on January 25, 1948, complaining of pain and purulent discharge from the right third toe. About 8 months prior to admission the patient had noted pain in the right third toe, which was followed shortly by a moderate amount of purulent discharge from the ulcer at that site. At about the same time small areas of ulceration appeared over the malleoli and the lower tibial regions. The ulcers were quite painful, especially at night, and the patient experienced great difficulty in walking. For an indefinite period, moreover, she had difficulty in walking, although less severe, because of a "high arch," and she wore metal arches in her shoes. Treatment at the hospital afforded some relief, but the symptoms returned shortly after discharge.

The patient had been treated for diabetes for the past 7½ years. She took 15 units of regular insulin and 15 units of protamine zinc insulin in separate syringes in the morning. However, at the age of 23, when bilateral cataracts developed, routine examination of the urine revealed the presence of sugar. At that time she underwent a bilateral cataract extraction. Five years before entry glaucoma had developed in the right eye. Three years later this eye had become infected, and despite the use of penicillin she had lost the vision of that eye.

She had been told on numerous occasions that she had "pituitary and thyroid trouble." From about the age of 15 she had noted that the upper and lower extremities were very thin and that the skin of the extremities was "tight" and hard especially toward the distal regions. She had also noted the development of large "corns" over the bony prominences of the soles of the feet. Ulcerations developed relatively recently as noted above. She had had scattered gray hairs since the age of 32, she studiously dyed these as they appeared, and it was not possible to determine the extent of the canities. The hair had become more sparse in recent years.

In 1943 she noted a mass in the right breast and underwent a radical mastectomy for carcinoma. Since that time she had had no complaints because of the malignant growth.

The menses had begun at the age of 11. The periods occurred every 21 days and lasted for 7 days. The flow was rather profuse. For 2½ years prior to August, 1947, there had been no vaginal bleeding, but at that time she had a period. There was no further vaginal bleeding until her stay on the wards of this hospital, where she had a 3-day period of rather scanty vaginal bleeding. She had been pregnant once, with delivery after 7 months' gestation, the son was 7 years old and in good health. She believed her thinness had been aggravated during this pregnancy. She was legally separated from her husband, who was in a mental institution. She claimed normal libido. There were no symptoms referable to the cardiovascular, respiratory, genitourinary or gastrointestinal systems.

The parents of the patient were first cousins. The father had "kidney trouble" but was otherwise normal. Diabetes had developed in the mother at the time of the menopause, and she had died in diabetic coma at the age of 57; she had had asthma. The parents had no canities or any of the other signs of progeria manifested by the patient. The mother had three sisters, 2 of whom were diabetic and none of whom had gray hair, cataracts or the characteristic habitus of Werner's syndrome. The father had 3 half-sisters, all of whom were alive and well, and 2 brothers, of the latter, 1 had died during an intestinal operation, and the other of carcinoma of the throat. None of the father's siblings manifested the stigmas of the syndrome. The patient has a sister (Case 2) who suffered from similar symptoms. A brother

was completely normal. Three other siblings had died at birth, a fourth had died at the age of 2 weeks.

The patient weighed 102 pounds and was 4 feet, 10 inches in height. Her habitus was strikingly characteristic—spindly arms and legs, with a normally developed trunk. She had the typical bird-like facies resulting from a receding chin, tendency to beaking of the nose and the wearing of poverl lenses in her eyeglasses. Her gait was unsteady because of the atrophy of the muscles of the lower extremities and the high plantar arch, but she walked without any characteristic aberration. Her hair was diffusely sparse and was dyed black. She was of average intelligence and of rather cheerful disposition. No respiratory distress or asthenia was noted.

The right eye showed a buphthalmos (post-glaucoma), and the left a surgical coloboma. Some fibrosis of the lens bed was noted. The fundus seen through a $\times 15$ lens was slightly paler than normal, the vessels were moderately sclerotic, but there were no hemorrhages, exudates or pigmentation. The movements of the extraocular muscles were normal. There was mild circumcorneal injection of the left eye. The teeth were in good condition. The tongue was moist, with well developed papillae. The pharynx was clear. The ears were normal and did not project from the sides or the head in any unusual fashion. The eardrums were also normal. The eyelashes and eyelids were sparse. The voice appeared to be weak and somewhat high pitched (confirmed by the patient's statement), but indirect laryngoscopy did not reveal the hyperemic or keratotic changes described in this condition. The neck was supple. There was no distention of the veins, no tracheal deviation and no palpable thyroid gland.

The lungs were clear to percussion and auscultation. The heart was not enlarged, and the sounds were of fair quality. The aortic second sound was louder than the pulmonic. There was a Grade III, blowing systolic murmur over the entire precordium, maximal over the base, there were no thrills. Sinus rhythm was normal.

The left breast showed normal development, no masses or tenderness was noted. On the right side there was a healed mastectomy scar with no evidence of infiltration or tenderness in this region.

The abdomen was moderately obese and flabby. There was slight tenderness in the right upper quadrant, but no palpable masses or viscera.

Neurologic examination was entirely normal.

There was marked atrophy of the musculature of all the extremities, most pronounced in the distal segments, and this was accompanied by a moderate degree of weakness. The skin also appeared to be atrophic and over some of the terminal phalanges appeared to be tightly bound down to the underlying tissues, although true scleroderma was not present. Owing to the muscular atrophy the bony prominences of the fingers and toes were more prominent. The instep was markedly arched, and the patient used metal arches in her bathroom slippers for ambulation. There was bilateral hallux valgus. Callosities, the size of a 25-cent piece, were noted in the skin over the heads of the first and fifth metatarsals and over the calcanei; these areas were not tender. On the right medial and the left lateral malleoli there were ulcerations about the size of a dime. These were excavations bordered by corn-like areas similar to those described above. The bases were greyish yellow, and there was no discharge. The areas were quite tender to the touch. Three scabrous callosities were also noted over the lower tibial areas. The tip of the third right toe was reddened, but no discharge was noted. There was no clubbing or edema. There were good pulsations of the posterior tibial and dorsalis pedis vessels.

The skin was dry and atrophic, with a moderate degree of fine scaling. There were no telangiectases, petechiae or jaundice. The nails were well developed but showed evidence of having been bitten. No fat pads were noted. There was a normal distribution of the female hair.

Rectal examination was negative.

Pelvic examination showed a parous introitus. There were no abnormal findings.

The temperature was 98.6°F, the pulse 80, and the respirations 20. The blood pressure was 110/70.

Examination of the blood revealed a red-cell count of 2,500,000, with a hemoglobin of 10 gm per 100 cc., and a white-cell count of 12,900, with 40 per cent neutrophils and

60 per cent lymphocytes. The sedimentation rate (Linzenmeier method) was 18 mm in 45 minutes. The urine, which had a specific gravity of 1.010, gave a negative to $+++$ test for sugar, a negative test for albumin and a negative test for acetone, the sediment contained an occasional white cell. The blood sugar was 105 to 225 mg, the urea nitrogen 15 mg, the calcium 9.5 to 11.0 mg, the phosphorus 3.0 to 6.5 mg, the uric acid 5.4 mg, the creatinine 1.6 mg, and the cholesterol 200 mg per 100 cc., with 25 per cent cholesterol esters. The total protein was 6.8 gm. per 100 cc., with 4.7 gm of albumin and 2.1 gm of globulin, and the carbon dioxide combining power 36 to 68 vol. per cent. The urea clearance was 32 per cent. The phenolsulfonphthalein test showed 45 per cent excretion of the dye in 2 hours. The galactose tolerance test showed the excretion of 3.2 gm in the urine. The alkaline phosphatase was 1.6 Bodansky units per 100 cc. The cephalin flocculation and Mazzini tests were negative. The basal metabolic rate was -1 per cent.

Ossilometric findings on the left were 2.5 at the wrist, 2 above the ankle, 4 below the knee and 4 above the knee, and on the right, 1.5 at the wrist, 4 above the ankle, 4 below the knee and 4 above the knee.

Electrocardiograms, which revealed a tendency to left-axis deviation (with a small Q wave and isoelectric T wave in Lead 3, inverted T wave in Lead CF₂ and upright but low-voltage T wave in Lead CF₁), were interpreted as showing questionable myocardial damage.

X-ray examination of the chest was negative except for evidence of removal of the right breast. Films of the feet demonstrated marked hallux valgus on the right and a moderate degree on the left. There were no apparent gross abnormalities in the bones of the upper and lower extremities. The hands disclosed normal bone texture and density. Films of the skull showed hyperostosis of the frontal and parietal bones bilaterally. The pituitary fossa was small but within normal limits. There was no evidence of increased intracranial pressure or bone erosion.

The patient was placed on partial bed rest and given 200 gm of carbohydrate, 75 gm of protein and 40 gm of fat. She was fairly well regulated on 15 units of protamine zinc insulin and 15 units of regular insulin given in separate syringes in the morning. She also received the following medications three times daily: nicotinic acid, 200 mg, vitamin C 200 mg and vitamin B₁, 20 mg. Papaverine, which had been given in doses of 0.1 gm (1½ gr) three times daily, was discontinued because of nausea. The patient claimed considerable subjective improvement on this medication, she stated that her legs felt "looser and stronger." The ulcerations healed slowly, leaving thin scabrous lesions. Of course, it is not possible to determine the relative roles played by the bed rest and the medications in the healing of these longstanding lesions. She was placed gradually on an ambulatory status and discharged as "improved" after 7 weeks in the hospital.

CASE 2. M B, a 45-year-old woman, the sister of the patient in Case 1, was admitted to the Cumberland Hospital on February 10, 1948, complaining of chest pain of 2 days' duration. The pain was described as precordial and substernal and continuous in severity, with no radiation. She complained of weakness and had noted dyspnea only on talking. There was no cough, edema or palpitations and no previous similar episodes.

The past history included diabetes of 16 years' duration, the diagnosis had first been made during routine urine examination while the patient was undergoing treatment for a foot infection. The disease had been fairly well controlled on 10 units of regular insulin and 10 units of protamine zinc insulin taken in separate syringes in the morning. Three and a half years prior to admission a cataract developed in the right eye, and this was removed 6 months later. One year before admission a cataract extraction was done on the left eye. Vision had been poor. Glaucoma developed in the right eye postoperatively. The patient had bad gray hair since the age of 40. Three years prior to admission ulcers on the legs entirely similar to those described in Case 1, as well as corns over the bony prominences on the soles of the feet, developed. The ulcers were painful, and she had great difficulty in walking. She stated that the legs felt very cold and she was bothered by cold weather.

dermatous extremities, but on more careful examination, it is found that the skin can be elevated easily from the subcutaneous structures. It is in the latter structures that the fault lies. The subcutaneous fat tissue is practically absent, and the underlying muscle is extremely thin and atrophic.

Areas of circumscribed hyperkeratoses and ulcerations are not long in appearing, superimposed on the underlying skin changes. That the ulcers are not completely trophic is shown by their readiness in successfully taking a skin graft. The ulcers appear most frequently on areas subjected to pressure—the malleoli of the ankles and over the Achilles tendon, heels and toes. They are due merely to pressure on areas where the skin is tightly drawn over the bone without any protective, subcutaneous fat padding. The hyperkeratotic areas are present chiefly on the soles and over the heels and the heads of the first and fifth metatarsals.

Cataracts fall into the class of juvenile cataracts. Werner, as a student on the ophthalmology wards, first described the occurrence of juvenile cataracts with scleroderma. Star-like opacities develop, mostly on the posterior pole and on the periphery of the lens.

Diabetes may be present in the overt or latent states. There may be only a tendency to this disorder of metabolism as evidenced by abnormal glucose tolerance curves, or the disease may be full blown. Both cases reported below were in diabetic patients, and one, particularly, is rather difficult to control with the usual measures.

Generalized arteriosclerosis is another manifestation of Werner's syndrome. It is the usual type of arteriosclerosis and may result in early complications involving the circulatory system.

Underdevelopment of the sexual organs is a constant finding. Most of the female patients menstruate for some time at least, whereas in the males, erections and the ability to have intercourse are also preserved for a period.

Osteoporosis can readily be demonstrated in roentgen-ray studies of the bones. It has been found, too, in some cases that areas of metastatic calcification exist.

THERAPY

In view of the abiotrophic nature of the disease, one cannot hope to accomplish a great deal along curative lines. However, a certain degree of symptomatic improvement can be obtained. The diabetes can be controlled by the usual methods. Generally, the diabetic state in these patients is not too severe, although occasionally they present problems in control. Thyroid should be given for the usual indications of a hypothyroid state. The cataracts may require iridectomy as in the cases reported below. For the skin changes we have been using large doses of components of the vitamin B complex, especially nicotinic acid, with satisfactory results. Some of the

tautness of the skin and the immobility of the ankles has been relieved, and the patients have expressed considerable subjective relief. The smaller ulcerations have healed. Larger skin ulcerations are said to respond to grafting.

Finally, in view of the hypogonadism, negative calcium balance, diabetes and increased urinary gonadotropins, it has been suggested that estrogenic therapy be given a trial. We have not used it in our cases.

CASE REPORTS

CASE 1 R. W., a 41-year-old woman, was admitted to the hospital on January 25, 1948, complaining of pain and purulent discharge from the right third toe. About 8 months prior to admission the patient had noted pain in the right third toe, which was followed shortly by a moderate amount of purulent discharge from the ulcer at that site. At about the same time small areas of ulceration appeared over the malleoli and the lower tibial regions. The ulcers were quite painful, especially at night, and the patient experienced great difficulty in walking. For an indefinite period, moreover, she had difficulty in walking, although less severe, because of a "high arch," and she wore metal arches in her shoes. Treatment at the hospital afforded some relief, but the symptoms returned shortly after discharge.

The patient had been treated for diabetes for the past 7½ years. She took 15 units of regular insulin and 15 units of protamine zinc insulin in separate syringes in the morning. However, at the age of 23, when bilateral cataracts developed, routine examination of the urine revealed the presence of sugar. At that time she underwent a bilateral cataract extraction. Five years before entry glaucoma had developed in the right eye. Three years later this eye had become infected, and despite the use of penicillin she had lost the vision of that eye.

She had been told on numerous occasions that she had "pituitary and thyroid trouble." From about the age of 13 she had noted that the upper and lower extremities were very thin and that the skin of the extremities was "tight" and hard especially toward the distal regions. She had also noted the development of large "corns" over the bony prominences of the soles of the feet. Ulcerations developed relatively recently as noted above. She had had scattered gray hairs since the age of 32, she studiously dyed these as they appeared, and it was not possible to determine the extent of the canities. The hair had become more sparse in recent years.

In 1943 she noted a mass in the right breast and underwent a radical mastectomy for carcinoma. Since that time she had had no complaints because of the malignant growth.

The menses had begun at the age of 11. The periods occurred every 21 days and lasted for 7 days. The flow was rather profuse. For 2½ years prior to August, 1947, there had been no vaginal bleeding, but at that time she had a period. There was no further vaginal bleeding until her stay on the wards of this hospital, where she had a 3-day period of rather scanty vaginal bleeding. She had been pregnant once, with delivery after 7 months' gestation, the son was 7 years old and in good health. She believed her thinness had been aggravated during this pregnancy. She was legally separated from her husband, who was in a mental institution. She claimed normal libido. There were no symptoms referable to the cardiovascular, respiratory, genitourinary or gastrointestinal systems.

The parents of the patient were first cousins. The father had "kidney trouble" but was otherwise normal. Diabetes had developed in the mother at the time of the menopause, and she had died in diabetic coma at the age of 57, she had had asthma. The parents had no canities or any of the other signs of progeria manifested by the patient. The mother had three sisters, 2 of whom were diabetic and none of whom had gray hair, cataracts or the characteristic habitus of Werner's syndrome. The father had 3 half-sisters, all of whom were alive and well, and 2 brothers, of the latter, 1 had died during an intestinal operation, and the other of carcinoma of the throat. None of the father's siblings manifested the stigmas of the syndrome. The patient has a sister (Case 2) who suffered from similar symptoms. A brother

was completely normal. Three other siblings had died at birth, a fourth had died at the age of 2 weeks.

The patient weighed 102 pounds and was 4 feet, 10 inches in height. Her habitus was strikingly characteristic — spindly arms and legs, with a normally developed trunk. She had the typical bird-like facies resulting from a receding chin, tendency to heaving of the nose and the wearing of powerful lenses in her eyeglasses. Her gait was unsteady because of the atrophy of the muscles of the lower extremities and the high plantar arch, but she walked without any characteristic aberration. Her hair was diffusely sparse and was dyed black. She was of average intelligence and of rather cheerful disposition. No respiratory distress or asthenia was noted.

The right eye showed a buphthalmos (post-glaucoma), and the left a surgical coloboma. Some fibrosis of the lens bed was noted. The fundus seen through a +15 lens was slightly paler than normal, the vessels were moderately sclerotic, but there were no hemorrhages, exudates or pigmentation. The movements of the extraocular muscles were normal. There was mild circumcorneal injection of the left eye. The teeth were in good condition. The tongue was moist, with well developed papillae. The pharynx was clear. The ears were normal and did not project from the sides of the head in any unusual fashion. The eardrums were also normal. The eyelashes and eyelids were sparse. The voice appeared to be weak and somewhat high pitched (confirmed by the patient's statement), but indirect laryngoscopy did not reveal the hyperemic or keratotic changes described in this condition. The neck was supple. There was no distention of the veins, no tracheal deviation and no palpable thyroid gland.

The lungs were clear to percussion and auscultation. The heart was not enlarged, and the sounds were of fair quality. The aortic second sound was louder than the pulmonary. There was a Grade III, blowing systolic murmur over the entire precordium, maximal over the base, there were no thrills. Sinus rhythm was normal.

The left breast showed normal development, no masses or tenderness was noted. On the right side there was a healed mastectomy scar with no evidence of infiltration or tenderness in this region.

The abdomen was moderately obese and flabby. There was slight tenderness in the right upper quadrant, but no palpable masses or viscera.

Neurologic examination was entirely normal.

There was marked atrophy of the musculature of all the extremities, most pronounced in the distal segments, and this was accompanied by a moderate degree of weakness. The skin also appeared to be atrophic and over some of the terminal phalanges appeared to be tightly bound down to the underlying tissues, although true scleroderma was not present. Owing to the muscular atrophy the bony prominences of the fingers and toes were more prominent. The instep was markedly arched, and the patient used metal arches in her bathroom slippers for ambulation. There was bilateral hallux valgus. Callosities, the size of a 25-cent piece, were noted in the skin over the heads of the first and fifth metatarsals and over the calcaneus, these areas were not tender. On the right medial and the left lateral malleoli there were ulcerations about the size of a dime. These were excavations bordered by corn-like areas similar to those described above. The bases were greyish yellow, and there was no discharge. The areas were quite tender to the touch. Three scabrous callosities were also noted over the lower tibial areas. The tip of the third right toe was reddened, but no discharge was noted. There was no clubbing or edema. There were good pulsations of the posterior tibial and dorsalis pedis vessels.

The skin was dry and atrophic, with a moderate degree of fine scaling. There were no telangiectases, petechiae or jaundice. The nails were well developed but showed evidence of having been bitten. No fat pads were noted. There was a normal distribution of the female hair.

Rectal examination was negative.

Pelvic examination showed a parous introitus. There were no abnormal findings.

The temperature was 98.6°F, the pulse 80, and the respirations 20. The blood pressure was 110/70.

Examination of the blood revealed a red-cell count of 2,500,000, with a hemoglobin of 10 gm per 100 cc., and a white-cell count of 12,900, with 40 per cent neutrophils and

60 per cent lymphocytes. The sedimentation rate (Linzenmeier method) was 18 mm in 45 minutes. The urine, which had a specific gravity of 1.010, gave a negative to +++ test for sugar, a negative test for albumin and a negative test for acetone, the sediment contained an occasional white cell. The blood sugar was 103 to 225 mg, the urea nitrogen 15 mg, the calcium 9.5 to 11.0 mg, the phosphorus 3.0 to 6.5 mg, the uric acid 3.4 mg, the creatinine 1.6 mg, and the cholesterol 200 mg per 100 cc, with 25 per cent cholesterol esters. The total protein was 6.8 gm per 100 cc, with 4.7 gm of albumin and 2.1 gm of globulin, and the carbon dioxide combining power 56 to 68 vol per cent. The urea clearance was 32 per cent. The phenolsulfonephthalein test showed 45 per cent excretion of the dye in 2 hours. The galactose tolerance test showed the excretion of 3.2 gm in the urine. The alkaline phosphatase was 1.6 Bodansky units per 100 cc. The cephalin flocculation and Mazzini tests were negative. The basal metabolic rate was +1 per cent.

Oscillometric findings on the left were 2.5 at the wrist, 2 above the ankle, 4 below the knee and 4 above the knee, and on the right, 1.5 at the wrist, 4 above the ankle, 4 below the knee and 4 above the knee.

Electrocardiograms, which revealed a tendency to left-axis deviation (with a small Q wave and isoelectric T wave in Lead 3, inverted T wave in Lead CF₂ and upright but low-voltage T wave in Lead CF₄), were interpreted as showing questionable myocardial damage.

X-ray examination of the chest was negative except for evidence of removal of the right breast. Films of the feet demonstrated marked hallux valgus on the right and a moderate degree on the left. There were no apparent gross abnormalities in the bones of the upper and lower extremities. The hands disclosed normal bone texture and density. Films of the skull showed hyperostosis of the frontal and parietal bones bilaterally. The pituitary fossa was small but within normal limits. There was no evidence of increased intracranial pressure or bone erosion.

The patient was placed on partial bed rest and given 200 gm of carbohydrate, 75 gm of protein and 40 gm of fat. She was fairly well regulated on 15 units of protamine zinc insulin and 15 units of regular insulin given in separate syringes in the morning. She also received the following medications three times daily: nicotinic acid, 200 mg, vitamin C, 200 mg, and vitamin B₁, 20 mg. Papaverine, which had been given in doses of 0.1 gm (1½ gr) three times daily, was discontinued because of nausea. The patient claimed considerable subjective improvement on this medication, she stated that her legs felt "looser and stronger." The ulcerations healed slowly, leaving thin scabrous lesions. Of course, it is not possible to determine the relative roles played by the bed rest and the medications in the healing of these longstanding lesions. She was placed gradually on an ambulatory status and discharged as "improved" after 7 weeks in the hospital.

CASE 2. M. B., a 45-year-old woman, the sister of the patient in Case 1, was admitted to the Cumberland Hospital on February 10, 1948, complaining of chest pain of 2 days' duration. The pain was described as precordial and substernal and continuous in severity, with no radiation. She complained of weakness and had noted dyspnea only on talking. There was no cough, edema or palpitations and no previous similar episodes.

The past history included diabetes of 16 years' duration; the diagnosis had first been made during routine urine examination while the patient was undergoing treatment for a foot infection. The disease had been fairly well controlled on 10 units of regular insulin and 10 units of protamine zinc insulin taken in separate syringes in the morning. Three and a half years prior to admission a cataract developed in the right eye, and this was removed 6 months later. One year before admission a cataract extraction was done on the left eye. Vision had been poor. Glaucoma developed in the right eye postoperatively. The patient had had gray hair since the age of 40. Three years prior to admission ulcers on the legs entirely similar to those described in Case 1, as well as corns over the bony prominences on the soles of the feet, developed. The ulcers were painful, and she had great difficulty in walking. She stated that the legs felt very cold and she was bothered by cold weather.

The menses had begun at the age of 12, occurring every 28 days and lasting 2 or 3 days, during which there was scanty flow. There had been no menses since October, 1947. The patient had had an ectopic pregnancy in 1930, and she had not been pregnant since, although she had attempted to conceive. She claimed normal libido. Prior to admission she had been treated in the Cumberland Hospital Out-Patient Department for diabetes and leg ulcers, receiving for the latter various ointments and vitamin B₁ without benefit.

The resident who first examined this patient thought that she looked vaguely familiar but it was not until the second hospital day, when he found her talking to her sister who was on the ward at the same time, that the diagnosis became evident.

Physical examination revealed slight dyspnea while the patient was talking, but she was otherwise in no distress. She was exactly 5 feet in height and weighed 101 pounds. In appearance she seemed to be the twin of the patient in Case 1, both in facies and in habitus. The hair was scanty and gray. The eyebrows and eyelashes were also scanty. The movements of the extraocular muscles were normal. The scleras were clear. The right eye revealed surgical coloboma. The vessels of the fundus showed minimal sclerotic changes, there were no hemorrhages, exudates or papilledema. The left fundus was obscured by a cataract, although a cataract had been extracted on this side. The ears were normal in size and shape. There were no fat pads of the face or neck. The tongue showed well developed papillae. The pharynx was normal. The voice was normal, and indirect laryngoscopy revealed no changes. The neck was supple, with no distended veins, palpable masses or tracheal deviation. The thyroid gland was not enlarged. The lungs were clear to percussion and auscultation. Examination of the heart showed the point of maximum intensity in the fifth intercostal space within the midclavicular line. The sounds at the apex were distant and poor in quality. There was a soft, blowing systolic murmur at the apex. There were no thrills. The pulmonic second sound was louder than the aortic. There was normal sinus rhythm. The breasts showed normal development, with no masses. There was no rigidity, tenderness or palpable masses in the abdomen. No viscera were palpable. There was a well healed suprapubic midline surgical scar. The extremities were practically identical with those of the patient in Case 1, including atrophy of the muscles and subcutaneous tissue, small superficial ulcers over the right tendo achilles and over the base of the left fifth metatarsal, callosities over the heads of the first and fifth metatarsal bones and calcanei bilaterally and a marked hallux valgus bilaterally. The pulsations of the posterior tibial and dorsalis pedis vessels were excellent. The plantar arches were accentuated. The second, third and fourth fingers of both hands were markedly nodular and somewhat distorted, resembling the gnarled fingers observed in burnt-out rheumatoid arthritis. The joints were only slightly painful on firm palpation. There were slight sclerodermatous-like changes over the terminal phalanges of the fingers. There was normal distribution of the hair. The skin over the extremities was atrophic and slightly scaly. No telangiectatic changes were noted. Neurologic examination disclosed some unsteadiness in gait, as in Case 1, but again this was due to muscular weakness, painful leg ulcers and high plantar arches, there did not appear to be any neurologic background for the difficulties in gait, position sense and so forth was intact. Rectal examination was negative. Pelvic examination revealed a parous introitus. The cervix was pointed anteriorly. The fornices were normal. The fundus was not felt.

The temperature was 99°F, the pulse 105, and the respirations 24. The blood pressure was 114/70.

Examination of the blood disclosed a red-cell count of 4,200,000, with a hemoglobin of 13 gm per 100 cc, and a white-cell count of 9200, with 52 per cent neutrophils, 45 per cent lymphocytes and 3 per cent monocytes. The hematocrit was 44 per cent. The urine gave a negative to ++ test for sugar and negative tests for albumin and acetone. The blood sugar on three occasions was 142, 181.8 and 200 mg per 100 cc. The blood urea nitrogen was 12 mg, the uric acid 3.6 and 2.6 mg, the creatinine 1.5 mg, the calcium 11.0 mg, the phosphorus 3.0 mg, and the cholesterol 238 mg per 100 cc, with 70 per cent cholesterol esters. The total plasma protein was 7.2 gm per 100 cc, with 5.2 gm of albumin and 2.0 gm of globulin. The blood Kline and cephalin

flocculation tests were negative. The alkaline phosphatase was 1.0 Bodansky unit per 100 cc. The basal metabolic rate was -27 per cent.

X-ray examination of the chest revealed definite striation of the pulmonary fields, which was possibly due to some peribronchial thickening. There was marked decalcification of the bones of both feet, and considerable hallux valgus formation bilaterally, more marked on the left side, with almost complete inward subluxation of the bases of the proximal phalanges of the great toes from their articulations with the heads of the corresponding metatarsals. The intermetatarsal arteries showed appreciable calcification. There was moderate loss of calcium of all the bones of the carpo-metacarpal region and of the phalanges of both hands. Examination of the skull demonstrated granular osteoporosis, with neither direct nor indirect evidence of increased intracranial pressure. A small amount of lime was noted in the region of the pineal gland.

An electrocardiogram taken immediately on admission showed only left-axis shift and was identical with one taken 1 year previously in the clinic.

The patient soon ceased to complain of chest pain and, aside from the disability caused by the leg ulcers, was quite comfortable. She was placed on a diet of 200 gm of carbohydrate, 70 gm of protein and 50 gm of fat. She was treated with 15 units of protamine zinc insulin and 30 units of regular insulin mixed in one syringe in the morning. She was not overly co-operative in the matter of diabetic control, additional foodstuffs being found in her bedside table on several occasions, however, this did not seem to disturb her metabolic balance to any significant degree. She received therapy for the leg ulcers similar to her sister's. However, therapy was not administered over as long a period, and the response was not quite so satisfactory, she was discharged as "improved" on the same day as her sister. During her hospital course the temperature, pulse and respirations were within normal limits. A follow-up electrocardiogram showed no significant changes. The sedimentation rate was 55 minutes (Linzenmeier method).

DISCUSSION

It is hardly necessary to review the diagnostic criteria in these cases. A review of them leaves little doubt that they are classic examples of Werner's syndrome. We have had the opportunity of presenting them to Dr. Thannhauser, and he concurred with our diagnosis, stating that they were typical examples of the syndrome. Indeed, our 2 patients look like the twin sisters of the 2 brothers whom Dr. Thannhauser described in his exhaustive review article.

It is important to remember that the syndrome may not develop in all its features but may occur as a *forme fruste*. A knowledge of all the features of the syndrome is necessary to enable one to recognize the incomplete forms. It will be noted that our patients, like those reported elsewhere, were treated for many years by internists, ophthalmologists and general practitioners without the syndrome as a whole being recognized. We are quite sure that the disorder is not so rare as it appears to be. The advantages of the early recognition of a hereditary disorder are obvious.

SUMMARY

The criteria of Werner's syndrome are reviewed. Two cases of this syndrome are reported.

Attention is called to the presence of incomplete forms of this syndrome and the eugenic importance of early recognition of the syndrome in its complete or incomplete forms.

MEDICAL PROGRESS

PERIPHERAL VASCULAR DISEASE*

ROBERT R. LINTON, M.D.†

BOSTON

THIS report considers peripheral vascular disease under the two main divisions of diseases of the arteries and diseases of the veins

DISEASES OF THE ARTERIES

The surgical treatment of peripheral vascular diseases has made tremendous strides in recent years. The role that the sympathetic nervous system plays in the control of the arterial circulation of the extremities and the benefits derived by sympathetic neurectomy in many conditions are certainly to be included in great advances made in the therapy of peripheral arterial disease. Improvements in surgical technic, especially of blood-vessel anastomoses, the availability of blood transfusions through the establishment of blood banks and the development of the antibiotics, which have practically eliminated serious surgical infections, are other important factors in the widening of the scope of the surgical treatment of all vascular disorders.

Peripheral Arteriosclerosis

Arterial diseases secondary to peripheral arteriosclerosis are increasing in frequency because of the advancing age of the general population. The treatment of these conditions is becoming of ever-increasing importance because of this fact and since they represent one of the degenerative diseases that develop with old age.

The surgical therapy of peripheral arteriosclerosis of the lower extremities has become more of a surgical problem in recent years because of the improvement that can be obtained in the peripheral circulation by lumbar sympathectomy. This is especially true in patients that present themselves for treatment before actual gangrene of the extremity has developed. The chief indication for sympathetic neurectomy in these patients is the demonstration of normal or increased vasoconstriction or vasospasm. Various tests have been described to determine which patients will benefit by this procedure. Morton and Scott¹ used anesthesia, general, spinal or local, to determine vasomotor sympathetic activity. White² recommended paravertebral injections of procaine to block the sympathetic nerves. Gibbon and Landis³ described their method of reflex vasodilatation by heating the unaffected extremities or portions of the body. These

tests have been found to be of value in certain cases, but in others in which a negative response is obtained sympathectomy frequently improves the circulation. Smithwick⁴ described a test that is simpler and gives consistently more accurate results in determining which patients will benefit by sympathectomy. It consists in exposing the affected limb for an hour at a temperature of 68°F. If the skin temperature of the extremity reaches or approaches room temperature within a few degrees, under these conditions the presence of vasomotor activity is demonstrated and indicates that benefit will be derived from sympathetic neurectomy. Another simple clinical test that has been found of value is the observation of sudomotor activity in the extremity, which usually means that the blood vessels of the extremity will dilate if the vasomotor constrictor impulses are eradicated by an effective sympathetic denervation. Freeman⁵ has warned that in certain cases of advanced peripheral arteriosclerosis, especially those without evidence of normal vasoconstriction, sympathectomy may be detrimental because much of the blood may be shunted directly into the veins through the opening up of numerous small arteriovenous anastomoses. Burch⁶ and Goetz⁷ have recommended the use of a digital plethysmograph as a method of investigating peripheral vascular disease. They believe that with it exact information can be obtained about the degree of occlusion, the degree of vasospasm and the degree of collateral circulation. For practical clinical purposes, the method has not yet been proved, and at present it remains as a laboratory procedure for investigative studies in peripheral vascular disease. Another diagnostic procedure that has been recommended in recent years is arteriography. A roentgenographic visualization by the intra-arterial injection of a radio-opaque substance has been utilized as a diagnostic procedure for a number of years. Various types of solutions have been used. Shumacker⁸ and Kleinsasser⁹ recommend the use of 35 per cent diodrast solution. Each patient should be tested for sensitivity to the solution before it is employed. Visualization of the chambers of the heart, the pulmonary circulation and the great vessels has been successfully demonstrated by Robb and Steinberg,¹⁰ using 70 per cent diodrast solution. X-ray visualization of the abdominal aorta has been described by Wagner¹¹ and Nelson.¹² They recommend an 80 per cent sodium iodide solution

*From the Department of Surgery, Massachusetts General Hospital.

†Assistant clinical professor of surgery, Harvard Medical School, visiting surgeon, Massachusetts General Hospital.

It should be pointed out that arteriography is not without its dangers because of reactions from the drugs, which may in a few cases result in death and, in others, tragic ischemic difficulties in the injected limb. Arteriography should therefore be employed only when indicated and not as a routine in cases of arterial disorders. The most recent method of studying the peripheral arterial circulation is by means of radioactive isotopes. Smith and Quimby¹³ first reported the use of sodium 24 to show the level of adequate circulation in a limb and so determine the site of amputation in patients with obliterative arterial disease. Mufson et al,¹⁴ from the same clinic, used this method to determine the efficacy of drugs used in the treatment of peripheral vascular disease. Elkin and his associates¹⁵ have reported studies to determine the adequacy of peripheral arterial circulation using sodium 24 by intravenous and subcutaneous intramuscular injections. At the present time these studies and reports are extremely interesting, but further investigations with this new technic must be performed before the true value of the method can be determined.

The benefit of sympathectomy in the treatment of peripheral arteriosclerosis has been reported by a number of surgeons during the past year—Hendrick and Aycock,¹⁶ de Takats,¹⁷ Freeman⁵ and Yeager and Cowley.¹⁸ A careful selection of the patients subjected to this form of therapy should be made. The younger the patient is and the more evidence there is of vasomotor activity in the extremity, the greater the benefit that will be obtained. Intermittent claudication, as a rule, does not improve spectacularly after sympathectomy, but it has been observed to disappear gradually several years after the operation. The immediate benefit derived by sympathectomy is chiefly in the vascular supply to the integument. This in itself may be of great importance, since it will prevent the breaking down of the skin especially of the toes, which if it occurs frequently results in gangrene necessitating amputation. There appears to be definite evidence, however, not only that the extremity derives an immediate benefit from this form of treatment but also that it is the best protection that can be given to prevent serious vascular disorders with gangrene in old age. In other words, it appears at the present writing that the symptoms and signs of peripheral arteriosclerosis may be reversible if sympathectomy is performed early in the course of the disease and provided the sympathetic neurectomy is sufficiently extensive to prevent regeneration.

In the therapy of peripheral vascular disease there is a constant rivalry between the internist and the surgeon, the former to find nonsurgical methods of therapy to supplant surgical ones, and the latter to develop new surgical procedures. This form of competition should not be discouraged, but unfortunately too frequently some of the methods are

reported as the final answer to a problem without a sufficiently critical analysis of the results and procedures used. Both nonsurgical and surgical methods fall into this error. The chief criticism of the latter is that too many unqualified surgeons from lack of study and experience perform, with poor or disastrous results, surgical operations that have been established by authorities in their fields. This naturally discredits the procedure in the eyes both of many of the profession and of the laity. A number of nonspecific substances have been recommended for the improvement of peripheral arterial circulation during the past two decades. Some are given parenterally and others orally. These include the intravenous injection of a hypertonic solution of sodium chloride,¹⁹ or a nonspecific foreign protein (typhoid vaccine)²⁰ or diethyl oxide (ether)²¹, the intramuscular injection of sodium tetrathionate²², the oral administration of cytochrome C²³ or alpha tocopherol (vitamin E)²⁴, and finally the subcutaneous injection of histidine combined with the oral administration of ascorbic acid (vitamin C).²⁵ The beneficial effect on the peripheral circulation obtained by any of these methods, if it occurs, may only be transitory, and in most of the clinical reports other forms of therapy were utilized concomitantly on the patients, so that the improvement in the circulation cannot be attributed entirely to them. Borst and Holleman²⁶ have recently reported 3 cases of coronary thrombosis in 18 patients treated with intravenous sodium chloride solution and advise against its use.

Chemical sympathectomy by means of adrenergic and sympatholytic drugs has been utilized for many years without much success, but recently in this country it is being investigated with new drugs that show considerable progress in this field. Acheson and Moe,²⁷ in 1946, described tetraethylammonium chloride, or bromide, a ganglionic blocking agent. Nickerson and Goodman,²⁸ also in 1946, reported another drug, dibenamine (dibenzylbeta-chlorethylaminohydrochloride), which blocks the terminations of the sympathetic motor pathways in smooth muscle. Coller et al²⁹ and Lyons and his co-workers,³⁰ in 1947, reported the effects obtained with tetraethylammonium chloride in the diagnosis and treatment of peripheral vascular disease, including such conditions as causalgia, thromboangitis obliterans and thrombophlebitis. Both drugs produce peripheral vasodilatation, but their side effects are frequently so disagreeable that their clinical use seems somewhat limited and in some cases dangerous complications have been reported, one recently by Friedlich, Chapman and Stanbury.³¹ Priscol (2-benzyl-4, 5-imidazoline hydrochloride) is the most recent of these drugs to be employed in this country, although it was first reported in 1939 by Hartmann and Isler,³² and since then numerous reports of its clinical use have appeared in the European and South American medical litera-

ture Grimson,³² in this country, has recently reported the results in the use of this drug in a variety of peripheral vascular diseases, including Raynaud's disease, peripheral arteriosclerosis, thromboangitis obliterans, popliteal aneurysms, causalgia, acute arterial occlusion and venous thrombosis. It may be administered intravenously, intramuscularly or orally in doses of 25 to 75 mg. The results are sufficiently encouraging to warrant further investigation and clinical trial, but as yet it seems doubtful that a panacea for all these vascular diseases has been found. Chemotherapy for peripheral arterial diseases may eventually supplant sympathetic neurectomy, but at the present writing the latter, because of its more lasting effects and in most cases its few disadvantages, remains the best form of therapy in the majority of cases. Intermittent venous occlusion by the use of a pneumatic tourniquet cuff on the extremity, although of value in acute arterial occlusions, seems to have little if any benefit in the treatment of peripheral arteriosclerosis.

Despite the recent development of sympathectomy in the treatment of peripheral arteriosclerosis, amputations must still be performed in a certain number of patients. Improvements in technic are still being devised in the various types of amputations. Holden³⁴ again draws attention to the increased morbidity and mortality with toe amputations performed in this group of patients, many of whom require major thigh amputations because of failure to heal after the toe amputations. McKittrick,³⁵ on the other hand, has recently recommended transmetatarsal amputation in patients with gangrene secondary to lesions involving the toes in the diabetic patient with peripheral arteriosclerosis. This has proved to be a great advance in the surgical treatment of these patients, since it obviates an amputation at a higher level and preserves the foot with a surprisingly good functional result. He admits that the indications for this type of amputation are not yet completely clear, but they are continuing to be extended until a careful follow-up study of all patients satisfactorily demonstrates a clear-cut conception regarding whether it should or should not be undertaken. He points out that the use of this type of procedure has been greatly extended through the use of penicillin. Allredge³⁶ reviews the surgery of amputations and reports some of the technics of specific procedures. Silbert³⁷ recommends that the lower-leg amputation should be used more frequently than a mid-thigh or low-thigh amputation, since he claims that it reduces the mortality and because of preservation of the knee joint results in better function. Pearl³⁸ describes a modification of the supracondylar Calander type of amputation.

Thromboangitis Obliterans

Thromboangitis obliterans, or Buerger's disease, is the most common obliterative arterial disease

that affects the young male. Freeman³⁹ reported that the diagnosis was made in 274 of 3778 patients admitted to all the vascular centers during World War II. It is still a rare disease in the female. Only one probable case has been seen in a woman in the Peripheral Vascular Clinic of the Massachusetts General Hospital since it was organized in 1928. It rarely affects the Negro race, but in the last year Davis⁴⁰ and Breidenbach and Palmer⁴¹ have reported it in several Negroes. It is generally agreed that in the earlier cases sympathetic ganglionectomy offers the patient the best form of surgical therapy.⁴² Desensitization of the foot by means of crushing the peripheral nerves to it, described by Smithwick and White,⁴³ is still an important method of treatment in patients who present painful ulcerating lesions of the toes. This form of therapy not only relieves the patient of pain but also produces an improvement in the circulation since it sympathectomizes the limb distal to the level at which the nerves are crushed. Smoking, although not a definite etiologic factor, results in the progression of the disease in the majority of cases even in the sympathectomized extremity. Freeman³⁹ reports that in 77 patients who stopped smoking completely, there was progression of the disease in only 2, whereas in a group of 16 who admitted further smoking there was progression in 8. Adrenolytic and sympatholytic drugs, including tetraethylammonium chloride or bromide, dibenamine and priscol, are being used in various clinics in the nonsurgical treatment of this disease. Encouraging reports are appearing in the literature regarding this form of therapy, but as yet their true value has not been determined. It seems doubtful that they will replace sympathectomy, since the effect is only transient, whereas if the sympathectomy is performed properly a permanent vasodilatation is obtained.

Raynaud's Disease

Raynaud's disease characteristically affects the young and emotional person and is seen most frequently in women. Since the disease seems to be the result of an increased vasomotor activity in the sympathetic nervous system in a majority of cases and in only a few due to a local fault in the arterioles of the fingers, sympathectomy is the best form of surgical therapy. A preganglionic type of sympathetic neurectomy, as described by Smithwick,⁴⁴ is still the most generally accepted method of treatment. The results obtained for the upper extremity have not proved so lasting as those for the lower extremity.⁴⁵ For this reason further investigations are in progress in an attempt to improve the type of sympathectomy for the upper extremity. It is believed that a more radical and extensive ablation of the lower cervical and upper dorsal portions of the sympathetic nervous system should be performed. At the present time an attack on this problem along these lines is being car-

It should be pointed out that arteriography is not without its dangers because of reactions from the drugs, which may in a few cases result in death and, in others, tragic ischemic difficulties in the injected limb. Arteriography should therefore be employed only when indicated and not as a routine in cases of arterial disorders. The most recent method of studying the peripheral arterial circulation is by means of radioactive isotopes. Smith and Qumby¹³ first reported the use of sodium 24 to show the level of adequate circulation in a limb and so determine the site of amputation in patients with obliterative arterial disease. Mufson et al,¹⁴ from the same clinic, used this method to determine the efficacy of drugs used in the treatment of peripheral vascular disease. Elkin and his associates¹⁵ have reported studies to determine the adequacy of peripheral arterial circulation using sodium 24 by intravenous and subcutaneous intramuscular injections. At the present time these studies and reports are extremely interesting, but further investigations with this new technic must be performed before the true value of the method can be determined.

The benefit of sympathectomy in the treatment of peripheral arteriosclerosis has been reported by a number of surgeons during the past year — Hendrick and Aycock,¹⁶ de Takats,¹⁷ Freeman⁵ and Yeager and Cowley.¹⁸ A careful selection of the patients subjected to this form of therapy should be made. The younger the patient is and the more evidence there is of vasomotor activity in the extremity, the greater the benefit that will be obtained. Intermittent claudication, as a rule, does not improve spectacularly after sympathectomy, but it has been observed to disappear gradually several years after the operation. The immediate benefit derived by sympathectomy is chiefly in the vascular supply to the integument. This in itself may be of great importance, since it will prevent the breaking down of the skin especially of the toes, which if it occurs frequently results in gangrene necessitating amputation. There appears to be definite evidence, however, not only that the extremity derives an immediate benefit from this form of treatment but also that it is the best protection that can be given to prevent serious vascular disorders with gangrene in old age. In other words, it appears at the present writing that the symptoms and signs of peripheral arteriosclerosis may be reversible if sympathectomy is performed early in the course of the disease and provided the sympathetic neurectomy is sufficiently extensive to prevent regeneration.

In the therapy of peripheral vascular disease there is a constant rivalry between the internist and the surgeon, the former to find nonsurgical methods of therapy to supplant surgical ones, and the latter to develop new surgical procedures. This form of competition should not be discouraged, but unfortunately too frequently some of the methods are

reported as the final answer to a problem without a sufficiently critical analysis of the results and procedures used. Both nonsurgical and surgical methods fall into this error. The chief criticism of the latter is that too many unqualified surgeons from lack of study and experience perform, with poor or disastrous results, surgical operations that have been established by authorities in their fields. This naturally discredits the procedure in the eyes both of many of the profession and of the laity. A number of nonspecific substances have been recommended for the improvement of peripheral arterial circulation during the past two decades. Some are given parenterally and others orally. These include the intravenous injection of a hypertonic solution of sodium chloride,¹⁹ or a nonspecific foreign protein (typhoid vaccine)²⁰ or diethyl oxide (ether)²¹, the intramuscular injection of sodium tetrathionate²², the oral administration of cytochrome C²³ or alpha tocopherol (vitamin E)²⁴, and finally the subcutaneous injection of histidine combined with the oral administration of ascorbic acid (vitamin C).²⁵ The beneficial effect on the peripheral circulation obtained by any of these methods, if it occurs, may only be transitory, and in most of the clinical reports other forms of therapy were utilized concomitantly on the patients, so that the improvement in the circulation cannot be attributed entirely to them. Borst and Holleman²⁶ have recently reported 3 cases of coronary thrombosis in 18 patients treated with intravenous sodium chloride solution and advise against its use.

Chemical sympathectomy by means of adrenergic and sympatholytic drugs has been utilized for many years without much success, but recently in this country it is being investigated with new drugs that show considerable progress in this field. Acheson and Moe,²⁷ in 1946, described tetraethylammonium chloride, or bromide, a ganglionic blocking agent. Nickerson and Goodman,²⁸ also in 1946, reported another drug, dibenamine (dibenzylbeta-chlorethylaminohydrochloride), which blocks the terminations of the sympathetic motor pathways in smooth muscle. Coller et al²⁹ and Lyons and his co-workers,³⁰ in 1947, reported the effects obtained with tetraethylammonium chloride in the diagnosis and treatment of peripheral vascular disease, including such conditions as causalgia, thromboangitis obliterans and thrombophlebitis. Both drugs produce peripheral vasodilatation, but their side effects are frequently so disagreeable that their clinical use seems somewhat limited and in some cases dangerous complications have been reported, one recently by Friedlich, Chapman and Stanbury.³¹ Priscol (2-benzyl 4, 5-midazoline hydrochloride) is the most recent of these drugs to be employed in this country, although it was first reported in 1939 by Hartmann and Isler,³² and since then numerous reports of its clinical use have appeared in the European and South American medical litera-

doubtful Johns⁶⁵ compared the results of the suture and the nonsuture method for the anastomosis of veins in animals. He reported 90 per cent functioning patent end-to-side splenorenal anastomoses and 73 per cent end-to-end ones, utilizing the suture technic, whereas with the nonsuture vitallium tube method only 17 per cent were patent in a group of end-to-end splenorenal anastomoses. There seems little doubt that in venous anastomoses at least the suture technic is preferable because it reduces the danger of thrombosis from a relatively low differential pressure between the blood vessels and the slow rate of blood flow. It also permits the construction of an end-to-side anastomosis, which is not so feasible with the nonsuture technic. The use of the everting type of mattress suture to produce an intima-to-intima approximation in the anastomosis is recommended by most surgeons.⁶⁵⁻⁶⁶ The vessels must also be of sufficient caliber, otherwise thrombosis results in the majority of cases.⁶⁶ The utilization of rapid freezing permits the preservation of blood vessels indefinitely so that it is recommended that blood-vessel banks be established. The recent experimental work of Williamson and Mann⁶⁷ throws some doubt on the feasibility of such a project, since they report good results with autogenous transplantations of both arteries and veins, whereas they found that homogeneous transplantations are not justified in the light of present knowledge. Gross et al.,⁶⁸ however, have reported that chemically preserved blood vessels may be of value to bridge arterial defects.

Aneurysms and Arteriovenous Fistulas

Numerous papers reporting large series of aneurysms and arteriovenous fistulas have appeared in the recent surgical literature, the results of vascular injuries from missiles in World War II^{55-58, 69} and treated in the vascular centers established by the United States Army Medical Department. The advances in the treatment of these conditions have been chiefly through the utilization of sympathectomy to enhance the collateral circulation⁷⁰ and also in various types of blood-vessel repair and anastomoses. Another advance in the treatment of arteriovenous fistulas is that a number of surgeons have expressed the opinion and also demonstrated that if possible the continuity of an artery should be maintained⁷¹⁻⁷³ because the generally accepted method of treatment by quadruple ligation with excision of the fistula, although it restores normal vascular physiology of the body and preserves the limb, is always followed by a diminished blood flow to the extremity. The surgical therapy of the degenerative type of aneurysm secondary to arteriosclerosis has received added impetus because the incidence of it in various sites of the arterial system seems definitely to be on the increase. One of the most noteworthy contributions has been made by Blakemore,⁷⁴ who used a method of wiring and

electrothermic coagulation. Whenever possible the restoration of a pulsating arterial blood flow to an extremity, after the removal of an aneurysm, should be attempted, as a number of surgeons have demonstrated.⁷¹⁻⁷³ Blakemore⁷⁵ has adapted the nonsuture method of blood-vessel anastomosis, using the vitallium-tube cuffs and a vein graft inlay in the operation of restorative endoaneurysmorrhaphy for popliteal aneurysm. The external reinforcement of the aneurysmal wall by the application of cellophane has received considerable attention, since a number of apparently successful results have been reported.⁷⁶⁻⁷⁷ The true evaluation of the method, however, must await further experience and time. The application of cellophane around an artery proximal to an aneurysm for the purpose of gradual occlusion of the vessel has been attempted,⁷⁸ but the results have not been outstanding. Elkin⁷⁹ has recently re-emphasized the fact that aneurysms and arteriovenous fistulas may develop secondary to surgical procedures and warns against mass ligation of arteries and veins, especially transfixion sutures. Linton⁸⁰ has recently reported, as others have, the dire effects in the conservative treatment of the arteriosclerotic type of popliteal aneurysm and demonstrated the value of a preliminary sympathectomy followed later by an aneurysmectomy in the treatment of this condition.⁸¹⁻⁸³

The surgical treatment of congenital hemangioma in cases in which the area involved is not great is a simple procedure, but it is still a challenge to the surgeon if the lesion is an extensive one, when improvement rather than a cure is the best result that can be obtained.⁸⁴

Chronic lymphedema is the one peripheral vascular lesion in which little if any progress has been made since Kondoleon described his radical method of surgical excision of the diseased subcutaneous tissues. Minor modifications of this method appear now and then,⁸⁵ but further investigations and study are necessary to improve the results of the present forms of therapy, which at best are none too good.

DISEASES OF VEINS

Varicose Veins

Varicose veins of the lower extremity constitute one of the most common ailments affecting man. Therapy for this condition in the past for the most part has been inadequate because of recurrence or persistence of the varicosities. The injection of sclerosing solutions, it is generally agreed, gives only temporary benefit even when combined with a high saphenous interruption. It should be pointed out that this form of therapy also is not without its dangers. Boyd and Robertson⁸⁶ have reported that deep thrombophlebitis and incompetence of the communicating veins in the lower extremity may develop, and Vaughn and Lees,⁸⁷ in 1947, collected

ried out in the Peripheral Vascular Clinic at the Massachusetts General Hospital. The adrenolytic and sympatholytic drugs are also being used for the treatment of this condition in many clinics. As in thromboangitis obliterans, the results are somewhat encouraging, but the benefits derived persist only as long as the drug is used. Because of the high percentage of recurrence following the usual dorsal sympathectomy, these drugs are considered in a more favorable light than surgery in a number of clinics that are using them. Further experience is necessary, however, to determine their true value as a permanent form of therapy.

Peripheral Arterial Embolism and Thrombosis

Peripheral arterial embolism occurs most frequently in patients with auricular fibrillation and after acute myocardial infarction. The diagnosis as a rule is not difficult, but it is important to differentiate this disease from acute arterial thrombosis. The latter develops as a rule in elderly patients with advanced arteriosclerosis. The treatment of the latter should consist of conservative nonsurgical measures, such as the use of the anticoagulants heparin and dicumarol, and intermittent venous occlusion. Peripheral arterial embolism, on the other hand, is primarily a surgical disease in a majority of cases, and even a saddle embolus at the bifurcation of the aorta may be successfully removed, as demonstrated in recent years by a number of surgeons (Murray,⁴⁶ Linton,⁴⁷ Keeley⁴⁸ and Tendler⁴⁹). The most satisfactory surgical approach to peripheral emboli is a direct one to expose the artery at the point of embolization, even those of the aorta, as demonstrated by the above reports. Warren and Linton,⁵⁰ in 1948, reviewed the results in 179 arterial emboli in 98 patients. Surgical embolectomy saved 85.7 per cent of 21 limbs, whereas 65.8 per cent were preserved by conservative treatment. Arterial embolism is a true emergency, since if treatment, either surgical or conservative, is withheld for more than eight to ten hours the incidence of gangrene is greatly increased, owing to the formation of a distal propagated thrombosis from the site of embolism, if this condition develops, no therapy will re-establish the circulation to the limb.⁵¹ Surgical embolectomy should be considered and immediately performed provided a competent vascular surgeon is available. If not, conservative treatment with the anticoagulants and intermittent venous occlusion should be instituted at once.⁵² The patient should not be first subjected to the latter therapy and if it is not successful then turned over to the surgeon. Leriche⁵³ has recently reported the successful resection of the bifurcation of the aorta for arterial thrombosis of this large blood vessel. This appears to be a heroic procedure for a condition that might respond well to adequate lumbar sympathectomy. Therapeutic venous occlusion or the interruption

of the concomitant vein, when a major artery is severed, was first recommended by Makins⁵⁴ in 1919. During World War I it was ordered to be performed for major arterial injuries, whereas in World War II the benefit seemed so doubtful that it was not so ordered and was performed only in a relatively small number of cases.⁵⁵ A great deal of experimental work has been done to evaluate the effect of this procedure. At the present time there is experimental evidence that the blood inflow to an extremity is diminished using indirect measurements of blood flow,⁵⁶ whereas by means of direct methods utilizing the Rein thermostromuhr an actual increase has been observed.⁵⁷ The clinical application of therapeutic venous occlusion, utilizing the method of intermittent venous occlusion by means of a pneumatic venous tourniquet, has saved extremities that otherwise would have been lost from gangrene.⁵⁸ Its chief value is for extremities with an acute arterial occlusion, such as arterial embolism or arterial thrombosis, and it deserves a definite place in the therapy of such conditions. It must be begun within a few hours of the vascular accident, otherwise, intra-arterial thrombosis distal to the point of occlusion will result, and gangrene will develop regardless of the therapy used. It is probably of little or no benefit in the therapy of chronic or obliterative arterial diseases, such as that seen in peripheral arteriosclerosis and thromboangitis obliterans. It is believed that the beneficial effect obtained by the Pavaex (passive vascular exercise) method of Hermann and Reid⁵⁹ can best be explained by the fact that it probably causes intermittent venous occlusion.

Blood-Vessel Surgery

The recent interest in blood-vessel surgery to produce arterial and venous shunts has stimulated the experimental evaluation of the relative merits of the nonsuture and suture method of blood-vessel anastomoses. Blakemore and Lord⁶⁰ deserve much credit for stimulating surgeons in the practicability of blood-vessel repair and anastomosis utilizing the nonsuture vitallium-tube method. However, the results in the armed forces using it in battle injuries during World War II^{61, 62} were not outstanding because of the difficulty in getting the patient early, the necessity of working under battle conditions and, probably not least, the lack of training of the surgeons in this branch of surgery who had to use it under these conditions. Nevertheless, the method, at least in acute arterial injuries of the young, deserves a place in the field of vascular surgery and should not be completely discarded.

The use of absorbable fibrin tubes instead of vitallium ones for vein anastomoses has been advocated by Swenson and Gross⁶⁴ and reported results are extremely good, thrombosis having occurred in only 1 case out of 27. The availability of this type of tube for general use, however, seems

modifications consist of interruption of the superficial femoral vein, ligation and stripping of the long saphenous vein, excision of the short saphenous vein and a partial excision of the deep fascia of the lower leg, only one incision being used on the inner side of the lower leg

Venous Thrombosis and Pulmonary Embolism

During the last decade great interest has been shown in the prevention and treatment of venous thrombosis and pulmonary embolism. No longer is the attitude tenable that death from massive embolism is inevitable in a certain number of medical and surgical patients, or that expectant conservative treatment is satisfactory. Carotti et al,¹⁰³ in 1947, showed that pulmonary embolism and infarction occurred more frequently in medical than surgical patients, and also that 87 per cent of a series of 273 medical patients were over forty years of age. This agrees with Allen et al,¹⁰⁴ who showed that in 367 surgical patients with thromboembolism 82 per cent were in the same age group. Despite the fact that most cases of thromboembolic disease occur in middle-aged or elderly patients the young are not immune, as demonstrated by Zuschlag¹⁰⁵ and Myers and Artsis,¹⁰⁶ who report the occurrence of thromboembolism in children under fifteen years of age. Fatal embolism in this age group, however, is rare.

Pulmonary embolism from other sources is recognized. Of special interest are articles that have appeared in the last year reporting cases of maternal pulmonary embolism by contents of the amniotic fluid.¹⁰⁷⁻¹⁰⁹ The majority of the patients die, and the diagnosis is not made until autopsy. The condition apparently is rare, but it may be more common than it appears, since in one hospital 3 patients died from this cause and they represented all the maternal deaths occurring during one year.¹⁰⁸ Ingersoll and Robbins,¹¹⁰ in 1947, called attention again to the danger of oil embolism following hysterosalpingraphy.

Prophylaxis Greater attention should be directed to the prophylaxis of venous thrombosis because deaths from massive pulmonary embolism still occur in patients without clinical evidence of deep venous thrombosis. Evans¹¹¹ reports 54 deaths from fatal embolism under these conditions in a series of 238 cases of postoperative thromboembolism, an incidence of 23 per cent. Allen,¹¹² in 1947, demonstrated the value of prophylactic interruption of the femoral vein in a series of 458 patients over sixty-five years of age, as compared to a comparable group of patients who received no special prophylactic therapy. In the former there was 1 death from massive pulmonary embolism, whereas in the latter there were 26 deaths from the same cause. At the present time there are no statistics that demonstrate that prophylactic use of dicumarol or heparin will give the same or better

protection in this aged group of patients in which thromboembolism is so prone to develop. Allen,¹¹² Bishop¹¹³ and Golodner et al¹¹⁴ have drawn attention to the relatively high incidence of fatal embolism in elderly patients with fractured hips, and recommend prophylactic measures such as interruption of the femoral vein or the use of anticoagulants. Veal¹¹⁵ has stressed the importance of interruption of the femoral vein in thigh amputations for the prevention of pulmonary embolism.

The prophylactic use of dicumarol has also been demonstrated to be of value in the average post-operative patient. Smith and Mulligan¹¹⁶ reported its use in 2353 surgical patients with only 1 death from fatal embolism. Allen¹¹⁷ reported the effect of dicumarol in 647 patients between forty and sixty-five years of age undergoing major surgical operations, without a single death from pulmonary embolism. Barker et al¹¹⁸ and Murray,¹¹⁹ in 1947, likewise reported 100 per cent protection by the prophylactic use of the anticoagulants in the post-operative patient. It should be pointed out, however, that the use of dicumarol in this manner is not without its dangers, since Allen¹¹² reports 2 deaths and Smith¹¹⁶ 1 from hemorrhage.

Treatment Homans,¹²⁰ in 1934, was the first to recommend interruption of the femoral vein for the treatment of venous thrombosis and pulmonary embolism. Since then numerous articles on the subject have appeared in the surgical literature. Allen and his associates¹²¹ at the Massachusetts General Hospital have demonstrated the efficacy of bilateral femoral-vein interruption in the treatment of venous thrombosis and the prevention of massive pulmonary embolism by this method. Other surgeons¹²²⁻¹²⁶ agree that this method is of value, especially in patients who have had nonfatal pulmonary emboli, to prevent fatal embolism. Carloti et al¹⁰³ also showed a reduction in the over-all mortality in cardiac patients with thromboembolic disease who were subjected to bilateral femoral-vein interruption, as compared to a control group not so treated.

It should be emphasized that interruption of the femoral vein if performed by capable surgeons is a safe procedure, but it is not without its dangers for the average surgeon, as pointed out by Sarnoff,¹²⁶ who reports a case of gangrene of both legs following the procedure. Dennis¹²⁷ also reports serious impairment of the circulation after interruption of the common femoral vein and the saphenous vein in the same extremity. It is believed that if femoral-vein interruption is to be performed, the interruption should never include the common femoral vein and the saphenous vein, since under these circumstances there may be insufficient collateral venous return from the extremity, as demonstrated in the report by Dennis.¹²⁷ In competent hands it is recommended that if a clot is found in the common femoral vein, the interruption of this vessel be performed after thrombectomy distal to the saphenofemoral

44 cases of fatal pulmonary embolism following injection therapy Smith and Johnson,⁸⁸ in 1948, reported from the Mayo Clinic 17 nonfatal pulmonary emboli and 1 death following this treatment in 11,700 patients. In the same year Luke and Miller⁸⁹ collected 4 additional fatal cases and 10 other cases of deep thrombophlebitis after ligation and injection of the saphenous vein. Accidents following the operative treatment have also occurred. Luke and Miller⁸⁹ also report several cases of ligation of the femoral artery or vein instead of the saphenous vein, and in 1 case injection of the distal femoral artery with the sclerosing solution resulting in gangrene of the extremity. Many similar unreported accidents have occurred undoubtedly (I know of 6 patients in whom the femoral artery was ligated and divided instead of the saphenous vein). The procedure of high interruption of the saphenous vein should not be condemned because of these mistakes since they were the result of poor surgery. New types of sclerosing solutions continue to appear in the surgical literature. The most recent one, sotradecol (sodium tetradecyl sulfate),⁹⁰ has certain advantages over the older ones, but it will not cure varicose veins without surgical removal of the main saphenous trunks. High interruption with retrograde injection of the sclerosing solution perhaps gives better results than injection therapy alone, but few patients obtain permanent relief. Because of the poor results by these forms of therapy, there has been during the past few years the revival by a few surgeons (Hodge,⁹¹ Prouleau,⁹² Vaughn,⁹³ Summers,⁹⁴ Sherman⁹⁵ and Linton⁹⁶), of high interruption and removal of the saphenous veins, both long and short, by stripping or excision. The stripping of varicosities was first recommended by Mayo⁹⁷ and Babcock.⁹⁸ The intraluminal type of stripper described by the latter has proved to be the more satisfactory, since with its use the vein can be removed more readily and completely. Unfortunately, many patients will continue to have the injection treatment, only to come finally to the surgeon for more radical therapy. The results in these cases are never so good as those in the patients who have not been treated with injections, since it is often difficult to remove the saphenous veins completely because of local areas of fibrosis and obliteration, which prevent insertion of the stripper and the complete removal of the main saphenous trunks. In addition the valves of the communicating veins, especially in the lower leg, become incompetent, the result of the sclerosing solution damaging these structures, so that in these patients recurrences are more prone to develop. It is my opinion that the most satisfactory therapy is ligation of the long saphenous vein at the saphenofemoral junction with the removal of the main trunk of this vein by stripping from the groin down to a point just distal to the internal malleolus. In a few cases excision of

some of the large tortuous varices may be necessary, and in some the saphenous trunk may be bifid, in which case both are removed. If the short saphenous vein is incompetent it should be removed also, after ligation at the saphenopopliteal junction, by stripping it to the level of the external malleolus. The stripping procedure is best performed under a general anesthetic to obtain the most radical removal of these veins. In most cases only a few injections of a sclerosing solution are necessary in the few remaining varicosities. These, for the most part, are for cosmetic effect.

Simple Varicose Ulcers

The cure of simple varicose ulcers due to varicose veins, in essence, consists of eradication of the varicosities. Numerous types of ointments have been recommended for the cure of this condition, but none, even those including the antibiotics and sulfonamides, have any special virtues. The use of these drugs should be discouraged since their topical application frequently sensitizes the patient to them so that their parenteral use at a later date, when they are needed for serious infections, may be prohibited owing to an acquired sensitization.

Post-Thrombotic Varicose Ulcers

The cure of this distressing type of ulceration remains a serious problem. Numerous methods of therapy have been recommended but few give better than temporary healing. The application of a gelatin-paste (Unna) boot or an elastic adhesive bandage (elastoplast) will heal, at least temporarily, the majority of these ulcers. These methods should be used chiefly to prepare the extremity for surgery by healing the ulcer and as postoperative dressings for periods of a few weeks to months. A new type of operation recently developed for the less extensive ulcers includes interruption of the superficial femoral vein, with ligation and stripping of the long and short saphenous veins. Buxton and Coller⁹⁹ and Homans¹⁰⁰ were the first to suggest interruption of the femoral veins. Linton and Hardy⁹⁶ have reported good results in a number of patients combining superficial femoral-vein interruption with radical stripping of the long and short saphenous veins. Further experience and a longer follow-up study on these cases are needed before a true evaluation of this method can be obtained. The method described in 1917 by Homans,¹⁰¹ consisting of radical excision of the ulcer with an immediate split-thickness skin graft, still deserves a place in this field of surgery, especially in the large indolent ulcers. The superficial femoral vein should be interrupted also if this procedure is performed, and the saphenous veins removed if they are large and incompetent. In some cases a less disfiguring operation, described by Linton¹⁰² in 1938, has given excellent results. The operation has been modified somewhat since it was originally described. These

junction and proximal to the origin of the profunda femoris vein. If no clot is found, in the majority of cases interruption of the superficial femoral vein just distal to the profunda femoris will suffice. Interruption of the inferior vena cava is chiefly indicated, as pointed out by a number of authorities,¹²⁸⁻¹³¹ for pulmonary emboli arising from pelvic thrombophlebitis, especially the septic variety. It should not be performed for the usual case of thromboembolic disease, since it is a major surgical procedure that may carry a relatively high mortality, as demonstrated by Thebaut,¹³² and in most cases it is an interruption of the venous system at a level higher than necessary to prevent further pulmonary emboli.

The treatment of deep venous thrombosis by procaine block of the lumbar sympathetic nerves, as recommended by Ochsner,¹³³ is of chief value in patients with the obstructing type of femoroiliac thrombosis to relieve pain and swelling. It does not necessarily protect the patients from pulmonary embolism.

The use of the anticoagulants in the treatment of thromboembolism has received great impetus also, especially since dicumarol has become so readily available. Heparin was the first anticoagulant to be used and is still recommended by some authorities (Murray,¹¹⁹ Bauer,¹³⁴ Jorpes,¹³⁵ Loewe¹³⁶ and Evans¹¹¹). The chief exponents of heparin have been in the Canadian and Swedish schools. Loewe,¹³⁶ in this country, has developed a preparation that is slowly absorbed and is given intramuscularly. Despite the fact that it is the ideal anticoagulant yet developed because of its rapidity of action and its ease of control, heparin has not found wide usage on account of its expense. Dicumarol, more recently discovered, is now more generally used because it is cheap and may be given orally.^{118, 127, 128} It is generally agreed that it should not be used unless laboratory facilities are available for the accurate determination of the prothrombin time. It is significant to note that deaths still occur from massive pulmonary embolism in clinics that treat patients with the anticoagulants after a diagnosis of venous thrombosis with or without pulmonary embolism has been made.^{109, 118, 136, 141} The same drawback to the treatment by femoral-vein interruption has also been reported by Allen¹¹⁷ in a large series of cases, so that at the present time there is no method that will prevent massive pulmonary embolism in 100 per cent of the patients. In conclusion, it appears that the safest method of treatment, once thromboembolism has developed and is recognized in any patient, is to perform bilateral femoral-vein interruptions and to supplement this treatment by anticoagulant therapy.

Portal Hypertension with Bleeding Esophageal Varices

One of the important advances in peripheral vascular surgery in the last few years has been the

treatment of bleeding esophageal varices secondary to a portal bed block, either of the intrahepatic type (portal cirrhosis) or the extrahepatic (the so-called Banti's syndrome) by the construction of various types of venous shunts between the portal and the general venous systems. Whipple¹⁴² and Blakemore¹⁴³ deserve great credit for this renewed attack on a problem that has long baffled the medical profession. They first recommended as the operative procedure a splenectomy, a left nephrectomy and an end-to-end nonsuture anastomosis between the splenic and renal veins. In 1947 the operation was modified by an end-to-side suture type of splenorenal anastomosis with preservation of the kidney as recommended by Linton et al.¹⁴⁴ Direct anastomoses between the portal vein and the inferior vena cava, both end-to-side and side-to-side, have been performed safely a number of times by Blakemore.¹⁴⁵ Further experience and observations of these patients with portacaval shunts are necessary before a true evaluation of this form of treatment can be determined. Furthermore, the relative merits of splenorenal, end-to-side portacaval and side-to-side portacaval anastomoses have yet to be determined. It appears quite definite, however, that a surgeon should not perform a splenectomy alone for bleeding esophageal varices, especially of the extrahepatic (Banti) type, since this may be the only opportunity at which a satisfactory venous shunt can be performed.¹⁴⁶

CASE 35161

PRESENTATION OF CASE

A ten-year-old girl was admitted to the hospital because of a progressive swelling in the neck.

She was seen for the first time five months before admission in the Out-Patient Clinic. The cervical mass, then of two months' duration, had not been accompanied by any systemic symptoms. There was no change in weight, appetite or bowel habit. No unusual sweating was noted, nor was there any preference for cold or warm weather. There was no tremor or exophthalmos. The patient is said to have frequently cleared her throat "as though she had some obstruction" after the mass appeared, but she had no difficulty swallowing. Two years before admission her mother noted that the patient's emotional pattern had changed: she became unhappy, cried easily and was "less peppy" than she had previously been. These changes persisted.

The patient's mother had had a goiter during pregnancy and for some months thereafter. She received 5 drops of an iodine solution daily for about a year altogether. Iodine was taken during the entire period of pregnancy.

The patient's maternal grandfather had had an operation for hyperthyroidism.

On examination the thyroid gland was diffusely enlarged and not nodular. The left lateral lobe was more easily palpable than the others. There were no other abnormal findings. The temperature was 97.8°F, the weight 66 pounds, and the height 53 inches. X-ray examination of the wrists demonstrated that the bone age was not at variance with the chronologic age. The blood cholesterol was 200 mg per 100 cc.

The patient was seen regularly in the Out-Patient Department. The mass in the neck persisted and increased in size. Three weeks before admission the gland was diffusely and evenly enlarged. The right lobe, particularly the upper pole, was prominent. The enlargement was firm and granular. Lymph nodes were enlarged, two Delphian and one of the posterior chain on each side. On the same day the decision was made to admit the patient for a surgical biopsy and possibly a more extensive procedure.

On admission the child was quiet and sad, crying on the slightest provocation. The thyroid gland was estimated to be twice its normal size, diffusely enlarged, granular and firm. There was no generalized lymphadenopathy.

The temperature was 99°F, the pulse 86, and the respirations 20. The blood pressure was 98 systolic, 68 diastolic. The height was 54 inches, and the weight 64 pounds.

The urine was normal. The white-cell count was 5600, with a normal differential. The hemoglobin was 12.9 gm. After a barium swallow the esophagus was questionably displaced to the left in the region of the thyroid gland. There was no obstruction to the flow of barium through the esophagus and no evidence of any substernal extension of the thyroid gland.

In the opinion of the last examiner in the Out-Patient Clinic there was definite change in the gland during the three-week interval. It was smaller, and only the right upper pole retained its abnormality; the isthmus and left-lobe processes had receded. The Delphian node and the enlargement of the right-posterior-triangle lymph node persisted.

Operation was deferred in lieu of further clinical observation. Radioactive iodine was administered. There was a 39 per cent uptake in the gland, which was interpreted as the upper limit of normal.

She was discharged on the third hospital day.

Second admission (ten weeks later). During the interval the patient was followed in the Out-Patient Department. Several observers felt that the thyroid gland progressively increased in size during subsequent weeks. She gained about 5 pounds and felt well.

Except for the findings in the neck, there were no changes on physical examination.

On the third hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR J H MEANS: This the first time at one of these conferences that I have been given a case that seems to be goiter. Perhaps it is not a goiter, but it appears to be.

I will make a few comments on the history, then if there is other evidence, we will ask for it and attempt to make a diagnosis. It is apparently clear that this girl had a goiter. I do not believe we need consider other enlargements in the neck. Let us say that it was a goiter. The descriptions fulfill that definition perfectly well. It is interesting that she had no symptomatic changes early in the history, but a change of personality is described. She had crying and depression, which might be seen in Graves's disease. There is little else to suggest Graves's disease, however. Whether or not the mother had a goiter during pregnancy is not perfectly clear. I think that any physician who has a patient going through pregnancy with a thyroid

case in which it was proved that a cancer of the colon had metastasized to the thyroid gland. Lymphoma may involve the thyroid gland diffusely and apparently without much lymphoma elsewhere, so that lymphoma must be considered. There is one type of non-neoplastic disease that must be mentioned—that is amyloidosis. We have had 4 or 5 cases of amyloid disease of the thyroid gland. I do not believe that amyloidosis was present in this case. In fact, I will rule it out, although we have no right to rule it out absolutely because there has been nothing said about a Congo-red test. Amyloidosis of the thyroid gland might be part of what we call idiopathic amyloidosis, but I would expect lesions elsewhere. A chronic, suppurative process or tuberculosis we cannot throw out, but I think it is entirely unlikely.

Of the primary tumors of the thyroid gland I do not believe it is any kind of benign tumor because I would expect that to be nodular, at least in the beginning. Benign tumors of the thyroid gland do not start, in my experience, as a diffuse process. They may become so later by multiplicity of nodules closing together to give the appearance of a diffuse lesion. I think that is unlikely and I therefore believe the diagnosis lies between some kind of chronic thyroiditis and some kind of malignant tumor, which might be epithelial. There are various types of adenocarcinoma of the thyroid gland, papillary and otherwise, and some highly undifferentiated cancers. I do not think we need to go into the classification of the various types of tumor because one cannot possibly make a differentiation except histologically. As between chronic thyroiditis and a malignant process the regional lymph nodes strongly suggest a malignant process but we have found the Delphian node, so-called, in chronic thyroiditis, so that that is not absolutely of differential diagnostic value. The mass has never been tender so far as we know. Sometimes these chronic processes are not. There is nothing in the story suggesting an acute thyroiditis, but our general concept of the chronic forms is that they are not an aftermath of an acute type but an independent condition generally of a different etiology in all probability. As between the two types I have mentioned, the lymphadenoid type of chronic thyroiditis or Hashimoto's struma and Riedel's struma I would think that the former was more likely simply because it is more common. The Riedel type is very rare, and the description of this gland does not sound like it. It is not described as stony hard. It was firm and granular. I do not know what is meant by granular. I never felt a thyroid gland that I would call granular. The choice lies, I believe, between Hashimoto's struma and some kind of malignant goiter, but I have not the faintest idea which it was. It was not growing very rapidly, which would make it possible to rule out a highly undifferentiated cancer. The

regional lymph nodes are frequently involved in papillary types of thyroid cancer but I would not rule out lymphoma even in the absence of a lymphoma elsewhere. So I am going to leave it as a choice between Hashimoto's struma and a rather diffuse malignant tumor of the thyroid gland, and I think on the chances, a papillary adenocarcinoma would be more likely than any other kind. I am prepared to be told, however, that it is either or neither of them. What is needed here is histologic evidence so far as I am concerned.

DR CASTLEMAN: Are the x-ray films helpful?

DR STANLEY M. WYMAN: They are not contributory.

DR TALBOT: Like Dr Means, we came to the conclusion that this child probably had either thyroiditis or a neoplasm of the thyroid gland. Not wishing to run the risk of neglecting a neoplasm while it still might be amenable to therapy we urged surgical biopsy examination. In this connection we also thought that should the diagnosis turn out to be thyroiditis, there might be some prophylactic value in excising a portion of the thyroid isthmus since there is some tendency for thyroiditis to result in constriction of the trachea and adjacent structures. Perhaps Dr Means would like to comment on this subject.

DR MEANS: About the matter of constriction from chronic thyroiditis particularly the Riedel type, it may produce severe tracheal obstruction, but so may the Hashimoto type and a partial resection may have to be done to remove pressure symptoms. This child apparently was getting slight pressure symptoms. In this type of goiter, if it is Hashimoto's, being a lymphadenoma type of thing, one might get good results with x-ray therapy. One does not operate on Hashimoto's struma unless there is an indication for relieving pressure.

That was one other point I did not discuss much. It puzzled me a little whether this posterior gland was part of the same process or a red herring. I was not sure.

DR TALBOT: It was just posterior to the thyroid gland itself.

DR MEANS: Quite close to the thyroid gland. I suppose that would favor a little bit the diagnosis of a malignant process because I would expect one might find a Delphian node with thyroiditis, but I would not expect it so much in the lateral region. Another thing is that the gland in Hashimoto's struma is sometimes described as being more or less like an ameba, with pseudopodia sticking out. One can feel scallops at the edge of it, and that is not mentioned here so I am a little bit more inclined to think that it was malignant but I am not at all sure. That just gives it a little edge.

CLINICAL DIAGNOSIS

Chronic thyroiditis, Hashimoto type?
Carcinoma of thyroid gland?

enlargement does well to give iodine, particularly if there is any evidence of hyperfunction during pregnancy, more than would be explained by the pregnancy itself. I also have the feeling that when women who are pregnant have low metabolism they should be given thyroid. I cannot get any more out of that information than just that, nor can I place any great amount of weight on the fact that the patient's maternal grandfather had an operation for hyperthyroidism. I would like to know more about the family situation, however. I would like to know where the patient was born, where her parents were born and where this operation on her grandfather was done. I would like to know also whether she did or did not come from an endemic goiter region.

DR BENJAMIN CASTLEMAN Both she and her mother were born in Massachusetts.

DR MEANS We do not know where in Massachusetts, but we know that the goiter region in Massachusetts is in the Berkshires, where minimal thyroid enlargement has been found among school children.

DR CASTLEMAN She came from Cambridge.

DR MEANS It is stated that the thyroid gland was enlarged and not nodular. It is important to know whether it was a diffuse goiter or a nodular goiter. We have to take this story at face value, it was diffusely enlarged, and no nodules were felt.

Laboratory examination showed a blood cholesterol within normal limits. The finding of enlarged lymph nodes is of importance, the so-called Delphian node. One of the students suggested calling it that to Dr Cope. The point was that since the Delphian oracle foretold things, and the node just above the isthmus may enlarge when some process is going on in the thyroid gland, it is a tell-tale node. Sometimes one confuses an enlarged pyramidal lobe with a lymph node. I assume that there were enlarged nodes and some of them were in the posterior triangle. Also quite important is the negative evidence that no adenopathy was found elsewhere. There is no mention of splenomegaly or hepatomegaly or anything of that kind. The radioactive-iodine collection was at the upper border of normal, and I will say that it probably was normal. I will conclude, therefore, from that much of the history and the physical findings and that one bit of laboratory evidence, that this patient had a goiter causing no disturbance in function — that is, a state of euthyroidism. I wonder why they sent her in for a biopsy and out without having it done. That is not clear. I wonder why they waited for ten weeks. Perhaps the family refused or it took them ten weeks to convince those in charge that it was indicated. Is that a fair question?

DR CASTLEMAN Can you answer that, Dr Talbot?

DR NATHAN B TALBOT I was anxious to have a biopsy done, but it was difficult to persuade the surgeons.

DR MEANS All I can say, then, is that I do not know why they sent her in for a biopsy and then did not do it, because it might have made the diagnosis. The most important thing in diseases of the thyroid gland, as of any other part of the body, is to establish a diagnosis. When one sees an enlarged thyroid gland, particularly when it is not giving rise to any change in function, one almost always has to have a histologic examination. That is the only way to determine its character. If one is dealing with a full-blown picture of Graves's disease, one knows what the thyroid gland will show and does not have to worry about the histologic diagnosis. There are no other laboratory tests recorded in this history, such as the protein-bound iodine. I suppose they were normal, but if they were not done, I would not worry about them because the clinical evidence for euthyroidism is quite impressive. I do not know what was going on during the ten weeks' observation when the gland was smaller, not larger. I do not know how to interpret that. I do not know from the record whether or not the goiter was larger at the time of operation than at the time the patient was first seen. Is that a fair question? Whether it had increased in size or remained stationary is all important in making a differential diagnosis.

DR TALBOT There were differences of opinion about the size of this gland as time progressed.

DR MEANS It is evident that it was not growing at a great speed. I do not believe they said whether or not it was tender.

DR TALBOT It was not tender.

DR MEANS They finally did an operation. Whether it was a biopsy or a radical neck resection, I do not know. There was a surgical procedure, which, I suppose, disclosed a diagnosis. What must we consider? I think we have to consider every kind of goiter in differential diagnosis. I will try to be brief. I think we can rule out Graves's disease. The question whether or not it is endemic goiter would come up, but I would dismiss it because she did not come from an endemic region. A goiter due to cabbage or goitrogenic drugs might be considered. Did she have any of these things?

DR TALBOT No.

DR MEANS Another possibility is tuberculosis of the thyroid gland. I cannot exclude that. I do not know whether we have ever seen a case at this clinic. It is extraordinarily rare. We are now down to some kind of neoplasia or some kind of chronic inflammatory process. It seems to me this case could be one of the forms of chronic thyroiditis such as Hashimoto's struma or Riedel's struma. It could be any one of a considerable variety of tumors. One thinks of primary tumors, of course, although metastatic tumor to the thyroid gland does occur. We have had 2, I think perhaps 3, cases of hypernephroma that metastasized to the thyroid gland. When I was in California a year ago I was told of a

day penicillin was started and the sulfadiazine discontinued. During the next two to three days the urine output dropped to 60 cc per day, and the nonprotein nitrogen was found to be 60 mg per 100 cc. At this time the carbon dioxide was 24.5 milliequiv per liter, and the sulfadiazine level was 13.2 mg per 100 cc. The total protein was 5.9 gm per 100 cc. The prothrombin time was 33 seconds (normal, 16 seconds). The clotting time was 18 minutes, and the clot retraction was normal. The joint pains, which had been quite bothersome, began to subside, and the temperature returned to near normal. The nonprotein nitrogen continued to rise, being 90, 106 and 150 mg per 100 cc on the fifth, sixth and seventh hospital days. The urinary output was still low (150 cc per day), and disorientation was a prominent symptom. At this time the hemoglobin was 10 gm, and the white-cell count 7200, with 76 per cent neutrophils, 2 per cent young polymorphonuclears and 1 per cent blast forms. A blood culture revealed no growth. A few petechiae appeared over the trunk and extremities. On the eighth hospital day the urinary output began to increase, but the nonprotein nitrogen continued to rise, and a to-and-fro friction rub was then heard over the anterior chest, being loudest over the second and third interspaces on the left. By the ninth hospital day the erythematous rash had faded considerably. She became dyspneic and drowsy, and twitchings occurred at intervals of one second. On the thirteenth hospital day the nonprotein nitrogen had risen to 200 mg per 100 cc. A platelet count at this time was 58,000. The urine gave a +++ test for albumin, and the sediment contained 50 red blood cells and 6 white blood cells per high-power field. A swelling developed over the left parotid region. On the fifteenth hospital day the nonprotein nitrogen was 280 mg per 100 cc. The patient was comatose and exhibited choreiform movements. A uremic frost appeared on the forehead and lips, and she died later that day.

DIFFERENTIAL DIAGNOSIS

DR ALFRED KRANES: Have you any idea what form this patient's sensitivity took? Was it asthma?

DR MARIAN ROPES: It was simply sneezing, with no real asthma.

DR KRANES: We are faced with the ever-recurrent problem of trying to predict the histologic picture of a kidney in a patient who obviously died of renal insufficiency and uremia. By and large, that is not likely to be a very accurate clinical exercise, but there is no reason why we should not keep trying. In this case we are limited, it seems to me, to consideration of only the acute forms of renal disease, since this patient's illness lasted exactly one month—unless one wants to make the assumption, hardly justified by the facts given here, that this represents an acute exacerbation of some chronic renal disease. From the information available there is no reason

to think that this patient had pre-existing renal disease. The original urine examination, with a specific gravity of 1.022, indicates good function of the kidneys, although no other renal-function tests are given. So I will limit myself to a discussion of certain types of acute, rapidly fatal kidney disease.

We can eliminate from our discussion any of the acute poisonings such as mercury, arsenic or carbon tetrachloride since there is no reason from the history why we should consider them seriously. The most common acute renal disease that will produce this type of picture is acute glomerulonephritis, and there are many parts of this picture that can be well explained by such a diagnosis. Certainly, the hematuria, the oliguria, the pulmonary edema that developed and the eventual uremia and death are readily explainable on this basis. However, several aspects of the picture are a bit unusual. In the first place, nothing is said about the finding of any casts in the urine, although they may have been present. One would expect a patient with acute glomerulonephritis to have a fair number of casts in the urine.

DR WALTER BAUER: She had frequent granular casts on one specimen only.

DR KRANES: One would expect more than that. We are given only one blood pressure reading of 120 systolic, 68 diastolic. Nothing is said about the subsequent course of this patient's blood pressure. I am assuming that there was no appreciable change, but that assumption may be wrong. If the blood pressure showed no rise, it certainly would be strong evidence against the diagnosis of acute glomerulonephritis. But what bothers me even more about such a diagnosis is the early part of the history: the degree of fever, and the amount of pain in the calves, thighs and joints. Did this patient have much joint pain in the upper as well as the lower extremities?

DR ROPES: Not as much in the upper extremities. She definitely had joint pain occasionally over the course of two or three years, usually in the upper extremities. About six or eight months prior to entry she had begun to have cerebral symptoms. There was a definite change in judgment and memory. She had a responsible job, and from being a very efficient person she became relatively inefficient, forgetting things and showing evidence of poor judgment.

DR BAUER: She also was fatigued and complained of being tired going upstairs. Dr Ropes elicited that information from the nurse and secretary some time after admission. The blood pressure never did rise. The highest recorded is 170, and some time later it was only 140 or 150.

DR KRANES: A fairly normal blood pressure during the development of renal insufficiency is evidence against the diagnosis of glomerulonephritis. As I have just stated, what disturbs me more than either the absence of casts or the elevation of blood pressure is the fever and peripheral discomfort that she had. Fever, of course, is not an uncommon ac-

DR MEANS'S DIAGNOSIS

Carcinoma of thyroid gland?

Chronic thyroiditis, Hashimoto type?

ANATOMICAL DIAGNOSES

Chronic thyroiditis, Hashimoto type

Hyperplasia of thyroid gland

PATHOLOGICAL DISCUSSION

DR CASTLEMAN I am sorry that Dr Cope is not here. He operated on the patient and first exposed some lymph nodes that were grayish white and slightly firm, but he did not believe they were neoplastic and at operation he favored chronic thyroiditis. The isthmus of the pyramidal lobe and part of the left lobe were excised and they also appeared grayish white. We performed a frozen section on the thyroid gland and found no neoplasia but a Hashimoto struma, and I will show the sections from it. This is the low-power view showing a uniform infiltration with lymphoid germinal centers throughout the thyroid gland. Of particular interest is the condition of the acini, which are definitely hyperplastic. The epithelium is high, and there is scalloping of the colloid, which is quite common in hyperplasia. It is not unusual to find actual hyperplasia in the early stages of Hashimoto struma. One theory of the pathogenesis of Hashimoto struma is that it is really a burned-out hyperthyroidism, this may be an early stage. Ordinarily patients with this disease are women between forty and fifty years of age, in these cases we may not see as much germinal center formation but more of a diffuse lymphocytic infiltration, with compression and replacement of colloid acini, which may give rise to a low basal metabolic rate and myxedematous signs and symptoms.

DR MEANS Another possible explanation would be compensatory hyperplasia due to the fact that the infiltrative process had destroyed the rest of the parenchyma. The remnant became hyperplastic to take care of the function. In the older patient did you find any areas of hyperplastic parenchyma?

DR CASTLEMAN Not usually. The older patient tends to develop myxedema.

DR MEANS That is when all the parenchyma is knocked out, and there is nothing left to become hyperplastic. That was another point in differential diagnosis between cancer and chronic thyroiditis. If one can prove that there is hypothyroidism, it is real evidence in favor of chronic inflammation rather than cancer, because cancer, no matter how diffuse, rarely knocks out the parenchyma completely with resulting myxedema.

DR CASTLEMAN This patient did not have a basal metabolic rate before operation. One month

following operation a basal metabolic rate is recorded as -4 per cent.

DR ALLAN M BUTLER Do you endorse the diagnostic biopsy, Dr Means?

DR MEANS Yes

CASE 35162

PRESENTATION OF CASE

A forty-nine-year-old woman was admitted to the hospital because of joint and muscle pains.

Two weeks prior to admission the patient developed a sudden sharp pain in the right anterior thigh that extended down to the knee. Two days later a similar pain developed in the left anterior thigh and sacroiliac region. Aspirin seemed to relieve most of the pain, but she took as much as 0.6 gm (10 gr) four or five times a day. Several days before entry she stopped the medication because of the development of ringing in the ears and nausea. Four days prior to admission both calves became stiff and tender, and the temperature rose to 101°F. Two days before entry a swelling, redness, some pain and tenderness occurred over the left internal malleolus, and a similar swelling occurred on the right heel on the day before admission.

There was no history of previous joint or muscle pains. She was said to be sensitive to house dust. She denied ever having taken sulfonamides.

Physical examination revealed a fairly comfortable woman, with a warm, moist skin. There was a blotchy, erythematous rash about the elbows, left wrist (1 to 3 cm in diameter) and the left internal malleolus. These areas were not indurated or elevated. There was a soft, Grade II systolic murmur at the apex. There was slight bilateral calf tenderness and a soreness of the heels.

The temperature was 103°F, the pulse 120, and the respirations 24. The blood pressure was 120 systolic, 68 diastolic.

Examination of the blood disclosed a hemoglobin of 14.6 gm and a white-cell count of 13,200, with 70 per cent neutrophils, 27 per cent lymphocytes, 2 per cent monocytes and 1 per cent basophils. Frequent band forms were seen. The platelets appeared normal. The urine gave a +++ test for albumin, with a specific gravity of 1.022, and the sediment contained as many as 20 red blood cells and 25 white blood cells per high-power field.

Sulfadiazine therapy was begun on admission. The erythematous blotches on the skin appeared to come and go from hour to hour. On the second hospital day 2000 cc of dextrose in physiologic saline solution and 200 cc of sodium lactate were given. The urinary output decreased to 250 cc on this day, and simultaneously the patient appeared to go into acute cardiac decompensation. Digitalis and other measures were required. The temperature continued to remain elevated up to 102°F, and on the third

cases that clinically seemed to have one disease and pathologically the other

Finally, I think one other disease should be mentioned, although it is pretty far-fetched. I am sure those who saw the patient will think it absurd. But as I get the picture from the description in the record of the initial symptoms in her legs—pain, stiffness of the calf and tenderness, the possibility occurred to me that the patient had an acute thrombophlebitis, although nothing further is said about it. If that were so, one might easily conceive of this process extending up into the iliac veins, possibly to the vena cava, and if it extended up far enough, it might occlude the mouths of both renal veins or extend into the renal veins causing hemorrhagic infarction of both kidneys and renal insufficiency. I realize it is a rare and unusual possibility but, as the picture is given here, not an impossible one.

In summary, then, I think we have to consider only three general possibilities: glomerulonephritis, one of the lesions produced by sulfonamides and periarteritis nodosa. Of these three possibilities it seems to me that the least objectionable one would be periarteritis nodosa. So I shall guess that that was what this patient had.

DR TRACY B MALLORY: I take it that the x-ray films are not contributory?

DR STANLEY M WYMAN: No, there is just a question of pleural reaction at the left, which may perhaps tend to implicate the pleura rather than the pericardium. Whether that is a help, I do not know.

DR KRANES: I do not see how it casts any light on the renal problem.

DR BAUER: The following note shows what we thought about this woman at the time of entry and what we believed she might be suffering from, although we would be the first to admit that we were not too certain of the exact nature of the disease (this was written six days after admission).

When I first saw this patient I thought she was suffering from meningococcemia manifested by fever, headache, rash and arthritis. Sulfadiazine was started on the same day (3 gm). After a total of 7 gm of sulfadiazine, oliguria was evident, although there was no history of previous ingestion of any type of sulfonamide. On the same day she received 2200 cc. of physiologic saline solution as well as two ampules of sodium racemic lactate. This added sodium intake was sufficient to increase the patient's blood volume to a point where obvious signs of congestive failure

appeared. With the discontinuance of sulfadiazine, penicillin (400,000 units every twenty-four hours) therapy was instituted. Forty-eight hours after the start of sulfadiazine and twenty-four hours after penicillin the temperature fell, and the leukocyte count dropped from 13,000 to 6000. Up to today I felt reasonably certain that the patient had had a bacterial infection that had responded to specific treatment, but that she had the misfortune of developing a sulfonamide nephrosis and congestive failure by increasing her blood volume at a time when she had oliguria. The oliguria has improved, and the patient is now able to take fluids much better.

This morning the clinical picture resembles that seen on the day of entry, except that the rash is not as marked and the vesicular lesions on the chest are pruritic. Could the reappearance of these findings be related to the barbiturate she received last night? Is she sensitive to other agents than sulfonamides? For the time being it seems unwise to use any type of sedative.

At the moment I am unable to make a satisfactory diagnosis. I am still inclined to believe we have been dealing with a patient who had a bacterial infection, who is sensitive to sulfonamides and perhaps other drugs. There is little to suggest either rheumatic fever or rheumatoid arthritis. We must still entertain the possibility of subacute bacterial endocarditis, lupus erythematosus and periarteritis nodosa. Treatment for the time being should be good nursing and a minimum of drugs.

Subsequent to that Dr Ropes obtained additional information that the patient had not been feeling well for at least six months. Frankly, I must say that up to the time she died I did not know for certain what she was suffering from, but was inclined to believe it was more likely periarteritis nodosa or lupus erythematosus disseminatus. The last we heard from the Pathology Department they were not certain, but perhaps we will see.

CLINICAL DIAGNOSES

Periarteritis nodosa
Uremia

DR KRANES'S DIAGNOSIS

Periarteritis nodosa

ANATOMICAL DIAGNOSES

Lower-nephron nephrosis
Pericarditis, acute
Myocarditis, focal
Pneumonitis, interstitial
Bronchopneumonia, terminal
Hematopoiesis of spleen

PATHOLOGICAL DISCUSSION

DR MALLORY: The Pathology Department is far from certain about this case. We are able to name

companionment of glomerulonephritis, but fever of this degree and muscle and joint pains of this degree are not common symptoms of glomerulonephritis

Dr Bauer is showing me the chart, which indicates fever in the beginning, gradually coming down to normal. Perhaps the glomerulonephritis, if present, was a complication of some other acute infectious process. What that may have been, I certainly have no idea. There is no evidence on which to localize any type of acute infection. To be sure, during the latter part of the illness she developed a pericardial friction rub, but I am interpreting that as the type of fibrinous pericarditis that so often develops in the terminal stages of uremia. The swelling over the parotid area was a terminal, purulent parotitis in all probability. Whether she had subacute bacterial endocarditis and a complicating nephritis as a result is difficult to say. I am not able, on the evidence given here, to make a diagnosis of subacute bacterial endocarditis.

The presence of fever, pain and renal disease raises the question of acute pyelonephritis. The urinary sediment is not very helpful in establishing such a diagnosis. If this were pyelonephritis, one would have to assume that there was pre-existing renal disease. An acute attack would not be expected to produce death so rapidly.

We come now to a discussion of the possible role of sulfonamides in this patient's terminal illness. I would like to ask how certain we can be that she received no sulfonamides before coming to the hospital.

DR ROPES: I am very sure that she had not received any.

DR KRANES: That is important because there is some evidence on admission to the hospital that this patient already had renal disease as evidenced by the albuminuria and the hematuria. The picture as described indicates that sulfonamides may have played some role in the development of the subsequent renal insufficiency, since the urinary output seems to have diminished following their administration. If the history is accurate, and we have to believe it is, I do not see how we can incriminate the sulfonamides as underlying this renal disease. They may have aggravated it.

The usual types of lesions produced by sulfonamides, as you know, are precipitation in the renal tubules of sulfonamide crystals and the rapid development of oliguria. That is a possibility. Another

type of lesion is lower-nephron nephrosis, which, unless this patient had previously been given sulfonamides, seems improbable. The third type of lesion produced by sulfonamides is a periarterial lesion, periarteritis nodosa, first described by Rich* and subsequently confirmed by other workers on clinical cases. On the whole, I would be inclined to disregard the role of sulfonamides in this particular patient, since she had renal disease before they were given.

We know that periarteritis can exist in the absence of sulfonamide administration. It is a disease that has to be seriously considered in this patient. I see nothing in the history as given here that would be against such a diagnosis. The muscular and joint pains, the fever and the renal disease all fit that diagnosis. One thing that bothers me about such an explanation is the short course of this patient's illness. Dr Ropes has added further data indicating that this patient had not been in good health for six months. That would fit in very well with the diagnosis of periarteritis. Of course, all the features of the disease were not present here. There was no eosinophilia, but that is not too disturbing. There was no asthma.

In this regard I think it might be worth speculating about the possible role of sulfonamides, if this patient does turn out to have had periarteritis nodosa. I do not believe Dr Mallory will be able to answer that, but it is interesting to speculate about it. Given a patient with periarteritis nodosa, what would happen if sulfonamides were given, a drug we know is capable of producing the disease in a sensitized patient? I do not know. It does seem from the description that the disease might have been accelerated by the administration of sulfonamides, but I do not see how we can answer the question.

What I have said about periarteritis applies equally well to another disease — acute disseminated lupus. The differential between the two I do not believe I can make clinically. When I say "periarteritis nodosa" I mean that the patient might also have had the renal lesions of disseminated lupus, although pathologically they are quite different. The skin rash, joint pains and fever and even the pericardial friction rub, although it is much more likely to have been a uremic pericarditis, might have been evidences of disseminated lupus. We have seen

*Rich A. R. Role of hypersensitivity in periarteritis nodosa as indicated by 7 cases developing during serum sickness and sulfonamide therapy. *Bull. Johns Hopkins Hosp.* 71:123-140, 1942.

"I HAVE CANCER"

As ALREADY noted in these columns, April is the month in which interest in the control of cancer is brought to its sharpest focus. Consideration has been given to heart-disease month, and the nation is currently passing through cancer-control month, mindful of the 1949 goal of \$14,500,000 in donations to be achieved, according to a recently developed national tradition, the country is in fact encountering a succession of chronological periods especially consecrated to unusually worthy causes.

Of the hazards to life that mankind is now constantly combating with better equipment and with greater success than ever before, heart disease and cancer offer a significant comparison. Each is ac-

knowledgeed as particularly important among the diseases of later life, each, in certain aspects, being evidence of the inevitable wearing out of the human machine. Each is of increasing importance as a cause of death, largely because of the considerable control that has been acquired over the diseases of early life.

Here, however, the similarity ends. Degenerative diseases of the heart are accepted almost as a badge of merit. They are considered to be the penalty of industrious application to one's duty and the discharging of a personal debt to society, with interest. Like ulcer, they represent a wound stripe of modern civilization. Cancer, ominous and mysterious, inspires a terror that the conception of heart disease seems to lack. It still implies a portentous degree of finality, as if the knell were already struck, the tolling of the bell begun.

The reasons for these differences in viewpoint are obvious. Heart disease warns of its encroachment on the patient's health, and good behavior may postpone indefinitely the final accounting. The idea of a fighting chance for the prolongation of life, with reasonable activity and comfort, is almost always present. Cancer, on the other hand, is a fifth column that may have infiltrated beyond hope of eradication before it is discovered. The medical profession itself, with the label of "malignancy" that it has applied to cancer, has helped to emphasize the horror associated with it.

No enemy can be hopefully opposed that is allowed to entrench itself in the shadows. Implicit in the campaign against cancer is the bringing of it into the open. The lesson must be reaffirmed that cancer is a disease that can be combated and frequently conquered if early diagnosis is permitted. Many new agents both of diagnosis and of treatment are being brought to bear against it. Reticence is one of its most powerful allies.

The *Reader's Digest* for November, 1948, contains an article by a newspaper editor, entitled "I Have Cancer." The point of this courageous story, by one whose condition was apparently discovered too late for successful treatment, is that "the paralyzing hush hush that surrounds cancer" must be dispelled. In the interest of early diagnosis with its increased

the renal lesion, for what that is worth. She had a severe lower-nephron nephrosis, with pigment casts in many of the distal tubules and the usual degenerative changes in the ascending limbs of Henle's loops, the interstitial inflammation and thrombi of the large renal veins, which are all characteristic of this lesion. Beyond that we are in the realm of pure speculation. We found a fibrinous pericarditis. Microscopically, there was an extensive, focal myocarditis and also interstitial pneumonitis. There were a few granulomatous lesions in the portal areas of the liver. A complete surprise, since there was nothing to suggest a blood dyscrasia, was the presence of many foci of hematopoiesis in the spleen. The bone marrow was very hyperplastic in both red-cell and white-cell series. There was acute arteritis and phlebitis in a small tab of mesenteric fat in one of the epiploic appendices, but no other vascular lesions elsewhere in the body. The joints were normal, as were the heart valves. None of the lesions in the heart were characteristic of Aschoff bodies or other stigmas of rheumatic fever. We found nothing to substantiate a diagnosis of rheumatic fever, rheumatoid arthritis, lupus erythematosus or periarteritis nodosa. This type of case makes one think very seriously of the possibility of some of the rare infections — histoplasmosis or toxoplasmosis — but a number of us in the laboratory have searched the sections repeatedly and are unable to find any organisms of such character.

I am also unable to explain the development of the lower-nephron nephrosis in this case. I agree with

Dr. Kranes that the history strongly suggests that the patient had renal disease before she had sulfonamides, and I do not believe we can attribute the lesion to sulfonamide therapy. The possibility that the lesion develops following the sensitization to other drugs has been raised on a few occasions. I have seen a case in which it was attributed to streptomycin, though on flimsy evidence. I have never heard of it following aspirin, which is the only drug mentioned in the immediate past history.

DR. BAUER: In retrospect, I wish we had never given sulfonamides because the sequence of events that ensued following the administration of the sulfonamides was perhaps coincidental but, nevertheless, very impressive. Would you agree to that, Dr. Ropes?

DR. ROPES: Yes, it was very impressive.

DR. BAUER: If I had to do it again, I would never have employed sulfonamides. The patient's brother was a physician, her sister was a teacher and very intelligent, and on more than one occasion we tried hard to get a history from them of the previous taking of sulfonamides but could not. Whether that rules out sulfonamide sensitivity, I do not know.

DR. JACOB LERMAN: It seems to me that it is easy to get sensitivity to sulfonamides by the use of ointments and nose drops that almost every doctor gives in his practice every day.

DR. MALLORY: Yes, there was one case that, as far as we could make out, was sensitized by a sulfonamide chewing gum.

In the interest of early diagnosis with its increased

opportunity for cure, for the sake of encouraging the patient with cancer to lead as normal a life as possible, the disease must be accepted simply as another of the hazards that encompass life, and that man is slowly conquering

POTASSIUM IODIDE AND STREPTOMYCIN FOR TUBERCULOSIS

Most of the clinical experience with the streptomycin treatment of pulmonary tuberculosis has indicated that this antibiotic is effective against the acute exudative lesions and that little or no benefit may be expected in the chronic fibroid or fibrocaseous types of pulmonary lesions, in which the antibiotic may not have adequate access to the organism. In an attempt to create experimentally a more favorable opportunity for streptomycin to act on such lesions Woody and Avery¹ have utilized the well known clinical observation that the administration of iodides causes tubercle bacilli to appear in the sputum of patients with pulmonary tuberculosis in whom the organisms were previously absent.

The rationale for their experiments is based upon the observations of Jobling and Petersen² that iodides may act on the tuberculous lesion in two ways: it may combine with the unsaturated fatty acids of the tubercle bacilli and neutralize their ferment-inhibiting properties, the enzymatic action that then occurs within the areas of caseation liberates the bacilli from these foci. In addition, the iodides facilitate the solution and absorption of the caseous material, thus exposing the bacilli that might otherwise be inaccessible to the agents.

After determining that potassium iodide has no effect on the antibiotic properties of streptomycin, Woody and Avery set up controlled experiments in guinea pigs to determine whether potassium iodide in combination with streptomycin would be more effective than streptomycin alone against a virulent tuberculous infection. The early results seem to justify their expectation. In their first experiment, treatment was started three weeks after infection, and all animals were killed seven weeks after infection. The control animals and those receiving only potassium iodide all showed heavy tuberculous in-

fection, some of the animals treated with streptomycin alone demonstrated a spread of infection to the organs during treatment while the organs of the animals treated with the combination of potassium iodide and streptomycin were entirely free of infection on gross examination. In a second experiment in which animals were observed for fifteen weeks after infection, all the control animals died, 6 of 13 streptomycin-treated animals died, whereas only 2 of 14 given streptomycin and potassium iodide died.

These results seemed impressive enough to stimulate clinical trials of this type of therapy, which are now in progress. It should be borne in mind, however, that the treatment is not without some risk. If potassium iodide causes a breakdown of the tuberculous lesion and if streptomycin treatment results in the rapid appearance of streptomycin-resistant organisms, as is usually the case, one defense of the body has been eliminated. In some of the patients in whom the resistant organisms appear, the lesions may then be expected to progress more rapidly after this treatment, and streptomycin may then be without effect and potentially harmful.

"HONOUR A PHYSICIAN"

A SPECIAL convocation was held on Sunday afternoon, January 23, at Hobart and William Smith Colleges to mark the one hundredth anniversary of the graduation from Geneva (now Hobart) College of Elizabeth Blackwell, the first woman to receive a degree in medicine. Ten leading women physicians from the United States and Canada and one each from England and France were cited by Dr. Alan W. Brown, president of the Geneva Colleges, in the name of Elizabeth Blackwell, the response was by Dr. Priscilla White, of Boston.

New England received its share of the honors of the day, for of the ten American and Canadian physicians selected by the deans of the medical schools of the two countries, four are natives of New England.

Dr Martha May Eliot, associate chief of the United States Children's Bureau, is also the first woman to have been president of the American Public Health Association. A native of Dorchester, Massachusetts, she graduated from Johns Hopkins University School of Medicine in 1918.

Dr Alice H. Hamilton, of Hadlyme, Connecticut, professor emeritus of Industrial Medicine at Harvard, was the first woman to be a member of the Harvard faculty. A graduate of the University of Michigan Medical School in 1893, she was cited for her contributions to industrial toxicology.

Dr Helen B. Taussig, born in Cambridge, Massachusetts, received her degree in medicine at Johns Hopkins University School of Medicine, where she is now associate professor of pediatrics. She is the winner of many awards for her work with Dr Alfred Blalock in studying and developing operative techniques for the correction of congenital cardiac defects.

Dr Priscilla White, a graduate in 1923 of Tufts College Medical School, is a clinical teacher at that school, a practicing physician in Boston and a member of the staff of the New England Deaconess Hospital. She is, in the words of Dr Brown, "known throughout the land for her research in the field of diabetes with special reference to diabetic children and mothers. Representing here today the women doctors of the world, we are proud to cite her for her own service to medicine and medical research."

The *Journal* takes pride also in honoring these four women, and with them their illustrious colleagues. Dr Florence R. Sabin, of Denver, Colorado, Dr Gerty T. Cori, of Webster Groves, Missouri, Dr Helen V. McLean, of Chicago, Illinois, Dr Margaret D. Craighill, of Topeka, Kansas, Dr Helen MacMurchy, of Toronto, Canada, Dr Elise S. L'Esperance, of New York, Dr Helen M. Mackay of London, England, and Dr Thérèse Bertrand Fontaine, of Paris, France.

TRANSCUTANEOUS JET PROPULSION

THOSE Americans have invented a new gadget, described first by Hingson and Hughes¹ in 1947, employed by Hirsh and his co-workers² in 1948 and commented on not unfavorably, although with cau-

tion, in a recent issue of the *British Medical Journal*.³ It consists of a machine that can propel, painlessly and at a speed perhaps only slightly faster than sound a therapeutic or immunizing substance into, through and beyond the apparently unbroken epidermis.

The damvankees, long considered technical masters of the subject, have discovered a new way of getting under people's skin.

The Microjet or Hypospray is based on the principle that a fine, high-pressure jet can pierce the skin, with little if any pain. In its practical application, the material to be injected is placed in a metal ampule (or Metapule) with a capacity of 0.25 cc. The Metapule, shaped like a blunt-nosed bullet, has an orifice 0.003 inches in diameter in the rounded tip. The butt end is stoppered with a rubber plug, the Metapule is locked into the front end of the machine, and, when all is ready, a high-tension spring attached to a plunger is released by pressure on a button.

When this occurs "The plunger explodes against this rubber stopper which forces the material out of the Metapule and through the skin as a fine spray. The material is deposited subcutaneously and intramuscularly to depths varying from 0.2 to 2 cm depending on the tension of the spring and the site of injection." The jet exerts a pressure of 2300 to 3500 pounds per square inch on the skin, "which has no alternative but to let it through."

Hingson and Hughes find that blood concentrations of penicillin obtained with the Hypospray are higher and more prolonged than when needle and syringe are used, probably because parts of the solution are deposited subcutaneously as well as intramuscularly.

The warning is issued that a frontal attack must be made against the taut skin. If the skin is wet or the nose of the ampule is not in close contact with it or is tilted, the injection produces a cut or a blister.

This instrument is said to eliminate the fear incident to injection by needle and syringe.

opportunity for cure, for the sake of encouraging the patient with cancer to lead as normal a life as possible, the disease must be accepted simply as another of the hazards that encompass life, and that man is slowly conquering

POTASSIUM IODIDE AND STREPTOMYCIN FOR TUBERCULOSIS

Most of the clinical experience with the streptomycin treatment of pulmonary tuberculosis has indicated that this antibiotic is effective against the acute exudative lesions and that little or no benefit may be expected in the chronic fibroid or fibrocaseous types of pulmonary lesions, in which the antibiotic may not have adequate access to the organism. In an attempt to create experimentally a more favorable opportunity for streptomycin to act on such lesions Woody and Avery¹ have utilized the well known clinical observation that the administration of iodides causes tubercle bacilli to appear in the sputum of patients with pulmonary tuberculosis in whom the organisms were previously absent.

The rationale for their experiments is based upon the observations of Jobling and Petersen² that iodides may act on the tuberculous lesion in two ways: it may combine with the unsaturated fatty acids of the tubercle bacilli and neutralize their ferment-inhibiting properties, the enzymatic action that then occurs within the areas of caseation liberates the bacilli from these foci. In addition, the iodides facilitate the solution and absorption of the caseous material, thus exposing the bacilli that might otherwise be inaccessible to the agents.

After determining that potassium iodide has no effect on the antibiotic properties of streptomycin, Woody and Avery set up controlled experiments in guinea pigs to determine whether potassium iodide in combination with streptomycin would be more effective than streptomycin alone against a virulent tuberculous infection. The early results seem to justify their expectation. In their first experiment, treatment was started three weeks after infection, and all animals were killed seven weeks after infection. The control animals and those receiving only potassium iodide all showed heavy tuberculous in-

fection, some of the animals treated with streptomycin alone demonstrated a spread of infection to the organs during treatment while the organs of the animals treated with the combination of potassium iodide and streptomycin were entirely free of infection on gross examination. In a second experiment in which animals were observed for fifteen weeks after infection, all the control animals died, 6 of 13 streptomycin-treated animals died, whereas only 2 of 14 given streptomycin and potassium iodide died.

These results seemed impressive enough to stimulate clinical trials of this type of therapy, which are now in progress. It should be borne in mind, however, that the treatment is not without some risk. If potassium iodide causes a breakdown of the tuberculous lesion and if streptomycin treatment results in the rapid appearance of streptomycin-resistant organisms, as is usually the case, one defense of the body has been eliminated. In some of the patients in whom the resistant organisms appear, the lesions may then be expected to progress more rapidly after this treatment, and streptomycin may then be without effect and potentially harmful.

"HONOUR A PHYSICIAN"

A SPECIAL convocation was held on Sunday afternoon, January 23, at Hobart and William Smith Colleges to mark the one hundredth anniversary of the graduation from Geneva (now Hobart) College of Elizabeth Blackwell, the first woman to receive a degree in medicine. Ten leading women physicians from the United States and Canada and one each from England and France were cited by Dr. Alan W. Brown, president of the Geneva Colleges, in the name of Elizabeth Blackwell, the response was by Dr. Priscilla White, of Boston.

New England received its share of the honors of the day, for of the ten American and Canadian physicians selected by the deans of the medical schools of the two countries, four are natives of New England.

SIGNIFICANT FIGURES

To the Editor It should be of interest to all the readers of the *Journal*, including the proponents of compulsory health insurance, to know about the recent results of a poll taken of the members of the Worcester District Medical Society. The results of this poll, incidentally, were printed in the *Secretary's Letter* (of the American Medical Association), No 99, March 14, 1949.

In response to the poll in which they were asked to answer whether they were in favor of or opposed to compulsory health insurance as proposed by Senate Bill S 5, 75 per cent of the members took the time to answer—a remarkable number of returns, particularly when doctors are concerned. Ninety-seven per cent were opposed to compulsory health insurance, and only three per cent were in favor of it. Out of 330 returns, 313 were opposed, 11 were in favor and 6 was undecided.

This should be the answer for those who use the word "many" with no facts or figures to back it up. When the minority groups make a statement that many doctors favor Government medicine, they should be shown that when transposed into percentages, 3 per cent looks a lot less than the word many.

N S SCARCELLO, Chairman
Public Relations Committee
Worcester District Medical Society

Worcester, Massachusetts

REGARDING GROUP PRACTICE

To the Editor The title of the fine editorial in support of Senator Chapman's Local Public Health Units Act of 1949 (S 522), which appeared in the February 24 issue of the *Journal*, caught my eye because of my interest in still "another bulwark against socialized medicine"—that is, prepaid group practice.

In 1947 Hunt and Goldstein, in the *New England Journal of Medicine* (237 71-77 and 719-731, 1947) and in the *Journal of the American Medical Association* (135-904-909, 1947, and 136 857-861, 1948), reviewed the services, organization, administration and professional opinion of 368 group-practice plans. Eight of the 368 were in New England, and 2 were in Massachusetts. None of the 8 were on a prepaid basis.

In May, 1948, the representatives of the American Medical Association at the National Health Assembly in Washington agreed "that voluntary prepayment group health plans offer to their members the best of modern medical care" and that "the people have the right to establish voluntary insurance plans on a co-operative basis." The more recent twelve-point program, as pointed out in the *Journal of the American Medical Association* (139 529, 1949), implies accession to these principles.

At the Massachusetts Health Conference held last month in Boston, the panel on medical-care costs and methods reaffirmed the advantages of group-practice prepayment plans, and encouraged their use, as noted in the editorial entitled "Massachusetts Five-Year Plan" in the March 10 issue of the *New England Journal of Medicine*. However, debate was largely between the proponents of the two extreme points of view—that is, improved coverage within the *status quo* and national health insurance. Consequently, the acknowledged best compromise measure yet proposed received little attention.

The response of communities that have been in urgent need of improved medical care and have also been afforded friendly and encouraging legislation and professional co-operation confirms the practical applicability of such plans. Since Texas passed its Rural Co-operative Health Plan bill in 1945, 50 consumer-sponsored medical-plan charters have been granted and 17 hospital clinics have been established. In Wisconsin enabling legislation enacted July, 1947, has been followed by at least 5 co-operative plans and a co-operative hospital opened in Wild Rose, Wisconsin, little more than a year later.

The American Medical Association argues that a broad federal health program at present is premature in the face of the lack of sound experience and experimentation. It has voiced its readiness to accept the types of medical service plans that, although voluntary, can afford the experience needed to provide better medical care at a minimum cost to

medically marginal communities. Those communities may be either sparsely settled areas or of marginal income populations. In either case, given the opportunity, many communities are ready and eager to experiment in this field of medical economics.

An American Medical Association questionnaire of doctors in the armed services indicated that 54 per cent preferred group practice. All, of course, had been experiencing a sort of prepaid group practice while in the service. It seems reasonable that these two groups, doctors and consumer patients, might with encouragement from national and local medical associations get together on a mutually satisfactory basis.

Therefore, it is to be hoped that some of the progressive steps outlined in the twelve-point program will be furthered by the active support of organized medicine in the removal of restrictive legislation and its positive encouragement of participation by doctors in voluntary medical-care plans of all types compatible with high standards of medical science and ethics.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

An Index of Treatment By various writers Edited by Sir Robert Hutchison, Bt., M.D., LL.D., F.R.C.P., consulting physician London Hospital and Hospital for Sick Children, Great Ormond Street. Assisted by Reginald Hilton, M.A., M.D., F.R.C.P., physician to St. Thomas's Hospital, consulting physician, Epsom Hospital, and consulting physician and cardiologist, Wembley Hospital. Thirteenth edition, revised 4th, cloth, 972 pp., with 99 illustrations. Baltimore: Williams and Wilkins Company, 1948. \$17.00.

This treatise was first published in 1907, and this edition has been thoroughly revised, and the subject matter brought up to date. The text is the joint work of seventy-four contributors. The material is arranged alphabetically, and there is a supplemental comprehensive index of sixty pages. The type and paper are good, and a light paper is used to advantage in such a large volume. The number of editions speaks well for the soundness of the work, and it should prove valuable to the practicing physician and is recommended for all medical libraries as a standard reference work.

Urology for Nurses By Oswald S Lowsley, M.D., director, Department of Urology (James Buchanan Brady Foundation), New York Hospital, consulting urologist, St. Clare's Hospital and Hospital for the Ruptured and Crippled, New York City, Monmouth Memorial Hospital, Long Branch, New Jersey, Englewood Hospital, Englewood, New Jersey, St. Luke's Hospital, Newburgh, New York, St. Agnes Hospital, White Plains, New York, and Norwalk Hospital, Norwalk, Connecticut, and Thomas J. Kirwin, M.D., attending surgeon, Department of Urology (James Buchanan Brady Foundation), New York Hospital, visiting genitourinary surgeon, New York City Hospital, consulting urologist, Conec Island Hospital, Monmouth Memorial Hospital, Long Branch, New Jersey, Benedictine Hospital, Kingston, New York, and St. Vincent's Hospital, Montclair, New Jersey. Second edition. 8^{vo}, cloth, 637 pp., with 130 illustrations by William P. Didmsch. Philadelphia: J. B. Lippincott Company, 1948. \$6.00.

The authors have revised this second edition of their manual for nurses, first published in 1936, to bring it up to date. Some chapters have been completely rewritten, and cystoscopy and radiography have been brought together in one chapter. Many illustrations have been added. A glossary of urologic terms and a good index conclude the text. The book is well published and should prove useful as a compendium of the subject.

MASSACHUSETTS MEDICAL SOCIETY POSTGRADUATE LECTURE COURSE

The April 25 session of the Postgraduate Lecture Course will be held in the New Lecture Hall, Cambridge, instead of at Sanders Theater

The New Lecture Hall is located across Kirkland Street from Sanders Theater, at the corner of Kirkland and Oxford streets

A M.A. ASSESSMENT

The following letter will, I am sure, interest many fellows of the Society

H. Quimby Gallupe, M.D.
8 Fenway
Boston 15, Massachusetts

Dear Dr. Gallupe

Enclosed is my check for special assessment.

I am impressed with the sincerity and efforts of the Society officers to meet the issues squarely. I also feel that the critical efforts through the town meetings of doctors has been effective in guiding the efforts that reached Chicago through our local organization.

From here on it is up to the younger members of the American Medical Association to attend the district meetings and see that constructive proposals are carried upward through our organization.

Sincerely yours,

EARLE M. CHAPMAN, M.D.

H. QUIMBY GALLUPE, *Secretary*

DEATHS

BAILEY — Florence Bailey, M.D., of Lawrence, died on December 24. She was in her seventy-second year.

Dr. Bailey received her degree from College of Physicians and Surgeons, Boston, in 1903.

CRITTENDEN — Samuel W. Crittenden, M.D., of Wakefield, died on March 27. He was in his ninety-third year.

Dr. Crittenden received his degree from Dartmouth Medical School in 1898. He was a member of the New England Society of Psychiatry.

His widow survives.

HUGHES — John Hughes, M.D., of Pittsfield, died on February 12. He was in his sixty-seventh year.

Dr. Hughes received his degree from University of Vermont College of Medicine in 1905. He was associate medical examiner of Berkshire District and was a member of the staffs of St. Luke's and Pittsfield General hospitals. He was a former councilor of the Massachusetts Medical Society.

His widow, two daughters, five grandchildren and his mother survive.

WARREN — Hobart E. Warren, M.D., of Palm Beach, Florida, died on March 17. He was in his eighty-first year.

Dr. Warren received his degree from Harvard Medical School in 1894. He was a former member of the Massachusetts Medical Society and a fellow of the American Medical Association.

His widow and a daughter survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS

The May schedule for Consultation Clinics for Crippled Children in Massachusetts under the provisions of the Social Security Act follows

CLINIC	DATE	CONSULTANT
Salem	May 2	Paul W. Hugenberger
Haverhill	May 4	William T. Green
Lowell	May 6	Albert H. Brewster
Greenfield	May 9	Charles L. Sturdevant
Gardner	May 10	Carter R. Rowe
Brockton	May 12	George W. Van Gorder
Springfield	May 17	Garry deN. Hough, Jr.
Pittsfield	May 18	Frank A. Slowick
Worcester	May 20	John W. O'Meara
Fall River	May 23	David S. Grice
Hyannis	May 26	Paul L. Norton

Physicians referring new patients to clinics should get in touch with the district health officer to make appointments. Patients are seen by appointment only.

MISCELLANY

INFANT MORTALITY, 1947

The infant mortality rate in 1947 was the lowest recorded in the United States, according to a release from the National Office of Vital Statistics of the Public Health Service, Federal Security Agency. The rate in that year fell from the 1946 figure of 33.8 infant deaths per thousand live births, to 32.2. It was expected that the decline would continue to a rate of 31.8 in 1948.

The five leading causes of infant deaths in 1947 and the rates for each are: premature birth, 11.1; congenital malformation, 4.6; pneumonia and influenza, 3.6; birth injury, 3.5; and asphyxia and atelectasis, 1.6.

CORRESPONDENCE

MORE ON THE CARE OF THE PATIENT

To the Editor: I fully agree with Dr. Henry F. Howe's letter, "The Care of the Sick" in the March 10 issue of the *Journal*. I should, however, like to add a word of advice, and it is this: every medical graduate should have, besides an internship, an externship. Every physician, when he first starts out to practice for himself, knows the clumsy and embarrassing situations he frequently finds himself in. He lacks bedside manners, he does not have the proper approach toward either the patient or his immediate family. He is unable to advise on home nursing care — (as an intern he seldom, if ever, had to make such decisions). The general practitioner, not infrequently, has to use his resourcefulness in improvising gadgets that the intern has no need for. No lectures, books or films can make one adept in doing things, and only by actually doing things can one learn to do them well. To solve these as well as many more unforeseen problems that arise, I suggest that every young physician, after completing his internship, should be apprenticed for a year to a busy country general practitioner. The actual practical experience thus obtained would benefit not only the patient, but much more so the physician beginner. He would acquire the skill in diagnosing correctly the largest number of his cases without having to resort to the so-called instruments of precision (most of them are not) and would thus save precious time. In a word, he would develop the self-confidence that goes to make a good physician.

TREATMENT OF MENTAL ILLNESS AT HOME BY SMALL DOSES OF INSULIN

A Follow-up Report and Appraisal of Results in Twenty-Six Cases

NEWMAN COHEN, M D *

BOSTON

THE belief that treatment of mental illness requires a hospital setting is no longer uniformly accepted. The extramural approach has been strengthened substantially by an increasing number of favorable reports.

Electroshock therapy, formerly used only in hospitalized patients, has been used successfully in ambulatory patients.¹⁻⁶ Today it is possible, in many cases, to administer this type of treatment outside the hospital, thus obviating loss of time and any stigma connected with hospitalization in a mental institution. However, such a procedure is recommended only in carefully selected cases and with adequate safeguards.

Insulin-coma therapy as a potent therapeutic agent in schizophrenia has been recognized.⁷⁻⁸ This treatment is drastic, however, and usually requires a hospital setting for proper administration.

There is a large group of patients who do not require hospitalization and whose mental condition lends itself to insulin sub-shock treatment carried out in the patient's home. Personal results with this latter form of therapy have been reported in a previous presentation,⁹ which contained short-term data in 12 cases treated with this method. The treatment has subsequently been continued, and the number of cases now totals 26. The purpose of this paper is to present a follow-up report of the previous cases and our clinical observations on the cases subsequently treated by insulin sub-shock in the home.

The use of modified insulin-coma therapy as a method of management in mental disorders was long overshadowed by the more drastic therapies and received scant attention and application.

The first reference to the therapeutic use of mild hypoglycemic shock was that of Cowe.¹⁰ In a previous paper,⁹ the important pertinent literature was summarized. There have been other workers who have directed attention to the value of sub-coma insulin.¹¹⁻¹⁵ In an evaluation of the "shock" therapies in 1945 Bennett¹⁶ mentioned the value of sub-coma doses of insulin as a method of sedation, to control

the patient's anxiety and excitement and to permit a better psychotherapeutic approach. Rennie²⁰ carried out the insulin sub-shock method of treatment on a group of 28 heterogeneous patients and described striking results with marked clinical improvement in 19 cases. Dramatic relief was achieved with insulin in excitement whenever anxiety prevailed. Rennie found that insulin sedation was superior to sedation by ordinary chemical methods. Insulin therapy permitted a marked degree of relaxation, enabled the patients to discuss their pre-occupations and provided a real opportunity to utilize psychotherapy.

Kalinowsky and Hoch²¹ observed that patients with anxiety states were more amenable to psychotherapy when treated with sub-coma doses of insulin. Disturbances in the autonomic nervous system quieted down under insulin, the patient had a better appetite, slept better and gained in weight.

Beneficial results with sub-coma insulin have been reported in the treatment of acute alcoholism.²²⁻²³

Hohman and Kline²⁴ used insulin sub-coma on 37 patients with anxiety states, depression and psychosomatic disturbances. The results indicated that this method of therapy was valuable, effective and safe in a variety of anxiety states, particularly those arising in the military service in men with combat experiences. Almost all the patients treated showed some degree of improvement, and many of the responses were dramatic.

Kelley and Thompson²⁵ also described favorable results in a report in 5000 patients treated by the method described by Sargant and Slater.²⁶

Sullivan,²⁷ summarizing his experiences in 393 cases (324 psychoses and 69 psychoneuroses), concluded that intensive sub-shock therapy was of value in all relatively acute psychoses with schizophrenic symptoms. Rapid clinical improvement was achieved in the psychoneurotic patients. These studies indicated that all patients with psychoneurotic states of the severe anxiety-tension type, all psychoses with schizophrenic symptoms, psychoses with feelings of depression and psychoses of mixed type

* Psychiatric consultant, Rehabilitation Board, Veterans Administration physician. Out Patient Department, Boston State Hospital.

Principles Governing Eye Operating Room Procedures By Emma I. Clevenger, R.N., supervisor, eye operating room, New York Eye and Ear Infirmary, New York City 8^o, cloth, 215 pp, illustrated St. Louis C. V. Mosby Company, 1948 \$5.50

This manual outlines the procedures for the operating room of an eye hospital. It discusses the care and handling of instruments and equipment, sutures, dressings, rubber gloves, linens and drugs. A large part of the book is devoted to a description of setups for various eye operations. It is based on experience gained in the New York Eye and Ear Infirmary. The books should prove useful to eye surgeons and hospital libraries.

"Elective Alimentary Rest" and the Elimination of So-called "Paralytic Ileus" after Abdominal Operations By V. J. Kinsella, M.B., Ch.M. (Sydney), F.R.C.S. 8^o, paper, 35 pp, with illustrations Sydney, Australia Australasian Medical Publishing Company, Limited, 1948 3 shillings

This pamphlet brings together a number of papers originally published in periodicals by the author. The author describes his postoperative plan, especially in cases of appendicitis, in which no solids or solid-forming liquids are given for six days after the operation. A diet for the six days is given, consisting of liquids, except milk, and soft foods. Aperients, enemas, hypodermic injections for retention of urine and drugs, such as pituitrin and eserine, are not permitted. The author claims excellent results for his treatment based on 344 cases of acute appendicitis treated during a period of twelve years.

General Endocrinology By C. Donnell Turner, Ph.D., associate professor of zoology, Northwestern University 8^o, cloth, 604 pp, with 163 illustrations Philadelphia W. B. Saunders Company, 1948 \$6.75

This textbook is designed for beginning students who are concentrating on experimental biology and is based on the lectures given at Northwestern University. The subject is approached from the experimental rather than the clinical point of view. The material is well organized and bibliographies are appended to the various chapters. A good index concludes the volume. The publishing is excellent. The book is recommended for all medical libraries and to all students interested in the subject.

NOTICES

ANNOUNCEMENT

Dr. George P. Sanborn announces that he has resumed the practice of medicine at Hotel Eliot, 370 Commonwealth Avenue, Boston.

HAMPDEN DISTRICT MEDICAL SOCIETY

The annual meeting of the Hampden District Medical Society will be held at the Longmeadow Country Club, Tuesday, April 26, and not at the Highland Hotel as formerly announced.

Cocktails will be served at 6:00 p.m.

The speaker of the evening will be Dr. Douglas T. Davidson whose subject will be "Convulsive Disorders."

94TH INFANTRY DIVISION LECTURES

The 94th (Bay State) Infantry Division is sponsoring a series of monthly lectures by prominent physicians in their respective specialties. The third lecture will be held in Room 720, United States Post Office and Court House, Post Office Square, Boston, on Wednesday, April 27, at 8 p.m.

Dr. Morton Brown will speak on the subject "Physiologic Approach to Congestive Heart Failure."

All interested physicians, whether reserve officers or not, are cordially invited to attend this carefully planned program. Reserve officers will be given one point credit. Excellent films will also be shown during this period.

NEW ENGLAND HEART ASSOCIATION

The annual Henry Jackson Lecture, under the auspices of the New England Heart Association, will be given by Dr. Harold G. Wolff, professor of medicine and associate professor of psychiatry, Cornell University Medical College, and attending physician, New York Hospital, at the Boston Medical Library, 8 Fenway, Boston, on Monday, May 9, at 8:15 p.m. His subject will be "Life Stress and Cardiovascular Disorders."

A short business meeting will precede the lecture. Interested physicians and medical students are invited to attend.

AMERICAN PSYCHIATRIC ASSOCIATION

The one hundred and fifth annual meeting of the American Psychiatric Association will be held at the Windsor Hotel, Montreal, Quebec, May 23-27.

The question of the reorganization of the Association, which has been under consideration for several years, will come up for further discussion at this meeting, and an unusually large attendance is expected.

TREATMENT OF MENTAL ILLNESS AT HOME BY SMALL DOSES OF INSULIN

A Follow-up Report and Appraisal of Results in Twenty-Six Cases

NEWMAN COHEN, M.D.*

BOSTON

THE belief that treatment of mental illness requires a hospital setting is no longer uniformly accepted. The extramural approach has been strengthened substantially by an increasing number of favorable reports.

Electroshock therapy, formerly used only in hospitalized patients, has been used successfully in ambulatory patients.¹⁻⁶ Today it is possible, in many cases, to administer this type of treatment outside the hospital, thus obviating loss of time and any stigma connected with hospitalization in a mental institution. However, such a procedure is recommended only in carefully selected cases and with adequate safeguards.

Insulin-coma therapy as a potent therapeutic agent in schizophrenia has been recognized.⁷⁻⁹ This treatment is drastic, however, and usually requires a hospital setting for proper administration.

There is a large group of patients who do not require hospitalization and whose mental condition lends itself to insulin sub-shock treatment carried out in the patient's home. Personal results with this latter form of therapy have been reported in a previous presentation,⁹ which contained short-term data in 12 cases treated with this method. The treatment has subsequently been continued, and the number of cases now totals 26. The purpose of this paper is to present a follow-up report of the previous cases and our clinical observations on the cases subsequently treated by insulin sub-shock in the home.

The use of modified insulin-coma therapy as a method of management in mental disorders was long overshadowed by the more drastic therapies and received scant attention and application.

The first reference to the therapeutic use of mild hypoglycemic shock was that of Cowe.¹⁰ In a previous paper,⁹ the important pertinent literature was summarized. There have been other workers who have directed attention to the value of sub-coma insulin.¹¹⁻¹⁵ In an evaluation of the "shock" therapies in 1945 Bennett¹⁶ mentioned the value of sub-coma doses of insulin as a method of sedation, to control

the patient's anxiety and excitement and to permit a better psychotherapeutic approach. Rennie²⁰ carried out the insulin sub-shock method of treatment on a group of 28 heterogeneous patients and described striking results with marked clinical improvement in 19 cases. Dramatic relief was achieved with insulin in excitement whenever anxiety prevailed. Rennie found that insulin sedation was superior to sedation by ordinary chemical methods. Insulin therapy permitted a marked degree of relaxation, enabled the patients to discuss their pre-occupations and provided a real opportunity to utilize psychotherapy.

Kalinowsky and Hoch²¹ observed that patients with anxiety states were more amenable to psychotherapy when treated with sub-coma doses of insulin. Disturbances in the autonomic nervous system quieted down under insulin, the patient had a better appetite, slept better and gained in weight.

Beneficial results with sub-coma insulin have been reported in the treatment of acute alcoholism.²²⁻²³

Hohman and Kline²⁴ used insulin sub-coma on 37 patients with anxiety states, depression and psychosomatic disturbances. The results indicated that this method of therapy was valuable, effective and safe in a variety of anxiety states, particularly those arising in the military service in men with combat experiences. Almost all the patients treated showed some degree of improvement, and many of the responses were dramatic.

Kelley and Thompson²⁵ also described favorable results in a report in 5000 patients treated by the method described by Sargant and Slater.²⁶

Sullivan,²⁷ summarizing his experiences in 393 cases (324 psychoses and 69 psychoneuroses), concluded that intensive sub-shock therapy was of value in all relatively acute psychoses with schizophrenic symptoms. Rapid clinical improvement was achieved in the psychoneurotic patients. These studies indicated that all patients with psychoneurotic states of the severe anxiety-tension type, all psychoses with schizophrenic symptoms, psychoses with feelings of depression and psychoses of mixed type

* Psychiatric consultant, Rehabilitation Board, Veterans Administration Physician, Out Patient Department, Boston State Hospital.

should receive intensive insulin sub-shock therapy. Noyes²⁸ and Smith and Branch²⁹ agree in essence with this view and point out that sub-coma doses of insulin are useful as a means of sedation to control anxiety, to improve physical health and to make a more favorable psychotherapeutic approach possible.

Psychotherapy has generally been employed as a routine procedure in conjunction with sub-coma insulin therapy for its important value in consolidating the clinical gains and maintaining improvement. A number of published reports have described the effective use of combinations of therapies. Among these is the work of Gottesfeld and Novaes,¹⁵ who described gain in weight in 2 cases of anorexia nervosa treated with sub-shock insulin and narcoanalysis.

Stratton et al.¹⁷ reported 60 consecutive cases in which the treatment featured psychotherapy as facilitated by combined sub-coma insulin and pentothal narcosis. The results were as follows: good recovery in 63 per cent, fair in 23 per cent, mild in 10 per cent and poor in 3 per cent.

In 1944 Weil and Moriarty¹³ explored the therapeutic possibilities of a course of insulin treatment in a group of 20 patients with schizophrenic reaction types who had responded poorly to electroshock treatment alone. Insulin was administered either according to Sakel's method or with sub-coma doses. Fifty per cent of these patients responded promptly to insulin. (Sub-shock doses of insulin produced satisfactory results in 4 of the present series of cases.) In 4 patients the authors tried a second course of electric shock after a rest period, with disappointing results.

In a more recent study Polatin and Spotnitz³⁰ attempted to determine whether rapid clinical improvement achieved with electroconvulsive therapy in schizophrenia could be maintained or enhanced by supplementary sub-coma insulin treatment. Thirty female patients with schizophrenia were treated with this procedure over a period ranging from ten to forty-two weeks. Improvement was noted in 80 per cent of the patients treated by this method over a period of thirteen weeks. It was generally found that best results were achieved if insulin treatment was employed after the sixth electric shock. After the sixth electroconvulsion, the two therapies were administered concurrently, electroshock treatment being given three times weekly. The authors believed that this method combined the rapid beneficial effects of electroshocks with the slowly cumulative favorable effects of mild daily hypoglycemic shocks.

Sullivan²⁷ utilized the combined therapeutic approach but reversed the procedure. A group of patients with hebephrenic schizophrenia, manic states and atypical depressive states with elements of schizophrenia who failed to benefit from insulin therapy were subsequently given a course of electro-

shock treatments. The patients with manic states responded fairly well to subsequent electroshock. According to the author this method increases the over-all rate of improvement and remission to 90 per cent in patients with psychoses who do not respond satisfactorily to intensive insulin sub-shock therapy. He found that when electroshock was administered before insulin therapy, the patients who showed symptoms of depression and schizophrenia usually lost the symptoms of depression but retained those of schizophrenia. Since the schizophrenic symptoms are considered more malignant, the importance of relieving these symptoms as soon as possible was pointed out, any remaining significant degree of depression could be treated with electroshock.

MANAGEMENT AND TECHNIC

The treatment^{20, 21, 24, 27, 30} should be carried out by a physician who has had training in neuropsychiatry as well as the shock technics. The initial handling of the patient's fears is frequently a project in itself, and psychotherapy is utilized in helping him accept the treatment. The attitude of the patient does not materially lessen the effectiveness of insulin sub-shock therapy, but lack of co-operation tends to create an awkward situation and is a definite drawback should subsequent psychotherapy be required. The physician should obtain the written consent of the patient's family before proceeding with the treatment.

Each patient to be treated is given a preliminary physical survey. This includes a general physical and neurologic examination, a roentgenologic study of the chest and an electrocardiogram. In addition to a carefully taken history and examination of the mental status, a urinalysis and blood chemical studies are done prior to treatment. Contraindications include metabolic disturbances, acute and chronic liver and kidney disease, active pulmonary tuberculosis and myocardial damage. Age alone should not be a reason for withholding this form of therapy. As a rule, a patient in relatively good health is suitable for treatment, since the physical risks with the sub-coma insulin method are usually minimal. In view of the possibility of complications, the physician must be in attendance and must observe the patient closely during the entire period of active treatment. Moreover, the physician should be easy of access for the remainder of the day in the event that the hypoglycemic state returns.

The possibility of hypersensitivity to insulin should not be overlooked. The occurrence of erythema, edema, pruritus, urticaria, tachycardia, nausea and vomiting has been described in persons treated with insulin. Insulin sub-shock as a method of management has been relatively free of complications, although such untoward insulin effects as convulsions were described in 35 out of 332 cases.

by Sullivan,²⁷ who reported a fatal case in a twenty-two-year-old soldier in excellent physical condition, who had been acutely psychotic for about three months. On the fifth day of treatment he suddenly went into full shock about twenty minutes after receiving a dose of 60 units. He died three days later without regaining consciousness.²⁷ Deaths resulting from the use of small doses of insulin were also described in sub-shock treatment of a case of schizophrenia and in tonic treatment of a case of delirium tremens.³¹ The clinical and patho-anatomic features in these two cases were identical with those observed in fatal complications of ordinary insulin shock therapy.

Insulin sub-coma is similar to the first phase of insulin shock treatment. The basic principle of this method is to inject insulin and after a variable period to terminate the hypoglycemic state by the administration of glucose and food. Efforts are directed toward stabilizing the dose of insulin and avoiding the occurrence of actual hypoglycemic coma. The site of the injection should be changed frequently to avoid local tissue irritation and necrosis. The patient, having fasted for from four to twelve hours, is given insulin by deep intramuscular injection of 5 to 15 units. The dose of insulin may be increased by about 10 units daily until mild hypoglycemic shock, manifested by lassitude, increased perspiration, hunger, thirst and somnolence, is produced. The dosage is then kept at a minimal level and shock reactions are avoided by feeding. The amount of insulin required to produce a state of hypoglycemia varies with the individual patient. Usually 50 to 100 units of insulin is sufficient to cause appearance of the desired hypoglycemic manifestations in about an hour. The patient is kept in a state of hypoglycemia for periods ranging from thirty to ninety minutes, and the reaction is then terminated by the administration of sugared fruit juice followed by a meal rich in carbohydrates. If treatment has to be interrupted early, the dosage should be decreased on the following day by 5 to 10 units. Weakness and clamminess after treatment generally indicate incomplete termination. In the mild hypoglycemic state the patient is usually able to take sugared fruit juice orally. Fluids should not be forced if the patient has difficulty in swallowing. Interruption of the hypoglycemia on such occasions is best carried out by the intravenous injection of 20 cc of a sterile 33.3 per cent glucose solution. This is usually effective in arousing the patient to the point where he will be able to drink.

After termination of treatment the clothing should be changed because of the increased perspiration that has occurred, and chilling of the patient is avoided. Most patients are routinely encouraged to exercise a few hours after treatment. They are routinely instructed to carry candy bars for use at the first sign of hypoglycemic symptoms. They are also encouraged to eat as much food as possible during the

remainder of the day. Insulin treatment is carried out six times a week with one day's rest. Duration of treatment is determined by therapeutic progress. As a rule, acute states require less time than chronic ones. Generally, treatment is indicated as long as the patient continues to show improvement. Patients should be observed for one month after completion of therapy, which should be resumed at once in the event of relapse.

THERAPEUTIC RESULTS

This report describes a group of 26 heterogeneous cases treated over a three-year period and includes several patients with schizophrenia of many years' standing who showed the usual clinical features of withdrawal, apathy, projection and negativism. Because of the prominent role that insulin occupies in mental disorders and because of the growing recognition of the possibilities of sub-coma insulin treatment, it is believed that some of the clinical observations and data merit attention. Sufficient time has elapsed for the over-all results in the original series of 12 cases to be more accurately appraised, and the increased number of cases treated with the ambulatory method permits more valid deductions concerning the applicability and effectiveness of this management. By and large, the progress of both groups of patients treated has been encouraging and gratifying.

Table 1 contains follow-up summaries of the cases previously reported in which insulin sub-shock treatment was given at home from January, 1945, to February, 1946. Table 2 presents a summary of data and short-term follow-up information of a group of patients subsequently treated during 1946 and 1947. A few of the patients have had follow-up examinations for periods up to two years.

The results in the 26 cases were as follows: all but 1 of the patients treated showed definite clinical improvement of varying degrees. In Group I, 7 out of 12 patients made complete recoveries and have remained well. One patient recovered and subsequently relapsed to a moderate degree. She has remained in a much improved state after a short course of electroshock therapy. This patient refused the full course of treatment, since she felt entirely well and preferred to spend the summer at the beach. One patient, who relapsed fourteen months after termination of treatment, was subsequently treated by narcoanalysis and electric shock and has continued to maintain a much improved state. Two patients who improved moderately discontinued treatment prematurely, but have maintained their clinical gains. One patient was much improved, and his clinical improvement has continued to date.

In Group II, 10 out of 14 patients made complete recoveries. One patient, a schizophrenic of many years' standing in whom an organic brain defect was suspected, made a slight clinical improvement, but subsequently relapsed and regressed. One patient

should receive intensive insulin sub-shock therapy Noyes²⁸ and Smith and Branch²⁹ agree in essence with this view and point out that sub-coma doses of insulin are useful as a means of sedation to control anxiety, to improve physical health and to make a more favorable psychotherapeutic approach possible

Psychotherapy has generally been employed as a routine procedure in conjunction with sub-coma insulin therapy for its important value in consolidating the clinical gains and maintaining improvement. A number of published reports have described the effective use of combinations of therapies. Among these is the work of Gottesfeld and Novaes,¹⁵ who described gain in weight in 2 cases of anorexia nervosa treated with sub-shock insulin and narcoanalysis

Stratton et al¹⁷ reported 60 consecutive cases in which the treatment featured psychotherapy as facilitated by combined sub-coma insulin and pentothal narcosis. The results were as follows: good recovery in 63 per cent, fair in 23 per cent, mild in 10 per cent and poor in 3 per cent

In 1944 Weil and Moriarty¹³ explored the therapeutic possibilities of a course of insulin treatment in a group of 20 patients with schizophrenic reaction types who had responded poorly to electroshock treatment alone. Insulin was administered either according to Sakel's method or with sub-coma doses. Fifty per cent of these patients responded promptly to insulin. (Sub-shock doses of insulin produced satisfactory results in 4 of the present series of cases.) In 4 patients the authors tried a second course of electric shock after a rest period, with disappointing results

In a more recent study Polatin and Spotnitz³⁰ attempted to determine whether rapid clinical improvement achieved with electroconvulsive therapy in schizophrenia could be maintained or enhanced by supplementary sub-coma insulin treatment. Thirty female patients with schizophrenia were treated with this procedure over a period ranging from ten to forty-two weeks. Improvement was noted in 80 per cent of the patients treated by this method over a period of thirteen weeks. It was generally found that best results were achieved if insulin treatment was employed after the sixth electric shock. After the sixth electroconvulsion, the two therapies were administered concurrently, electroshock treatment being given three times weekly. The authors believed that this method combined the rapid beneficial effects of electroshocks with the slowly cumulative favorable effects of mild daily hypoglycemic shocks

Sullivan²⁷ utilized the combined therapeutic approach but reversed the procedure. A group of patients with hebephrenic schizophrenia, manic states and atypical depressive states with elements of schizophrenia who failed to benefit from insulin therapy were subsequently given a course of electro-

shock treatments. The patients with manic states responded fairly well to subsequent electroshock. According to the author this method increases the over-all rate of improvement and remission to 90 per cent in patients with psychoses who do not respond satisfactorily to intensive insulin sub-shock therapy. He found that when electroshock was administered before insulin therapy, the patients who showed symptoms of depression and schizophrenia usually lost the symptoms of depression but retained those of schizophrenia. Since the schizophrenic symptoms are considered more malignant, the importance of relieving these symptoms as soon as possible was pointed out, any remaining significant degree of depression could be treated with electroshock

MANAGEMENT AND TECHNIC

The treatment^{20 21 24 27 30} should be carried out by a physician who has had training in neuropsychiatry as well as the shock technics. The initial handling of the patient's fears is frequently a project in itself, and psychotherapy is utilized in helping him accept the treatment. The attitude of the patient does not materially lessen the effectiveness of insulin sub-shock therapy, but lack of co-operation tends to create an awkward situation and is a definite drawback should subsequent psychotherapy be required. The physician should obtain the written consent of the patient's family before proceeding with the treatment

Each patient to be treated is given a preliminary physical survey. This includes a general physical and neurologic examination, a roentgenologic study of the chest and an electrocardiogram. In addition to a carefully taken history and examination of the mental status, a urinalysis and blood chemical studies are done prior to treatment. Contraindications include metabolic disturbances, acute and chronic liver and kidney disease, active pulmonary tuberculosis and myocardial damage. Age alone should not be a reason for withholding this form of therapy. As a rule, a patient in relatively good health is suitable for treatment, since the physical risks with the sub-coma insulin method are usually minimal. In view of the possibility of complications, the physician must be in attendance and must observe the patient closely during the entire period of active treatment. Moreover, the physician should be easy of access for the remainder of the day in the event that the hypoglycemic state returns

The possibility of hypersensitivity to insulin should not be overlooked. The occurrence of erythema, edema, pruritus, urticaria, tachycardia, nausea and vomiting has been described in persons treated with insulin. Insulin sub-shock as a method of management has been relatively free of complications, although such untoward insulin effects as convulsions were described in 35 out of 332 cases

excess and was domineering, selfish, abusive and assaultive. Thwarted in her attempt at separation or relief and faced with continued marital discord and stress, the patient sank into a deep depression marked by thoughts of suicide.

At a hospital a course of electroshock treatment brought partial relief for 5 months, but in September, 1946, the patient relapsed. Various forms of medical management as well as psychotherapy proved ineffective. Examination revealed a brow-beaten, preoccupied, depressed, resentful and discour-

been more harmonious, irritation and frustration have been minimal, and she has remained well for 20 months after termination of treatment.

CASE 14 A 48-year-old single man had shown mental symptoms for 10 years prior to hospitalization in September, 1939. While at the hospital he had been dull, disinterested and emotionally blunted. As time went on he continued to be evasive, suspicious and paranoid in his trends. Although he

*Cases reported in text.

aged woman. Her symptoms included anxiety, tension, insomnia, crying spells and many somatic complaints.

Insulin sub-shock therapy was begun in the patient's home in December, 1946. After 5 weeks of treatment there was a general remission of symptoms. The treatment was continued for 19 weeks, the maximum dose of insulin being 150 units. The patient became more accessible to psychotherapy. Her depression lifted, fear, anxiety and tension abated, and a happier and more satisfactory domestic relationship was effected.

She resumed her social activities and derived considerable pleasure and satisfaction out of life. The home situation has

denied hallucinations, there was evidence that he reacted to them at intervals. In 1944 family placement in the community was tried but he had to be returned because of poor adjustment. A full course of insulin and metrazol shock treatments brought partial improvement, but he soon relapsed into his former self-absorbed, seclusive state. He constantly refused to occupy himself in any way and, his appetite having been exceptionally good, he tended to be rather obese. A diagnosis of schizophrenia, paranoid type, was made but there had been considerable deterioration intellectually and emotionally during the rather prolonged course of his mental illness. He was not considered suitable

showed much clinical improvement, but progress was hampered by situational factors. Despite premature interruption of treatment, the clinical gains have been sustained. In 2 other cases, treatment was insufficient, and the clinical improvement was ultimately followed by relapse.

Of the 26 patients treated, 17 were restored to their pre-morbid state and were entirely free of any

In most cases insulin sub-shock therapy produced remarkable improvement in physical condition. The patients frequently gained weight rapidly and developed a feeling of well-being. Another attractive feature of the treatment was that they became more amenable to psychotherapy. Abnormal states marked by fear, doubt, inhibition and misconceptions were often relieved. The rapidity with which

manifest residual symptoms at follow-up examinations conducted at periods ranging from eleven months to three years and four months after completion of treatment. Premature interruption of treatment appeared to influence the clinical results in 6 cases. Two patients relapsed but subsequently improved with electroshock therapy. Only 2 patients relapsed and regressed.

symptoms of anxiety and tension diminished was often striking.

CASE REPORTS

In the interest of brevity only 5 illustrative cases are reported. They include 4 recoveries and 1 failure.

CASE 13. A 40-year-old married woman first developed symptoms of depression in May, 1944. Her husband drank to

Insulin sub-shock therapy is a less drastic procedure than insulin shock and in all probability produces no irreversible brain damage (Patients given as many as a hundred or more sub-coma treatments showed no evidence of mental deterioration)

Patients are spared the atmosphere of a hospital, with its locked doors and barred windows

The treatment is relatively economical, because therapy is administered at home and hospitalization is not necessary

Complications occur less frequently than with the more drastic forms of therapy^{27 31}

The treatment is not incapacitating, and the patient is usually able to be up and about promptly. This has two important advantages over other methods: the patient is more amenable to psychotherapy, and he is alert and able to join in activities immediately

Insulin sub-coma greatly relieves anxiety and tension and is often a better sedative than barbiturates^{9 24 27}. The effects are more incisive and lasting than those with chemical sedation,²⁰ which often increases anxiety rather than relieves it. An additional drawback to the use of chemical sedation, especially barbiturates, is the danger of intoxication

Insulin sub-shock treatment improves the patient's physical condition

Another reason favoring ambulatory treatment is advanced by Impastato et al.³ "Since the ambulatory patient gets well while at home, there is no need for subsequent home readjustment [which] must be achieved by the hospital patient at the end of treatment"

Supplementary treatment in the event of a relapse is often not feasible after the patient has left the hospital. In the ambulatory method there is usually no difficulty in maintaining post-treatment supervision, promptly resuming treatment or in administering occasional subsequent treatment

DISADVANTAGES

In general, the disadvantages of the ambulatory method of management are outweighed by its social and various other advantages

A natural disadvantage is the time factor, several hours of the physician's attention usually being required.⁹ There has been a tendency on the part of some therapists toward impatience with slower methods of treatment, and a preference for more rapid and less demanding procedures

The disadvantages of ambulatory treatment described by Fetterman³ are readily applicable to the method of therapy discussed above. They include the following

Increased responsibility on the part of the family — the patient may require help in eating

and guidance in activity. Those entrusted with the patient's safety must carry out such responsibilities zealously

The initial improvement may prompt the desire for premature discontinuance of treatment — a contingency that can usually be handled quite adequately in hospital treatment

The hazard of suicide is of paramount importance and may present a serious problem to home management of the patient. In cases in which the urge to self-destruction is overwhelming, or in which the patient's welfare or that of society is endangered, he should be hospitalized. The suicide hazard in ambulatory treatment can be minimized by careful selection of patients, by early treatment and by constant vigilance on the part of the family

Home treatment is hazardous and probably contraindicated if there is a clash of personalities in the home situation or if there is lack of understanding of the clinical problems

SUMMARY

Twenty-six patients treated with the insulin sub-coma method at home are described. Daily treatments were administered for periods ranging from two to eight months. All but 1 of the patients showed definite clinical improvement of varying degrees. Seventeen patients were restored to their pre-morbid state and were free of residual symptoms

Sub-coma insulin therapy is a relatively safe procedure and can be administered at home

The advantages and disadvantages of this type of therapy, the technic of administration and the necessary precautions to safeguard the patient are outlined

Several case histories are presented

In view of the favorable results achieved and the many advantages offered, further use of sub-coma insulin therapy in the patient's home appears justified

I am indebted to Dr. Herbert I. Harris, chief neuropsychiatrist, Veterans Administration Branch Office No. 1, Boston; Dr. Walter E. Barton, superintendent, Boston State Hospital; and Dr. Fred L. Landrigan, medical consultant, Rehabilitation Board, Veterans Administration, Boston, for their kind assistance in reviewing this manuscript. I am especially indebted to Dr. Milton Greenblatt, of the Boston Psychopathic Hospital, for helpful suggestions and advice in the preparation of the manuscript.

for leukotomy because of the absence of depression, anxiety and agitation

Through the efforts of his family, his release from the hospital was obtained. Despite the rather gloomy prognosis, insulin sub-shock treatment was undertaken at home in deference to the wishes of his family.

Daily treatment with sub-coma doses of insulin was begun on September 13, 1946. The clinical response was almost immediate. The patient became more spontaneous, rational and co-operative. His outlook became more objective, and his emotional response more adequate, and after 3 weeks of treatment he managed to work part time as a truck-driver's helper.

However, memory impairment, which had been quite pronounced, failed to improve, and an organic process was suspected. An x-ray film of the skull taken on October 22 was normal. An electroencephalogram was obtained on October 24, with findings consistent with organic brain damage.

Toward the end of November it was noted that he failed to make further improvement and had begun to regress. Carelessness in his personal habits, shallow affective responses and obsessive-compulsive features became prominent, and interest in work waned. The patient had received 11 weeks of treatment with no significant clinical change, the maximum dose of insulin being 90 units. Treatment was discontinued, and he returned to the hospital.

At follow-up examination 2 years later, he had regressed further. He displayed a marked memory defect, lack of interest, apathy and seclusiveness.

CASE 15 A 25-year-old overprotected single woman with a history of several frustrating experiences suffered additional bitter disappointment when rejected by her fiancé on his return from overseas duty. Overwhelmed by this series of psychic traumas, she succumbed to a schizophrenic psychosis marked by depression, paranoid trends, emotional instability, preoccupation and withdrawal.

Electroshock treatment at a hospital brought temporary relief for 3 months, but in September, 1946, the patient relapsed. Despite attempts at medical management and psychotherapy, little headway was made. She gradually became more depressed, withdrawn and paranoid in her trends. Her family refused permission for electroshock therapy and frowned upon further hospitalization.

Insulin sub-coma treatment was begun at home in December. The first short period of improvement was noted in 3 weeks. Thereafter, intervals of well-being became more prolonged, and symptoms continued to diminish progressively. Psychotherapy was employed advantageously with the patient, who previously had not been readily accessible to such a procedure. These psychotherapeutic sessions proved of value in hastening the disappearance of abnormal functioning and in restoring insight. After 9 weeks of treatment she had gained 14 pounds in weight. The maximum dose of insulin was 110 units. She gradually became more objective, contented and stable and was considered recovered.

She relapsed mildly a month later, and treatment was immediately resumed and weighted in the direction of psychotherapy for a 10-week period. Improvement continued steadily until complete recovery.

This patient subsequently remained entirely well. She has continued in a state of recovery for 13 months since completion of treatment and during the greater part of that time has been gainfully employed as a dressmaker. She continues to be personable, ambitious and objective. In an interview recently with her family, the remark was made, "She has never been so well in her life."

CASE 16 A 29-year-old woman, the product of a broken home, was emotionally labile, basically dependent and intellectually inadequate. Her husband, a laborer and of different faith, had an essentially similar personality profile. His overprotective mother was a constant source of friction in the household. As a result of the patient's basic shyness, limited educational and cultural background, she was unable to compete with others, and her social contacts were restricted. A childless marriage helped to make her life drab. There was marked disproportionate sex drive between husband and wife, and when future months left them childless, the patient began to blame herself and experienced feelings of guilt over past sexual indiscretions. Her history had been negative for preceding significant illnesses.

She began to have frequent crying spells, was intensely preoccupied and unable to sleep and began to mutter in a compulsive manner at frequent intervals, "I give my soul to the devil." Anxiety gradually increased, she suffered from anorexia, vomiting and frequent compulsive urges to run to the bathroom. She finally sank into a severe depression. Various types of medical management proved ineffective. The case was not suitable for psychotherapy. Her family refused to sanction hospitalization or electroshock therapy.

Insulin sub-shock therapy was begun at home 9 months after the onset of the illness. She was treated daily for 18 weeks. Her anxiety diminished after 3 weeks of treatment, and the symptoms began to abate. She gained considerable weight and became more cheerful, self-reliant and less preoccupied with feelings of guilt. She continued to improve, the obsessive-compulsive tendencies gradually disappeared, and the depression lifted completely. Even though her disorder was not suitable for psychotherapy, she improved steadily until complete recovery 18 weeks after the institution of treatment.

She subsequently remained somewhat timid, but her ability to mingle socially with others improved and she gradually developed new interests and lived more harmoniously with her husband. On follow-up examination 18 months later, she was entirely well and contented. Social and marital adjustment had continued to be satisfactory.

CASE 17 A 40-year-old Italian married man with an extremely unstable heredity and background, and with a history since 1942 of two separate psychotic episodes lasting approximately 8 weeks each, suffered an acute turmoil reaction in 1945.

A course of electroshock therapy and subsequent various forms of medical management brought some palliation, but in May, 1946, he succumbed to a fourth attack characterized by excitement, agitation, refusal of food and personal neglect and undue preoccupation with religion and the abstract, together with a compelling desire to become a crusader and reformer. Hallucinations and delusions were prominent. Aggressive behavior increased to ominous proportions. Hospitalization was not permitted largely because two of his brothers had already been hospitalized in a mental institution.

Insulin sub-shock therapy was begun at home at once. The clinical response was dramatic, and in approximately 2 weeks the excitement had subsided.

Gradually, there was a reduction and finally disappearance of confusion, hallucinations, paranoid ideas and feelings of unreality. Despite the rather recent psychotic manifestations, the patient was soon able to return to work. Anxiety disappeared completely even though he was unable to profit from psychotherapy. The treatment proved especially effective in controlling excitement and in checking hallucinations and delusions.

Improvement with further treatment was steadily progressive, and there was gradual abatement of all symptoms until complete recovery 20 weeks after the institution of treatment. Except for a mild, brief relapse, treated by a few additional episodes of sub-coma, he has remained well for the 25-month follow-up period.

ADVANTAGES

Ambulatory insulin sub-coma is considered a preferred therapeutic measure in psychiatric disorders. The treatment has proved of value in a variety of mental conditions and in many cases that have been refractory to other methods of management. Some of the advantages over the more drastic forms of therapy were described in a previous article.⁹ These advantages as well as several others have a practical bearing and deserve emphasis. They include the following:

The treatment can be administered at home and thus obviates the stigma (in the mind of the patient and his relatives) of hospitalization.

Comparison of the Digitalis and Nondigitalis Groups

Type and dosage of digitalis At the time of appearance of bigeminy whole-leaf digitalis was being administered orally in 45 cases and digitoxin in 3. In 2 cases a mixture of digitalis glycosides (digalen) was given intramuscularly. The amount of digitalis given and the length of time during which the patient had received the medication before the appearance of bigeminy varied considerably. In most cases bigeminy appeared when the maintenance dose was increased, even in such small amounts as 0.05 to 0.1 gm. In 4 cases a profuse diuresis induced by parenteral administration of mercurial diuretics resulted in bigeminal rhythm without an increase in the maintenance dose of digitalis. In another case the same phenomenon was observed after a massive gastrointestinal hemorrhage.

Age and sex The average age of the patients in the digitalis group was 53.9 years, whereas in the

group, and auricular and sinus nodal extrasystolic bigeminy were almost as common (Table 4).

The features of the ventricular extrasystolic bigeminy in the two groups are shown in Table 5.

TABLE 2 *Etiologic Types of Heart Disease in Patients with Digitalis and Nondigitalis Bigeminy*

DIGITALIS BIGEMINY*

An Analysis of Fifty Cases

ELLIOT L SAGALL, M D,† AND LOUIS WOLFF, M D‡

BOSTON

BIGEMINAL rhythm following the administration of digitalis is frequently encountered and is generally accepted as a sign of digitalis intoxication. The characteristics of this type of coupled rhythm, however, are not clearly defined, and there is little in the literature concerning the subject. The present investigation was undertaken in an attempt to elucidate the features of digitalis bigeminy that might be of practical clinical value.

METHODS

The patients studied were limited to those in whom paroxysmal or constant ventricular bigeminy was demonstrated electrocardiographically. Of the electrocardiograms taken from 1929 to 1948 at the Beth Israel Hospital, Boston, 183 separate cases of bigeminy in 174 patients were satisfactory for the purposes of this study. The classification of electrocardiographic bigeminal rhythms presented by Parsonnet et al¹ was employed.

The clinical records, progress notes and medication charts were examined in each case to evaluate the role of digitalis in the production of the arrhythmia. In 82 cases, referred to below as the nondigitalis or control group, digitalis had not been administered prior to the appearance of bigeminy. In 101

cases digitalis bodies had been administered during the month preceding the appearance of bigeminal rhythm. Digitalis was considered to be a definite causal factor in 50 of these because bigeminy appeared for the first time shortly after a large initial dose, after increase in the maintenance dose, or after a profuse diuresis without change in the maintenance dose. In these cases, referred to below as the digitalis group, confirmatory evidence of this relation was afforded by the disappearance of the arrhythmia with omission or reduction in the dosage of the drug, or by the presence of other symptoms or signs of digitalis intoxication. In a few cases, after reversion to normal rhythm, bigeminy was again induced by an increased dose of digitalis. The relation between digitalis and bigeminy in the remaining 51 cases could not be established or excluded, and these cases were classified as indeterminate.

RESULTS

In 172 cases bigeminy resulted from extrasystolic contractions occurring after each normal beat. The premature beats arose in the ventricles in 107 cases, in the auricles in 42, in the sinus node in 19, and in the auriculoventricular node in 4. In the remaining cases coupling was due to a shifting auriculoventricular block in 7, sinus pauses in 1, and fortuitous pairing of ventricular beats in auricular fibrillation in 3.

DIGITALIS BIGEMINY*

An Analysis of Fifty Cases

ELLIOT L SAGALL, M D,† AND LOUIS WOLFF, M D ‡

BOSTON

BIGEMINAL rhythm following the administration of digitalis is frequently encountered and is generally accepted as a sign of digitalis intoxication. The characteristics of this type of coupled rhythm, however, are not clearly defined, and there is little in the literature concerning the subject. The present investigation was undertaken in an attempt to elucidate the features of digitalis bigeminy that might be of practical clinical value.

METHODS

The patients studied were limited to those in whom paroxysmal or constant ventricular bigeminy was demonstrated electrocardiographically. Of the electrocardiograms taken from 1929 to 1948 at the Beth Israel Hospital, Boston, 183 separate cases of bigeminy in 174 patients were satisfactory for the purposes of this study. The classification of electrocardiographic bigeminal rhythms presented by Parsonnet et al¹ was employed.

The clinical records, progress notes and medication charts were examined in each case to evaluate the role of digitalis in the production of the arrhythmia. In 82 cases, referred to below as the nondigitalis or control group, digitalis had not been administered prior to the appearance of bigeminy. In 101

cases digitalis bodies had been administered during the month preceding the appearance of bigeminal rhythm. Digitalis was considered to be a definite causal factor in 50 of these because bigeminy appeared for the first time shortly after a large initial dose, after increase in the maintenance dose, or after a profuse diuresis without change in the maintenance dose. In these cases, referred to below as the digitalis group, confirmatory evidence of this relation was afforded by the disappearance of the arrhythmia with omission or reduction in the dosage of the drug, or by the presence of other symptoms or signs of digitalis intoxication. In a few cases, after reversion to normal rhythm, bigeminy was again induced by an increased dose of digitalis. The relation between digitalis and bigeminy in the remaining 51 cases could not be established or excluded, and these cases were classified as indeterminate.

RESULTS

In 172 cases bigeminy resulted from extrasystolic contractions occurring after each normal beat. The premature beats arose in the ventricles in 107 cases, in the auricles in 42, in the sinus node in 19, and in the auriculoventricular node in 4. In the remaining cases coupling was due to a shifting auriculoventricular block in 7, sinus pauses in 1, and fortuitous pairing of ventricular beats in auricular fibrillation in 3.

disease, but more often complicated rheumatic heart disease and auricular fibrillation. Although there was marked individual variation in the amount of drug administered prior to the development of the arrhythmia, bigeminy in the majority of cases was a sensitive manifestation of toxicity, appearing for the first time after a small increase in the maintenance dose.

The electrocardiographic features of digitalis bigeminy, as a rule, differed from those in the group that was unrelated to digitalis. Digitalis bigeminy was almost always due to ventricular extrasystoles, and the ventricular premature beats were more likely to be multifocal in origin and to arise in the right ventricle, in no case did they originate from the basal portion of the ventricles. Rare cases of coupled rhythm arising from other causes were also recorded in the digitalis group. One case of coupling due to shifting auriculoventricular block was similar to that described by Lutembacher.⁷ In addition 1 case each of bigeminy due to sinoauricular block and to auricular and auriculoventricular nodal premature beats were encountered.

In many of our cases bigeminal rhythm was the only evidence of digitalis intoxication. The appearance of an arrhythmia as the first sign of digitalis poisoning has also been noted by Marvin,⁸ who reported 5 cases of ventricular tachycardia following excessive dosage of digitalis. Similarly, Grishman and Dack,⁹ in a recent study of 50 cases of digitalis toxicity, observed that various arrhythmias were often the only clinical manifestation of overdosage. There was no definite relation between the appearance of digitalis bigeminy and other manifestations of toxicity. The arrhythmia preceded, followed or developed simultaneously with the other signs and symptoms.

The seriousness of digitalis bigeminy is difficult to evaluate. White¹⁰ has stated that the appearance of bigeminal rhythm "indicates that a considerable percentage of a lethal dose has been given, probably close to 75 per cent." The possibility that further administration of digitalis to a patient who has developed coupling will lead to serious or fatal poisoning is apparent. Bigeminy, therefore, is a danger signal that cannot be ignored. In some or all of the 14 fatal cases in our series death may have been due to digitalis, since all patients had received large amounts of the drug.

The conditions that must be present in the myocardium for the production of bigeminy are unknown. Although bigeminy occurs in the absence of heart disease, clinical observations indicate that digitalis bigeminy occurs only in the presence of a diseased myocardium. This thesis is further substantiated by animal experiments and observations on the effect of large doses of digitalis in people with normal hearts. In the intact mammalian heart in situ irregular extrasystoles occur only in the last stages of digitalis poisoning, and bigeminy is never

produced.¹¹ The subendocardial hemorrhages and necroses induced in animal hearts by large amounts of digitalis,¹²⁻¹³ therefore, apparently do not increase the susceptibility to bigeminy. In human subjects with normal hearts who have ingested large amounts of digitalis bodies in suicidal attempts, repeated electrocardiograms have revealed a variety of serious arrhythmias and only rare extrasystoles, but no bigeminy.^{5, 14-16} Digitalis was administered to 100 persons without heart disease by Wolff,¹⁷ and although repeated electrocardiograms revealed definite changes in the ST segments, T waves and PR intervals, only two ventricular premature beats were noted in 300 electrocardiograms. In the recent New York insurance fraud large doses of digitalis were ingested by a number of persons in an attempt to simulate heart disease, and in this group only occasional ventricular extrasystoles were detected and bigeminy was not reported.¹⁸

SUMMARY AND CONCLUSIONS

One hundred and eighty-three cases of bigeminy were studied in regard to the etiologic relation between digitalis and the coupled rhythm. Bigeminy was associated with digitalis in 50 cases and unrelated to digitalis in 82. In 51 the relation was indeterminate.

Bigeminal rhythm is common in patients with or without organic heart disease who have not received digitalis, and in 39 per cent is ventricular extrasystolic in mechanism.

Bigeminal rhythm may be induced in patients with organic heart disease by digitalis and is almost always due to ventricular extrasystoles.

The ventricular extrasystolic bigeminy associated with digitalis differs from that unrelated to digitalis in that the ventricular premature beats are more commonly multifocal and arise in the right ventricle. In nondigitalis bigeminy ectopic contractions arise more frequently in the left or basal portions of the ventricles.

Digitalis bigeminy occurs in all types of heart disease and with a variety of basic rhythms, but more often complicates rheumatic heart disease and auricular fibrillation.

Bigeminy may be induced by purified digitalis derivatives as well as the whole-leaf product.

Digitalis bigeminy is a sensitive manifestation of toxicity and may appear with a small increase in the maintenance dose.

Bigeminy may be the only evidence of digitalis intoxication and may precede, follow or develop simultaneously with other manifestations of toxicity.

Bigeminy may be a serious sign of digitalis toxicity and in some cases may herald sudden death.

Other manifestations of digitalis toxicity The relation between the appearance of bigeminy and other signs and symptoms of digitalis intoxication was inconsistent. In some cases bigeminy was the first or only manifestation of digitalis overdosage, in others it developed concomitantly with or followed the appearance of anorexia, nausea, vomiting or visual disturbances. In 7 cases digitalis overdosage produced paroxysmal arrhythmias in addition to bigeminy. The abnormal rhythms were ventricular tachycardia in 4 (2 with bidirectional complexes), auricular flutter in 1, auricular fibrillation in 1, and both paroxysmal auricular fibrillation and auriculo-ventricular nodal tachycardia in 1. In 6 of these cases bigeminy was recorded after cessation of the

Edens and Huber³ recorded 29 cases of digitalis bigeminy, but in only 6 were electrocardiograms taken. In 27 the bigeminal rhythm was due to ventricular extrasystoles as determined by jugular-pulse tracings, and in the remaining 2 the mechanism was indeterminate. Congestive heart failure was present in all, and 13 patients had auricular fibrillation. These authors concluded that digitalis bigeminy occurred only in hypertrophied hearts that manifested decreased muscular efficiency. Because 23 patients died within two years of the appearance of bigeminy digitalis coupling was considered to indicate a poor prognosis.

Gold and Otto⁴ reported the cases of 45 patients with digitalis bigeminy. All had organic heart disease, the etiologic type being arteriosclerotic in 8, rheumatic in 16, syphilitic in 4, not specified in 2 and unknown in 15. The basic cardiac rhythm was auricular fibrillation in 35 and normal sinus rhythm in 10. In the latter group 8 patients later developed auricular fibrillation. In all cases bigeminy was due to ventricular premature beats. In contrast to Edens and Huber,³ the authors believed that susceptibility to digitalis bigeminy did not indicate a grave prognosis beyond that due to the underlying heart disease and the functional capacity of the heart.

In 1926, Gallavardin⁵ presented a clinical discussion of digitalis coupling and summarized the previous French literature. He stated that although others had emphasized the frequency of digitalis bigeminy in patients with enlarged hearts with mitral disease, the arrhythmia could occur in patients with all types of heart disease and with normal sinus rhythm as well as auricular fibrillation. The bigeminy that he encountered was always due to ventricular extrasystoles, which in the majority of cases were polymorphic. He believed that digitalis bigeminy occurred only in the presence of a diseased myocardium, for in his experience the arrhythmia was never induced by digitalis in normal hearts.

Scherf and his co-workers have reported a number of experimental and clinical observations regarding digitalis extrasystoles and bigeminy. Their findings and conclusions have recently been summarized by Scherf and Boyd.⁶ They favor the view that digitalis alone will not produce extrasystoles or bigeminy and that other unknown conditions, which vary considerably from case to case, must be present for the induction of bigeminy by the drug. In their experience the arrhythmia was precipitated by digitalis more easily in patients with severe heart disease, and the extrasystoles in most cases arose from multiple foci.

On the whole, the results of our study are in agreement with the findings discussed above. In our cases bigeminal rhythm was induced by purified digitalis derivatives as well as the whole-leaf product. There was no specific relation to age or sex. It appeared in patients with all types of heart

paroxysmal arrhythmia, in 1 it appeared first, and was followed by paroxysmal tachycardia consequent to the administration of additional amounts of digitalis.

Duration of digitalis bigeminy Although in most cases bigeminy was a temporary phenomenon, in a few cases the bigeminal rhythm, once induced by digitalis, persisted for many days after omission of the drug and in some was apparently permanent. Fourteen patients in the digitalis group died during the period of observation. In 11 cases additional amounts of digitalis had been given despite the presence of bigeminal rhythm, and in 3 bigeminy appeared for the first time on the day of death.

DISCUSSION

Despite its clinical importance and the frequency with which it is encountered digitalis bigeminy has attracted but little attention, especially in the American literature. Most publications concerning digitalis bigeminy antedate 1930, and since then only an occasional reference to the subject has been made. As far as could be determined the only clinical analyses of relatively large series of cases were those of Edens and Huber³ in 1916 and Gold and Otto⁴ in 1926.

ment and not to adhere too strictly to a rigid schedule. Eleven cases were treated over one hundred days. The longest treatment period was one hundred and seventy-five days. Forty patients received streptomycin for forty-two days or less, and in 41 cases the length of treatment varied between fifty and one hundred days. A daily dosage of 0.5 gm divided into two intramuscular injections was used in 37 cases. A dose of 1.0 gm daily was received by 55 patients. In children only half the dose was used — 0.5 and 0.25 gm respectively.

SENSITIVITY

In the more recently treated cases, a dosage of 1.0 gm a day for forty-two days was adopted. Such a treatment schedule conforms with the present views of streptomycin fastness,¹ which is assumed to develop between thirty and sixty days in the majority of cases. In this study no attempt was made to demonstrate fastness by laboratory methods, but clinical observation in some cases of tuberculosis of the kidney bore out the fact that after as early as thirty days any improvement stops and decrease of urinary urgency and frequency ceases. Further administration of streptomycin in such cases was followed by aggravation of clinical symptoms.

SECOND COURSE

Streptomycin fastness is probably the reason why a second course² with streptomycin usually gives disappointing results. Six patients received a second course of streptomycin. None of these cases gave excellent results. In 3 cases good results were obtained, and 3 cases had to be labeled as failures. It is therefore advisable to determine the sensitivity to streptomycin before a second course is undertaken.

RESULTS

In this study 157 lesions were treated. Excellent results were obtained in 50 per cent, and good results in 36 per cent, 14 per cent were failures.

A summary of the results is presented in Table 1.

Recurrence

Recurrence or development of a new lesion during or after a course of streptomycin was seen in 7 cases, or 8 per cent. The impression was gained that the reactivated or newly developed lesion was altered and of less intensity. Two spinal lesions, for instance, diagnosed shortly after the beginning of streptomycin therapy, showed minimal evidence of destruction and soon became inactive.

Sinuses

Best results were achieved in the treatment of sinuses. A total of 48 tuberculous sinuses in 33 patients were treated, 67 per cent were closed in an average of sixty-two days, 33 per cent improved, and in none had failure to be conceded. The sinuses

had drained for an average of nine hundred and fifty-four days before treatment with streptomycin was started. These favorable results cannot be credited entirely to streptomycin since penicillin was frequently given before or simultaneously with streptomycin to combat secondary infection. In addition, a dressing technic comparable to the sterile requirements of surgical wounds was applied to prevent introduction of new pyogenic organisms into the sinuses.

Bones and Joints

Fifty-seven lesions of bones and joints were treated with streptomycin. Excellent results were obtained in 35 per cent, and good results in 47 per cent, and 18 per cent failed to respond to the drug. The evaluation of bone lesions is extremely difficult —

TABLE 1 Results of Streptomycin Therapy in 157 Tuberculous Lesions

Lesion	No of Cases	Excellent Result	Good Result	Failure
		No of Cases	No of Cases	No of Cases
Sinuses	48	32 (67%)	16 (33%)	—

bone changes are slow, and x-ray signs of healing are not immediately apparent. Gain in clarity and distinctness in the x-ray appearance, and repair and arrest of the destructive process could be observed either immediately after termination of treatment or within the next few months. Changes in the soft tissues surrounding the lesion are seen more promptly, as manifested in decrease or disappearance of abscess shadows and joint effusions. As valuable as this acceleration in the healing process may be, the emphasis should be placed upon the fact that streptomycin renders the tuberculous patient operable in a much shorter time than conventional treatment does and that it permits the surgeon to enter diseased tissue with less risk of propagation of the tuberculous process, thus allowing greater freedom in the choice of operation and more radical procedures. Under the protection of streptomycin, radical extirpation of a tuberculous bursa and removal of a sequestered femoral head were carried out and were followed by an uneventful postoperative course not marred by sinus formation or wound breakdown.

Genitourinary Tract

Twenty-three cases of tuberculous kidney were treated. Fifty-two per cent gave excellent results,

STREPTOMYCIN IN THE TREATMENT OF EXTRAPULMONARY TUBERCULOSIS*

Early Results

KURT JELLINEK, M D †

MIDDLEBORO, MASSACHUSETTS

THIS report deals with 92 cases of extrapulmonary tuberculosis treated with streptomycin in various amounts and over different lengths of time. In all cases the lesions were proved to be tuberculous by guinea-pig inoculation or x-ray study or both. No pulmonary activity was found except in 2 cases, in which an incipient pulmonary lesion was readily controlled by streptomycin. In the majority of these cases residua from previous pulmonary infection with tuberculosis could be demonstrated. In every case the intradermal tuberculin reaction was positive. Many of these patients had more than one tuberculous lesion, and 157 active lesions were present. No consideration was given to lesions arrested prior to streptomycin treatment. A tuberculous infection of one or both kidneys with urinary-bladder involvement was regarded as a single entity. A bone sinus originating from a tuberculous arthritis was counted as two separate lesions because of the somewhat different course these lesions might take, the bone sinus might heal promptly, but the tuberculous process in the joint might continue to smolder.

CLASSIFICATION

To obtain a clear-cut picture, the results were graded into excellent, good and failure. The term "excellent" was used in cases that fulfilled the following conditions: no material positive for tuberculosis on guinea-pig inoculation was obtainable, marked improvement in the general condition, cessation of pain, closure of sinuses, disappearance of palpable abscesses and freedom from symptoms were achieved, and subsidence of activity by x-ray

checks, disappearance of abscess shadows and effusions in and at the bones and joints were observed.

"Good" results were claimed when improvement in the general condition was noted, with a decrease of symptoms, such as diminished discharge from sinuses, reduction in the size of lymph-nodes and abscesses, improvement in the x-ray appearance of lesions and partial return of function in paralysis.

The term "failure" is self-explanatory.

By necessity this classification has to be arbitrary. An absolute and clear distinction between the effects of streptomycin and the results of sanatorium care combined with surgical operation could not be undertaken. It might be well to point out now, and again later, that the reported results could only be obtained under sanatorium care. As only one to nine months have elapsed since termination of streptomycin treatment, this report must be regarded as preliminary.

DOSAGE

One of the main difficulties of streptomycin therapy was, and still is, the selection of the proper dosage.^{1, 2} The initial recommendation to give streptomycin for prolonged periods (one hundred and twenty days and more) in high dosage (30 gm and more per day) divided into multiple intramuscular injections was soon abandoned because of the high incidence of untoward reactions. Only 3 cases in this study were treated according to the schedule mentioned above, and even in these cases the daily dose had to be dropped quickly from 30 to 20 gm or less, because of severe dizziness and beginning deafness.

Owing to the existing uncertainty concerning dosage an effort was made to individualize the treat-

* From the Lakeville State Sanatorium.

† Senior physician, Lakeville State Sanatorium.

ECONOMIC ASPECTS

Any treatment that is capable of shortening the exceedingly long course of tuberculosis will have profound effects on the economic, social and psychologic aspects of the disease. In the series of cases cited, the average time from onset of the disease to the beginning of streptomycin treatment was three years, eight months and six days. To salvage patients after such long suffering and to return them to active life after an average treatment period of one year is a significant achievement. The saving in taxpayer's money and the elimination of sources of infection are important considerations.

A most gratifying result is the change in the patients' psychology. The feeling of resigned suffering and doom and the passive acceptance has given way to hope and confidence. The doctor on a tuberculous ward is no longer a dispenser of analgesics and hypnotics, but is able to prescribe and direct active treatment.

CONCLUSION

It can be concluded that streptomycin is a valuable asset in the treatment of extrapulmonary tuberculosis. The first course is usually more effective

than a second course, and proper timing of the first course is therefore important. In surgical cases its use just prior to or shortly after surgery is recommended. A daily dose of 1.0 gm in adults for forty-two days is used at present. Encouraging results were obtained in tuberculosis of the bones and joints with and without draining sinuses, of the genitourinary tract, in paraplegia due to Pott's disease and in lesions of the skin and pharynx. Mild side reactions, if encountered, do not preclude continuation of treatment. More severe reactions, which interfere with the general condition of the patient, should be regarded as indications to terminate streptomycin treatment. Second courses have little, if any, value unless definite sensitivity of the bacilli to streptomycin can be demonstrated. Best results are achieved under a sanatorium type of treatment combined with surgical operation when indicated.

PRACTICAL CONSIDERATIONS OF CLINICAL OXYGEN LACK*

CHARLES S. HOUSTON, M.D.

EXETER, NEW HAMPSHIRE

WHEN confronted with a patient whose problem may in part be due to oxygen lack, the physician often bases his opinion upon the presence or absence of dyspnea and cyanosis, forgetting that these important signs are but two of the many changes due to anoxia. He may not realize that either or both may be present even though oxygenation is adequate, and he may not appreciate that both may be absent even when oxygen lack is severe. In its classic form anoxia may be recognized at a glance, but in other circumstances, not infrequently encountered in practice, the most elaborate laboratory procedures cannot give a definitive evaluation of the adequacy of the oxygen supply to the body. The best that a practitioner can hope to do in this complex situation is to maintain a high index of suspicion for the presence of anoxia in certain pathologic conditions, and to institute therapeutic or prophylactic procedures when certain signs and symptoms of anoxia are first noted. Some of the common conditions that frequently result in anoxia, as well as the more reliable indications of anoxia, are discussed in this paper.

CAUSES OF OXYGEN LACK

It is the relation of oxygen supply to demand, rather than either alone, that determines whether or not tissue anoxia is present. If tissue demand exceeds supply, no matter how great the latter may be, anoxia develops at once, for oxygen cannot be stored. Therefore, conditions that increase the bodily need for oxygen (exertion, fever and hyperthyroidism, for example) cause anoxia unless supply is accordingly increased, just as interference with oxygen supply (high altitude, pulmonary and circulatory disease and so forth) does unless tissue demand is decreased. Very often a disease both decreases supply and increases demand (pneumonia with fever, cardiac failure and exertion), which doubly impairs tissue oxygenation. Most physicians are aware of the seriousness of febrile disease, especially pulmonary disease, in the patient with hyperthyroidism. Discrepancy between supply and demand is further illustrated by the difficulty experienced on exertion by anemic persons, by those with chronic pulmonary disease and by patients with circulatory insufficiency. The high mortality that attends pneumonia in visitors

From the Exeter Clinic.

and 13 per cent good results, and 35 per cent were failures. The result of treatment of tuberculosis of the kidney and bladder had previously been extremely disappointing, and even after removal of the diseased kidney the majority of patients continued to excrete urine containing tubercle bacilli. Patients with bilateral involvement appeared doomed, and early detection during the period of unilateral involvement followed by radical surgery was therefore the only hope. The introduction of streptomycin promises a radical change for the better.

Out of the 15 cases in which nephrectomy was performed and in which the urine remained positive for tuberculosis after operation, 74 per cent were rendered negative, and no reversal of urine took place in only 13 per cent. In the nonoperative group treated with streptomycin the rate of failures ran as high as 75 per cent.

Early diagnosis and radical operation are still imperative, but by the administration of streptomycin shortly before and after nephrectomy the percentage of clinical arrest of the disease is greatly improved. At the same time, the development of postoperative kidney sinuses is in many cases eliminated or early closure of the existing sinuses ensured.

In a comparative study, not yet completed, dealing with postoperative results in tuberculous kidneys before the streptomycin era, urine free of tubercle bacilli was obtained in only 38 per cent of cases.

Fear that a patient with impaired kidney function will tolerate streptomycin poorly is not unfounded, and the incidence of side reactions is slightly higher (38 per cent) than that in cases with unimpaired kidney function. But by the employment of dosages not exceeding 10 gm daily, these side reactions rarely reach serious proportions. A slight rise in the nonprotein nitrogen during the treatment was seen. The greatest increase was 14 mg per 100 cc.

Lupus Vulgaris

The limited experience gained from 2 cases of lupus vulgaris, 1 involving the face and neck and the other involving the mucous membranes of the nose, confirmed other reports,³ that streptomycin causes prompt arrest. The same excellent results were obtained in a pharyngeal lesion.

Tuberculous Lymph Nodes

Of 5 cases of tuberculous adenitis, 2 reacted excellently and 3 showed improvement characterized by diminution of the size of the lymph nodes and closure of existing sinuses. Hard indurated nodes showed slow response.

Tuberculous Peritonitis

Three cases of tuberculous peritonitis were treated, 1 with excellent results, and 2 with marked im-

provement. Abatement of fever, cessation of pain and drying up of ascites were observed. These results were confirmed by x-ray films, which revealed increase in clarity and decreasing density of the abdominal structures. The more acute the disease, the more dramatic the rate of improvement.

Tuberculous Mastoiditis

Satisfactory results were also obtained in 4 cases of mastoiditis. One of these patients responded excellently. Not only was improvement noted in the x-ray appearance of the mastoid bones but also the hearing became more acute, the discharge from the chronically infected ears stopped or diminished, and the patients became free of pain.

Tuberculous Bursitis and Tendosynovitis

Four cases of tuberculous bursitis and tendosynovitis were treated — 2 with excellent results and 2 with good results as evidenced in a decrease of swelling and painless motion.

Paraplegia

Series of 3 or 4 cases have only limited significance and do not show more than a trend. Nevertheless, the results in even a small series of paraplegic cases were regarded as important. Paraplegia during the course of Pott's disease is not an uncommon occurrence. This paraplegia is rarely the result of the spinal deformity, but is caused either by pus formation or by tuberculous granulation tissue pressing against the cord.

Of the 4 patients treated with streptomycin, 2 responded with complete restitution of muscular power and return of normal reflex activity. One patient improved considerably. The fourth, a paraplegic patient of long standing who had not been helped by extensive surgical procedures, did not respond. At present 1 patient is under treatment, and the progress is quite promising.

SIDE EFFECTS

Owing to moderation in dosage, side effects were comparatively mild. Twenty-five per cent of the total cases showed some untoward effects. Vertigo was observed in 15 per cent, skin rash in 6 per cent, and vomiting, nausea and paresthesia of the lips or fingers in 2 per cent each. Only in 6 cases was it necessary to discontinue streptomycin. One of these cases was especially instructive, since the patient had become sensitized by the use of streptomycin ointment. A form of exfoliative dermatitis developed three days after intramuscular use of streptomycin. This dermatitis healed promptly after discontinuation of the drug. None of the side effects observed were permanent, although in some cases, which had received higher dosage, vertigo persisted for months.

alkalosis resulting from hyperventilation causes peripheral vasoconstriction and thereby may cause significant tissue anoxia

From these brief paragraphs it is apparent that cyanosis is often present even though oxygenation is adequate, and that severe anoxia may be present without clinically detectable cyanosis. Furthermore, oxygen lack is only one of the many causes of dyspnea, and sometimes an ineffective one at that.

The mental signs of anoxia may be subtle and easily mistaken for primary neurologic disease. Mental confusion, emotional lability, errors in judgment, inability to concentrate, headache or gross tremors are frequently caused by oxygen lack alone and may be a principal evidence of its presence. These signs and symptoms are often seen in elderly persons with arteriosclerosis, in patients with chronic pulmonary disease, anemia, carbon monoxide poisoning, and other conditions that cause chronic, low-grade tissue anoxia.

Circulatory Effects

Among the circulatory changes that occur, tachycardia is regarded by some workers as one of the most reliable signs of oxygen lack, and an indication of the need for therapy. The increase in heart rate, as well as an increase in stroke output, is an adaptive mechanism by which the body attempts to deliver a greater minute volume of oxygen-carrying blood in an effort to decrease the oxygen lack. An immediate increase in the apparent red-cell count occurs within forty-eight hours of anoxia, owing to hemoconcentration, the true increase in total red cells requires a longer time (seven to fourteen days).

Two dramatic and important responses to anoxia were seen during the training exposure of young aviators to high-altitude anoxia in decompression chambers during the war. If the oxygen lack were produced rather slowly (twenty to forty minutes) and in moderate degree (18,000 feet, or 10 per cent oxygen), about 1 or 2 per cent of these men developed pallor, sweating, nausea, bradycardia, fall in blood pressure and collapse. This syndrome, commonly known as vasovagal syncope or primary shock, is a nonspecific response to a wide variety of stimuli, among which are hunger, fear, emotional stress and pain. When full oxygen was restored, the men recovered consciousness at once, though the other symptoms were prominent for an hour or longer. By contrast, if the oxygen lack were sudden (one or two minutes) and severe (30,000 feet, or 7 per cent oxygen) vasovagal syncope was rarely seen. Instead the men grew confused, the pulse rate was increased, blood pressure normal, or elevated, and muscular incoordination and sudden loss of consciousness occurred rapidly. All effects were immediately reversed with oxygen. There is good reason to believe that either of these clinical pictures can occur as a result of disease or injury caus-

ing anoxia, and either type of reaction may be very confusing to the physician. Vasovagal collapse caused by anoxia probably is often mistaken for shock, hemorrhage, adrenal insufficiency, birth injury and so forth.

Once oxygen lack is suspected as contributing to a given symptom complex, the physician must attempt to correct the discrepancy between oxygen demand and supply. Increasing supply by providing an atmosphere high in oxygen (by mask, tent or nasal catheter) will greatly help many conditions, particularly those in which oxygen lack is from environmental or pulmonary causes. In other conditions it is the transportation of oxygen that must be improved — by digitalis if the myocardium is weak or by transfusion if circulating hemoglobin is low. Often, it is sufficient merely to decrease the tissue demand for oxygen, by strict rest or reduction of high fever, or by correction of an abnormally elevated metabolic rate. Obviously, optimum therapy will increase supply, improve transportation and reduce demand by all appropriate measures.

The physician must be careful not to interfere with natural mechanisms that the body develops to decrease anoxia, of which increased respiration may be very important. If respiration is depressed (by morphine, strapping the chest, ill advised recumbency) mild anoxia may become severe, and alarming symptoms may result. I was recently responsible for such an event in an obese, elderly man who had experienced a very severe gastric hemorrhage. Owing to his anemia he showed some air hunger, which greatly increased when his temperature rose to 103°F during a transfusion reaction. Morphine, given to allay restlessness, depressed his respirations, and he became irrational and violent. When the morphine was discontinued and respirations again increased, the symptoms of cerebral anoxia improved, but not until his anemia was further corrected did all symptoms of anoxia disappear. It is worthy of note that at no time was he cyanotic, for his circulating hemoglobin (less than 5 gm) was fully oxygenated, even though he was severely anoxic. In this case obesity, fever and activity all increased the need for oxygen, whereas anemia and morphine-suppressed respiration decreased the supply.

If the physician suspects that a patient's mental confusion, irritability, dyspnea or tachycardia may be due in part to anoxia, it is not sufficient simply to give oxygen therapy. Every effort must be made to visualize the dynamics of oxygen lack, and therapy should include all the measures that increase supply, improve transportation and decrease demand. To increase the supply, treatment should increase inspired oxygen, facilitate respiration, correct anemia and improve circulation, to decrease demand, it should reduce activity (mental and physical), lower fever and diminish abnormally elevated basal metabolic rate.

to high altitudes and in patients with chronic pulmonary or cardiac disease is well known

Table 1 presents some of the common conditions that often cause clinically important oxygen lack

DETECTION OF ANOXIA

As in so much of medicine, a high index of suspicion is the first prerequisite for the detection of anoxia except in its most flagrant form. It is the

TABLE 1 *Outline of Causes of Tissue Anoxia*

I Oxygen Demand Normal — Oxygen Supply Decreased	
(a) <i>Environmental</i> — low partial pressure of oxygen in inspired air (high altitude asphyxia)	
(b) <i>Pulmonary</i> — impaired respiratory exchange (emphysema, asthma, poliomyelitis)	
— diminished alveolar surface (pneumonia, infiltration, atelectasis)	
— impeded alveolar — arterial diffusion (pulmonary edema, fibrosis)	
(c) <i>Circulatory</i> — inadequate cardiac output (myocardial weakness, valvular disease, pericarditis)	
— inadequate or abnormal vascular bed (arteriosclerosis, arterial spasm, arteriovenous fistula, Paget's disease)	
— inadequate oxygen carrying power (anemia, carbon monoxide poisoning, methemoglobinemia)	
(d) <i>Tissue</i> — inadequate capillary flow (spasm, frostbite)	
— impeded capillary — tissue diffusion (?) (scleroderma, edema)	
— defective oxidation — reduction enzyme systems (cyanide poisoning, vitamin deficiency (?))	
II Oxygen Demand Increased — Oxygen Supply Normal	
(a) Generalized — exercise, fever, hyperthyroidism	
(b) Localized — infection	

old story of "seek and ye shall find, seek not and ye find nothing."

Cyanosis

Cyanosis is, of course, the most reliable indication of anoxia. This blueness of the lips, nail beds and mucosa depends upon the absolute amount of reduced hemoglobin in the capillary blood rather than upon the proportion of reduced to oxygenated hemoglobin. Years ago Lundsgaard and Van Slyke¹ showed that a minimum of 5 gm. of reduced hemoglobin per 100 cc. of blood must be present in capillary blood before cyanosis is apparent. Under ordinary circumstances arterial blood is 95 to 98 per cent saturated with oxygen, decreasing as it passes through the capillaries to 70 per cent saturation in mixed venous blood. Therefore, 25 to 28 per cent of the circulating hemoglobin, or 3.0 to 3.5 gm., is the maximum amount of reduced hemoglobin present at any point along the capillary, and this is less than the 5.0 gm. necessary to produce cyanosis. If, however, the saturation of either mixed venous or arterial blood decreases, so that the average amount of reduced hemoglobin in the capillary is 5 gm. or more, cyanosis will appear. The polycythemic patient who may have as much as 20 or 25 gm. of hemoglobin per 100 cc. of blood will show cyanosis even under the ordinary conditions outlined above, because more than 5.0 gm. of reduced hemoglobin is present. By contrast, in severe anemia when circulating hemoglobin may be as low

as 5.0 gm. cyanosis can never appear, because this would require total reduction of all hemoglobin, a manifest impossibility. In less severe anemia, cyanosis may appear only when the oxygen lack is already very marked.

Furthermore, as Comroe and Botelho² have demonstrated, cyanosis is dependent not only upon variable factors in the patient but also upon the ability of observers to recognize color changes, and serious degrees of anoxia frequently go undetected without laboratory aid. Kubicek,³ referring to anoxia in poliomyelitis, makes the following observation:

Clinically, cyanosis has too frequently been regarded as the first sign of oxygen deficiency and as an indication that remedial therapy should only then be initiated. Unfortunately cyanosis is seldom detectable if the saturation of hemoglobin is above 80%. When cyanosis is first visible, the flow of oxygen from capillary blood to nerve may be reduced by at least 65%. This makes it obvious why patients with bulbar poliomyelitis who become cyanotic so frequently succumb.

When a well equipped laboratory is available, arterial blood is easily analyzed for oxygen content and capacity, but even these figures represent only the oxygen available at the arterial end of the capillary, arterial oxygen content gives no hint of the amount of oxygen delivered to the tissues, which can only be estimated approximately if mixed venous blood is simultaneously analyzed. No methods at present available indicate whether or not oxygen supply is equal to oxygen demand.

Dyspnea

Dyspnea, the second major symptom of oxygen lack, has been defined as the consciousness of the necessity for increased breathing. Oxygen lack does stimulate respiration, probably through the carotid body rather than by direct action on the respiratory center, but its effect is variable and often weak. An impressive and practical demonstration of the weak stimulus given by anoxia to respiration was seen in the course of the altitude-training program during the war, when thousands of healthy young aviators briefly lost consciousness from oxygen lack alone, often without significant increase in respiration.⁴ Patients of low sensitivity may overbreathe considerably and yet be unaware of dyspnea. Conversely, the hypersensitive person may feel unable to get his breath, even though his respiratory exchange is normal or slightly increased. Furthermore, since the purpose of respiration is not only to provide oxygen for the body but also to eliminate carbon dioxide, a disturbance of this elimination will also cause dyspnea, the hyperventilation of acidosis is due not to oxygen lack but to carbon dioxide excess. Finally, the hysterical or neurasthenic patient, or one with a cerebral lesion, may overbreathe to a severe degree even though no metabolic abnormality may be present initially. Carrier⁵ has recently indicated that the

alkalosis resulting from hyperventilation causes peripheral vasoconstriction and thereby may cause significant tissue anoxia

From these brief paragraphs it is apparent that cyanosis is often present even though oxygenation is adequate, and that severe anoxia may be present without clinically detectable cyanosis. Furthermore, oxygen lack is only one of the many causes of dyspnea, and sometimes an ineffective one at that.

The mental signs of anoxia may be subtle and easily mistaken for primary neurologic disease. Mental confusion, emotional lability, errors in judgment, inability to concentrate, headache or gross tremors are frequently caused by oxygen lack alone and may be a principal evidence of its presence. These signs and symptoms are often seen in elderly persons with arteriosclerosis, in patients with chronic pulmonary disease, anemia, carbon monoxide poisoning, and other conditions that cause chronic, low-grade tissue anoxia.

Circulatory Effects

Among the circulatory changes that occur, tachycardia is regarded by some workers as one of the most reliable signs of oxygen lack, and an indication of the need for therapy. The increase in heart rate, as well as an increase in stroke output, is an adaptive mechanism by which the body attempts to deliver a greater minute volume of oxygen-carrying blood in an effort to decrease the oxygen lack. An immediate increase in the apparent red-cell count occurs within forty-eight hours of anoxia, owing to hemoconcentration, the true increase in total red cells requires a longer time (seven to fourteen days).

Two dramatic and important responses to anoxia were seen during the training exposure of young aviators to high-altitude anoxia in decompression chambers during the war. If the oxygen lack were produced rather slowly (twenty to forty minutes) and in moderate degree (18,000 feet, or 10 per cent oxygen), about 1 or 2 per cent of these men developed pallor, sweating, nausea, bradycardia, fall in blood pressure and collapse. This syndrome, commonly known as vasovagal syncope or primary shock, is a nonspecific response to a wide variety of stimuli, among which are hunger, fear, emotional stress and pain. When full oxygen was restored, the men recovered consciousness at once, though the other symptoms were prominent for an hour or longer. By contrast, if the oxygen lack were sudden (one or two minutes) and severe (30,000 feet, or 7 per cent oxygen) vasovagal syncope was rarely seen. Instead the men grew confused, the pulse rate was increased, blood pressure normal, or elevated, and muscular inco-ordination and sudden loss of consciousness occurred rapidly. All effects were immediately reversed with oxygen. There is good reason to believe that either of these clinical pictures can occur as a result of disease or injury caus-

ing anoxia, and either type of reaction may be very confusing to the physician. Vasovagal collapse caused by anoxia probably is often mistaken for shock, hemorrhage, adrenal insufficiency, birth injury and so forth.

Once oxygen lack is suspected as contributing to a given symptom complex, the physician must attempt to correct the discrepancy between oxygen demand and supply. Increasing supply by providing an atmosphere high in oxygen (by mask, tent or nasal catheter) will greatly help many conditions, particularly those in which oxygen lack is from environmental or pulmonary causes. In other conditions it is the transportation of oxygen that must be improved — by digitalis if the myocardium is weak or by transfusion if circulating hemoglobin is low. Often, it is sufficient merely to decrease the tissue demand for oxygen, by strict rest or reduction of high fever, or by correction of an abnormally elevated metabolic rate. Obviously, optimum therapy will increase supply, improve transportation and reduce demand by all appropriate measures.

The physician must be careful not to interfere with natural mechanisms that the body develops to decrease anoxia, of which increased respiration may be very important. If respiration is depressed (by morphine, strapping the chest, ill advised recumbency) mild anoxia may become severe, and alarming symptoms may result. I was recently responsible for such an event in an obese, elderly man who had experienced a very severe gastric hemorrhage. Owing to his anemia he showed some air hunger, which greatly increased when his temperature rose to 103°F during a transfusion reaction. Morphine, given to allay restlessness, depressed his respirations, and he became irrational and violent. When the morphine was discontinued and respirations again increased, the symptoms of cerebral anoxia improved, but not until his anemia was further corrected did all symptoms of anoxia disappear. It is worthy of note that at no time was he cyanotic, for his circulating hemoglobin (less than 5 gm) was fully oxygenated, even though he was severely anoxic. In this case obesity, fever and activity all increased the need for oxygen, whereas anemia and morphine-suppressed respiration decreased the supply.

If the physician suspects that a patient's mental confusion, irritability, dyspnea or tachycardia may be due in part to anoxia, it is not sufficient simply to give oxygen therapy. Every effort must be made to visualize the dynamics of oxygen lack, and therapy should include all the measures that increase supply, improve transportation and decrease demand. To increase the supply, treatment should increase inspired oxygen, facilitate respiration, correct anemia and improve circulation, to decrease demand, it should reduce activity (mental and physical), lower fever and diminish abnormally elevated basal metabolic rate.

SUMMARY

The common causes of clinically important oxygen lack are presented, together with the more prominent signs and symptoms that help in diagnosis. Cyanosis and dyspnea, though most reliable, may be absent in severe anoxia, and present even when oxygenation is adequate. Mental confusion and tachycardia are helpful and suggestive signs. The physician must realize that discrepancy between oxygen supply and demand is the cause of anoxia, and therapy

should include not only methods of increasing supply, but also measures that improve transportation and decrease tissue demand.

MEDICAL PROGRESS

ORAL SURGERY

KURT H. THOMA, D.M.D., F.D.S.R.C.S. (ENG.)*

BROOKLINE, MASSACHUSETTS

A NEW era of oral surgery has begun. In 1945 the American Society of Oral Surgeons appointed a seven-member committee and authorized them to form a certifying board and to conduct examinations for the certification of specialists in oral surgery. The American Board of Oral Surgery was incorporated under the laws of the State of Illinois in 1946 and subsequently approved by the Council on Dental Education of the American Dental Association. The Board conducted its first examinations in February, 1947. Among the qualifications¹ required of the applicant are the following:

Graduation from a recognized dental school in the United States or Canada.

Practice devoted exclusively to oral surgery for five years or more, including graduate training.

Graduate study in oral surgery for a period of two years or more in a recognized graduate school or hospital, or under the auspices satisfactory to the Board. (This period of training shall cover the clinical and technical phases of oral surgery, and the basic sciences as they are related to oral surgery.)

It is the aim of the Board that societies representing the specialty of oral surgery, teaching institutions, hospitals and Government services shall require the certificate of the Board for admission to the special societies and for advancement in hospitals, teaching institutions and Government services.

HISTORY

It may be interesting to look over the shoulder of time and review how this specialty was de-

veloped. At the time of Morton (the dentist who first demonstrated publicly the use of ether for the relief of pain in dentistry and surgery), no surgical specialties had evolved. By reason of their particular skill and interest in treating certain diseases, some practitioners attracted patients who had heard of their special ability and soon were obliged to limit their practices to narrower fields. A striking example is Simon P. Hullahen, who made a wide reputation with operations for harelip, cleft palate and cancer of the jaws. A pioneer in this field and a foremost man of his time, he was given an honorary D.D.S. and an honorary M.D. degree.

James E. Garretson,² influenced by the brilliant achievements of Hullahen, published the first comprehensive American text on oral surgery in 1869. He recognized that there was an isolated field in surgery that had been neglected, being somewhere between medicine and dentistry. He pointed out in the preface of the second edition of his book published in 1873 that there is a great need for special training in this field, which, if taken in hand by medicine, suffers from want of special information and knowledge, and if taken care of by dentistry meets with disaster because of lack of surgical training and operative skill. A reviewer of Garretson's text stated: "This book fills a hitherto unoccupied place in the literature, and bridges the chasm which has separated dentistry from medicine."

The first recognition of the specialty of oral surgery came in 1869 when James E. Garretson was appointed to the Hospital of the University of Pennsylvania with the title of "oral surgeon."

Though the specialty did not receive a very cordial reception at first, Garretson and his contemporaries, who limited their practices to surgery of the mouth and jaws, continued to develop this specialty. These men had strong personalities, became great teachers

*Emeritus professor of oral surgery and Charles A. Brackett Professor of Oral Pathology, Harvard University; lecturer in oral surgery, Graduate School of Medicine, University of Pennsylvania; member, Board of Consultation, Massachusetts General Hospital.

and contributed many valuable publications to the literature. They included Thomas Fillibrown, Truman W. Brophy, Matthew W. Cryer, Thomas L. Gilmer, John S. Marshall and George Van Jugen Brown. The names of these men have been spoken in heartfelt gratitude by countless patients and their parents, because of the skillful correction of a variety of horrible deformities, or the repair of the ravages of cancer that had made these patients outcasts of society.

Oral surgery in the twentieth century became a recognized specialty of dentistry, included in the curriculum of all dental schools. That this surgical specialty was fostered and developed under the aegis of dentistry is natural when one considers that both the diagnosis and the treatment of oral disease require special knowledge of the anatomy and pathology of the teeth and jaws and that dentists are primarily concerned with the preservation and restoration of the proper functioning of the masticatory apparatus. Furthermore, medical schools have, in the past, shown very little interest in oral disease and have taken no responsibility for investigation and research to prevent such disease and maintain health and adequate function of the tissues involved.

Oral surgery has been defined by the American Board of Oral Surgery as the branch of dental practice that deals with the diagnosis, treatment, prescribing for or operating upon any disease, injury, malformation or deficiency of the human jaws or associated structures. The assignment of this field to dentistry in most states is backed by provisions of the dental law.² Thus, oral surgery is legalized and authenticated as a specialty of dentistry.

GRADUATE TRAINING

A very important step in the development of oral surgery is the establishment of postgraduate courses by some of the leading dental schools. Waldron^{4, 5} points out that acceptable programs for graduate training in oral surgery may show considerable variation in their plan of operation.

Some schools offer a graduate degree at the conclusion of the training period, though this is no more essential in oral surgery than it is in the program of graduate training in surgery and its various specialties. The first year of the training period should include training in basic science and study of fundamentals of clinical oral surgery. The remaining years should be devoted almost entirely to clinical and operative oral surgery.

Other schools, having accommodations for only a small number of students for the clinical work, may, through affiliations with other institutions, provide training under the guidance of accredited oral surgeons in various hospital centers.

Training may be offered by certain hospitals and clinics not associated with universities but approved for graduate training in surgery.

The course offered by the Graduate School of Medicine of the University of Pennsylvania is a good example of the high ideals set by its sponsors. It offers, in the first year, graduate training in advanced regional anatomy, bacteriology, immunology, physiology, biochemistry, pharmacology and special pathology, with autopsy assignments and participation in clinicopathological conferences. In addition, courses are offered in principles of surgery, medical physical diagnosis, anesthesiology, roentgenologic diagnosis and therapy, and experience in the clinical laboratory. Similar courses of one year's duration are given by Minnesota, Northwestern and other schools. The first year is followed by two years of internship either in the institutions teaching hospital or in another approved hospital, where the head of the department is a diplomate of the Board of Oral Surgery. The importance of appointing well trained and able teachers to hospital staffs is therefore paramount. According to the chairman of the Committee on Hospital Training of the American Board of Oral Surgery, a field survey committee will be appointed to evaluate the various training services in oral surgery and to give recognition to institutions that conform to the Board's minimum standard requirements that will make a trainee eligible for examination for certification.

RECENT ADVANCES

The more recent past contains a number of milestones that mark distinct developments in the field of oral surgery. These are local anesthesia, the perfection of which made it possible to perform all kinds of minor operations painlessly in a dentist's office, the denouncement of septic dentistry, which was the result of the endeavor to save teeth at all costs — many of these teeth so assiduously treated in the past were found to be infected and presented a source of great danger to the patient's general health, the influence of World War I with its trench warfare, which caused facial wounds and shattered jaws in enormous numbers, making a great demand on the skill of the comparatively few trained men of that time, the new field of traumatic jaw surgery of the postwar period, when civilian accidents became more frequent because of the rapidly increasing use of automobiles and airplanes, and the speeding up of industrial machines, the discovery of a fertile field consisting of a variety of asymptomatic jaw lesions revealed by the popularization of roentgenologic examination by both the physician and the dentist as part of a general examination, and finally the great discovery of chemotherapy and the use of antibiotics, which altered many procedures and eliminated many

dangers from oral surgical operations performed in an infected region

ANESTHESIOLOGY

It should be noted that two of the most important anesthetic agents, which are still the most popular and safest means of producing surgical narcosis, have been discovered by dentists. In addition, special technics have been developed by the latter to relieve pain by means of anesthesia and analgesia, not only for oral surgical operations but also for general dental procedures

Anesthesia in the Dental Office

Recently, the use of pentothal sodium, with or without nitrous oxide and oxygen, has been employed for short procedures by those who perform minor operations on ambulatory patients in offices.

The two most important topics in the use of general anesthetics are the question of anoxia, often resulting during the induction of nitrous oxide and oxygen anesthesia, and the question of the safety of giving general anesthetics, especially pentothal sodium, to ambulatory patients without adequate physical examination and preparation.

Nitrous oxide and oxygen The effects of anoxia and hypoxia, which are frequently produced by incorrect technic of induction and administration of nitrous oxide anesthesia that has a very narrow margin of oxygenation, were described by Courville.⁶ He pointed out that damage to the cerebral cortex is the penalty for insufficient oxygenation. It should be remembered, according to Kaye,⁷ that absence of cyanosis does not necessarily mean that no anoxemia is present. In anemic patients gross and dangerous suboxygenation may exist without signs of cyanosis since the oxygen-carrying capacity of the blood is reduced. In thyrotoxic subjects, too, the metabolic rate may be so high that oxygen lack exists even when the oxygen supply maintains normal color. Kaye points out that the absence of cyanosis is no guarantee of safety, and careful attention must be paid to assuring adequate oxygen administration in such cases. Schreiber,⁸ who reported 9 cases of severe cerebral damage and death, showed that anoxia may be brought about by the improper administration of any anesthetic. In 5 of his cases brain damage followed spinal anesthesia, and in one an asphyxial episode resulted in irreparable personality change when a tonsillectomy was performed under local anesthesia with a 0.5 per cent procaine solution. In 4 cases of prolonged anoxia, reported by Steegmann,⁹ in which brain damage was caused in 2, nitrous oxide was used. In the other 2 cases, avertin and cyclopropane were employed.

Seldin¹⁰ defends the use of nitrous oxide and oxygen and points out that there is no necessity for severe or prolonged anoxia to occur when nitrous oxide is correctly administered. His tabulation of

14,790 administrations shows that most patients will accept a surprisingly high percentage of oxygen with nitrous oxide without its interfering with maintenance of the third stage of anesthesia. In 85 per cent of the patients, anesthesia could be maintained with a minimum of 20 per cent oxygen. He states that the formula of 7 per cent oxygen and 93 per cent nitrous oxide used in the past is definitely wrong. McQuiston, Cullen and Cook¹¹ showed that any appreciable reduction of oxygen below 20 per cent may become extremely dangerous to the patient and that a reduction of oxygen below 12 or 13 per cent presents a great risk. If a patient cannot be adequately anesthetized with such a mixture, Arrowood¹² recommends that the nitrous oxide be supplemented with a more potent agent, such as ether, vinethene or pentothal.

The advantage of proper premedication has been stressed by Curran¹³ and Wiggin,¹⁴ as well as Arrowood.¹² The first recommends for ambulatory patients the short-acting secenal and nembutal, whereas Macintosh and Pratt¹⁵ suggest phenobarbital, 30 mg ($\frac{1}{2}$ gr) the night before the operation, 15 mg ($\frac{1}{4}$ gr) at breakfast time and 15 mg an hour before operation. Atropine, 0.4 mg ($\frac{1}{150}$ gr), Arrowood¹² points out, is very useful for drying up secretions that may hinder respiration.

Nasoendopharyngeal intubation is recommended by Cooper and Hill¹⁶ to avoid obstruction of the airway by retraction of the tongue, or by mucus, blood, pus or fractured teeth. A pack should be placed back into the mouth to avoid the aspiration of this material.

The need of a physical examination has been discussed by many writers. Macintosh and Pratt¹⁵ state, "We believe that a patient who does not volunteer a history of illness, and who is able to walk into the dental surgery, can be presumed fit enough to submit to a short dental anesthesia." Arrowood¹² points out that such an attitude courts disaster. Most of the modern writers on the subject agree. Arrowood recommends that a brief medical history be taken, and the questions asked should be planned to include the possibility of such maladies as allergic conditions, heart disease, especially of the myocardial type, and chronic pulmonary disease, especially with reference to vital capacity. Better still is a consultation with the patient's physician. This may yield important information regarding conditions, of which the patient is unaware, that may contraindicate the use of certain methods. Foldes¹⁷ points out that the history and physical examination should, in certain cases, be supplemented by various laboratory studies, and that special attention should be given patients with conditions that are adversely affected by the biochemical changes produced by the various anesthetic agents. Patients with diseases of the circulatory or respiratory systems and those with thyroid disease, kidney disease, liver disease, diabetes, allergic condi-

tions, blood dyscrasias and so forth should be hospitalized

In response to a questionnaire sent to the members of the American Society of Oral Surgeons, Seldin¹⁰ reports that 207 who replied had, during the preceding five years, administered approximately 2,429,148 anesthetics in their offices. Fifteen deaths were reported in this series. Nine deaths occurred from nitrous oxide for the following reasons: 2 patients had cardiac disease, 3 died of unknown cause, 1 patient with hypertension died eleven days later, 1 jumped out of the window during induction, 1 died of necrosis of the spinal cord, 1 died from "status lymphaticus" and sarcoma, 4 patients with cardiac diseases died during sodium pentothal anesthesia, 1 death occurred with novocain and pontocaine, and 1 additional death occurred under ethylene. Seven personality changes were reported, 6 were reversible, and 1 irreversible. According to this report, the death rate in these office administrations of anesthetic was 1/161,943, as compared with 1/1000 during administration in hospitals as reported by Waters and Gillespie.¹³ It should be remembered, however, that the main reason for the comparative infrequency of fatal cases in office administration is the short duration of most operations performed on ambulatory patients. The comparative safety of a short anesthesia has been recognized by many writers. Macintosh and Pratt¹⁵ state that no operation of more than ten minutes' duration should be undertaken in the dental office. Gillespie¹⁹ places the limit at fifteen minutes. Since Chapman, Arrowood and Beecher²⁰ have demonstrated that it takes ten or fifteen minutes for full saturation with a given mixture of nitrous oxide, oxygen deprivation during these short procedures is not often sufficiently severe to be fatal, according to Arrowood.¹²

To facilitate the induction of nitrous oxide and oxygen anesthesia, especially in obstreperous patients, or to achieve a deeper anesthesia without decreasing the percentage of oxygen, the admixture of trichlorethylene,²¹⁻²² vinethene²³ and ethyl ether is recommended, the last being the safest means of fortifying nitrous oxide anesthesia.²⁴ Premedication of ambulatory patients treated in the office is desirable but not practical since the delayed action of some of these drugs will endanger the patient's safety, especially if he is driving an automobile. Short-acting barbiturates are recommended such as seconal, nembutal and evicyl if the patient is kept under observation postoperatively and is taken home by an attendant.^{10-13, 24}

Pentothal sodium. Intravenous anesthesia with pentothal sodium has been used in dentistry and oral surgery with increasing frequency and enthusiasm in recent years. Bullard,²⁵ in 1940, reported on 946 cases of anesthesia for exodontia and oral surgery with pentothal sodium. Olson²⁶ discussed a series of 8203 operations and stated

that he preferred pentothal to nitrous oxide and oxygen because of the almost total absence of the excitement stage and of postoperative nausea and vomiting. Other enthusiasts who advise its use for ambulatory patients are Archer²⁷ and Robert and Brown,²⁸ who recommend that pentothal be supplemented with oxygen.

Still others believe that it should be used as a synergist only. Seldin¹⁰ states, "This drug does not lend itself to unrestricted use as a principal anesthetic in prolonged oral surgery in the office because it is potentially dangerous if infection of the floor of the mouth or cellulitis of the neck is present." He recommends it for selected cases in combination with nitrous oxide and oxygen.

Many anesthesiologists approve of these methods if they are executed by a well trained person and if facilities are at hand to treat emergencies. Arrowood¹² believes that pentothal should be administered by a professional anesthetist only and not by the dentist himself. She points out that adequate premedication with atropine by depressing the parasympathetic system helps to protect against irritation of the larynx. Etsten and Himwich²⁹ state that the reflex irritability is markedly increased under light, and is not completely abolished even in deep pentothal anesthesia. Painful stimuli, especially from the region of the neck, may produce severe laryngeal spasm because the vagus nerve is not sufficiently depressed during this type of anesthesia to cause disappearance of the pharyngeal reflexes.³⁰ Spastic closure of the glottis, with extreme cyanosis, may result. Hubbell,³¹⁻³² however, who reported on 13,000 administrations, states that no complete laryngospasm occurred in his series of cases. Facilities for tracheal intubation and efficient suction should be immediately available if pentothal sodium is used. The importance of complete equipment is stressed by all the writers, but is especially emphasized by those who make anesthesia a specialty. Foldes¹⁷ states that the immediate availability of equipment necessary for resuscitation such as a suction apparatus, a laryngoscope and a variety of endotracheal tubes should always be on hand. There should also be equipment for the administration of oxygen under positive pressure and a sufficient number of competent assistants to aid in case of emergency.³³

According to Everson³⁴ pentothal anesthesia is contraindicated in patients with marked anemia, because of reduced oxygen-carrying capacity, hypertension (systolic blood pressure of 200 or more), hypotension (systolic blood pressure of 90 or less), since pentothal lowers the blood pressure by 8 to 40 per cent, impairment of respiratory function as caused by pulmonary secretions or metastatic disease and ankylosis of the jaw, as well as in very old and very young patients and those with coronary-artery disease, who should receive 100 per cent oxygen if this type of anesthesia is used.

dangers from oral surgical operations performed in an infected region

ANESTHESIOLOGY

It should be noted that two of the most important anesthetic agents, which are still the most popular and safest means of producing surgical narcosis, have been discovered by dentists. In addition, special technics have been developed by the latter to relieve pain by means of anesthesia and analgesia, not only for oral surgical operations but also for general dental procedures

Anesthesia in the Dental Office

Recently, the use of pentothal sodium, with or without nitrous oxide and oxygen, has been employed for short procedures by those who perform minor operations on ambulatory patients in offices.

The two most important topics in the use of general anesthetics are the question of anoxia, often resulting during the induction of nitrous oxide and oxygen anesthesia, and the question of the safety of giving general anesthetics, especially pentothal sodium, to ambulatory patients without adequate physical examination and preparation.

Nitrous oxide and oxygen The effects of anoxia and hypoxia, which are frequently produced by incorrect technic of induction and administration of nitrous oxide anesthesia that has a very narrow margin of oxygenation, were described by Courville.⁶ He pointed out that damage to the cerebral cortex is the penalty for insufficient oxygenation. It should be remembered, according to Kaye,⁷ that absence of cyanosis does not necessarily mean that no anoxemia is present. In anemic patients gross and dangerous suboxygenation may exist without signs of cyanosis since the oxygen-carrying capacity of the blood is reduced. In thyrotoxic subjects, too, the metabolic rate may be so high that oxygen lack exists even when the oxygen supply maintains normal color. Kaye points out that the absence of cyanosis is no guarantee of safety, and careful attention must be paid to assuring adequate oxygen administration in such cases. Schreiber,⁸ who reported 9 cases of severe cerebral damage and death, showed that anoxia may be brought about by the improper administration of any anesthetic. In 5 of his cases brain damage followed spinal anesthesia, and in one an asphyxial episode resulted in irreparable personality change when a tonsillectomy was performed under local anesthesia with a 0.5 per cent procaine solution. In 4 cases of prolonged anoxia, reported by Steegmann,⁹ in which brain damage was caused in 2, nitrous oxide was used. In the other 2 cases, avertin and cyclopropane were employed.

Seldin¹⁰ defends the use of nitrous oxide and oxygen and points out that there is no necessity for severe or prolonged anoxia to occur when nitrous oxide is correctly administered. His tabulation of

14,790 administrations shows that most patients will accept a surprisingly high percentage of oxygen with nitrous oxide without its interfering with maintenance of the third stage of anesthesia. In 85 per cent of the patients, anesthesia could be maintained with a minimum of 20 per cent oxygen. He states that the formula of 7 per cent oxygen and 93 per cent nitrous oxide used in the past is definitely wrong. McQuiston, Cullen and Cook¹¹ showed that any appreciable reduction of oxygen below 20 per cent may become extremely dangerous to the patient and that a reduction of oxygen below 12 or 13 per cent presents a great risk. If a patient cannot be adequately anesthetized with such a mixture, Arrowood¹² recommends that the nitrous oxide be supplemented with a more potent agent, such as ether, vinethene or pentothal.

The advantage of proper premedication has been stressed by Curran¹³ and Wiggan,¹⁴ as well as Arrowood.¹² The first recommends for ambulatory patients the short-acting seconal and nembutal, whereas Macintosh and Pratt¹⁵ suggest phenobarbital, 30 mg ($\frac{1}{2}$ gr) the night before the operation, 15 mg ($\frac{1}{4}$ gr) at breakfast time and 15 mg an hour before operation. Atropine, 0.4 mg ($\frac{1}{150}$ gr), Arrowood¹² points out, is very useful for drying up secretions that may hinder respiration.

Nasoendopharyngeal intubation is recommended by Cooper and Hill¹⁶ to avoid obstruction of the airway by retraction of the tongue, or by mucus, blood, pus or fractured teeth. A pack should be placed back into the mouth to avoid the aspiration of this material.

The need of a physical examination has been discussed by many writers. Macintosh and Pratt¹⁵ state, "We believe that a patient who does not volunteer a history of illness, and who is able to walk into the dental surgery, can be presumed fit enough to submit to a short dental anesthesia." Arrowood¹² points out that such an attitude courts disaster. Most of the modern writers on the subject agree. Arrowood recommends that a brief medical history be taken, and the questions asked should be planned to include the possibility of such maladies as allergic conditions, heart disease, especially of the myocardial type, and chronic pulmonary disease, especially with reference to vital capacity. Better still is a consultation with the patient's physician. This may yield important information regarding conditions, of which the patient is unaware, that may contraindicate the use of certain methods. Foldes¹⁷ points out that the history and physical examination should, in certain cases, be supplemented by various laboratory studies, and that special attention should be given patients with conditions that are adversely affected by the biochemical changes produced by the various anesthetic agents. Patients with diseases of the circulatory or respiratory systems and those with thyroid disease, kidney disease, liver disease, diabetes, allergic condi-

oxygen and ether also may be recommended. Sodium pentothal is a vasodilator,⁴² and when it is combined with local anesthesia, bleeding can be controlled. Nerve block as well as infiltration will, in addition, allow the anesthetist to carry the patient through the operation with as little pentothal as possible.

(To be continued)

Correction In the article by Dr Stanley E. Bradley entitled "Variations in Hepatic Blood Flow in Man during Health and Disease," which appeared in the March 24 issue of the *Journal*, the word "excretion" should be changed to "extraction" in the legend of Figure 5 and wherever it occurs in the text.

Local anesthesia The development of local anesthesia, especially conductive anesthesia (nerve block), with the discovery of novocain, has furnished the dentist a safe method by which he can perform operations in his office without resorting to general anesthesia and acting as his own anesthetist, avoiding the need of specially trained personnel and elaborate equipment. Unfortunately, this method made the undertaking of minor surgical procedures so easy from the anesthesia aspect that many inadequately trained dentists proclaimed themselves specialists in oral surgery.³⁴

However, local anesthesia has given the well trained oral surgeon an opportunity to perform dentoalveolar surgery safely on ambulatory patients without the preparation that is required for a general anesthetic. Performing minor procedures in the office under local anesthesia and using general anesthesia at a hospital for the more extensive operations, employing an expert anesthesiologist, is an ideal arrangement, though even with local anesthesia poor-risk patients should be hospitalized.³⁵ Greene³⁶ writes "regional anesthesia which is the method of choice should be urged on every patient in preference to general anesthesia if the patient is suitable for surgery in a conscious state."

The usual preparations to produce local anesthesia today contain procaine and epinephrine. More recently, monocaine with epinephrine has been recommended.³⁷ The same results are obtained with a 1 per cent solution of monocaine as with a 2 per cent solution of procaine.³⁸ In addition, monocaine has a synergistic action with epinephrine, and, therefore, smaller concentrations of this vasoconstrictor may be used (1:75000) than are required with procaine to which is added epinephrine 1:50000.

In oral surgery, epinephrine is considered indispensable. It aids in maintaining anesthesia long enough for the operation to be performed painlessly, and it produces hemostasis, which improves visibility of the field of operation. Many of the undesirable by-effects are due to the epinephrine rather than the procaine or monocaine since the use of epinephrine stimulates the myocardium, accelerates the heart rate and produces a rise in blood pressure. These have serious consequences in patients with cardiac complications³⁹ such as angina pectoris, coronary occlusion and severe hypertension or arteriosclerosis.

The combination of antibiotic agents and local anesthetic was recommended by Lundy and Osterberg,⁴⁰ who recommend the admixture of 250 units of penicillin per cubic centimeter of the anesthetic solution when it is injected into an infected region. They proved that penicillin does not interfere with anesthesia. Another suggestion was made by Copen,⁴¹ who advised premedication by comedication to overcome states of anxiety and fear. The inclusion of 25 mg of demerol hydrochloride with

monocaine and epinephrine is recommended, 12.5 mg for children. Others prefer premedication with secenal or pentobarbital sodium an hour before the administration.⁴⁴

Anesthesia for Oral Surgery in the Hospital

It is agreed by almost everyone that when a general anesthetic is necessary for a prolonged oral surgical operation, the patient should be hospitalized. I heartily concur with this recommendation. The obvious advantages are more careful physical checkup, preoperative correction of general disease, rest and control of food intake and hydration, proper premedication and preparation, maintenance of optimal conditions for the patient's metabolism in the postoperative period, and excellent postoperative general care and medication, not to speak of the proper use of antibiotics for the prevention or treatment of infections.

Endotracheal nitrous oxide, oxygen and ether anesthesia is by far the safest method for oral surgical operations.⁴²⁻⁴³ The Magill tube inserted through the nose leaves the oral cavity free, and the throat can be adequately packed to prevent aspiration of foreign material. Intubation minimizes leakage of the anesthetic agents. This type of anesthesia was highly approved of by Hunter⁴⁴⁻⁴⁵ for maxillofacial surgery in the British Army in World War II.

Pentothal sodium with endotracheal nitrous oxide and oxygen is believed to be the anesthesia of choice by others.⁴⁶⁻⁴⁷ However, Wilson and Hilmore⁴⁷ state, "The use of pentothal sodium alone is highly dangerous." They recommend "balanced anesthesia" of pentothal with nitrous oxide and oxygen. The induction is pleasant, less pentothal is required, the recovery is quicker, and there is complete freedom from straining and vomiting, which is important if intermaxillary fixation is used. Elliot and Arrowood⁴⁸ point out the advantages of pentothal sodium with tracheal intubation if diathermy procedures or electrocoagulation are contemplated in and around the head. Schultz and Guralnick,⁴⁹ besides combining nitrous oxide and oxygen with pentothal, believe that the addition of curare has advantages for more complicated cases in which maximum relaxation is essential during maintenance of a light plane of anesthesia. The combination of continuous pentothal sodium anesthesia with nerve block has been recommended by Thompson,⁵⁰ who reports on 100 consecutive cases. He points out that the method has many advantages, the most important of which is safety, since the amount of pentothal to carry the patient through the operation can be reduced to a minimum.

The combination of pentothal sodium with endotracheal nitrous oxide, oxygen and local anesthesia I find to be the ideal method when intravenous anesthesia is indicated. Its use with nitrous oxide,

mary adenocarcinoma of the second or third portion of the duodenum, which is rare but certainly occurs. We have all seen an occasional example of that disease. He may have had localized lymphoma of some sort, involving the same area, and a lymphoma at times is characterized by sharp localization of the tumor with infiltration of a given area of the gastrointestinal tract, but with no evidence of disease anywhere else.

This picture, to my mind, is not that of a duodenal ulcer. Peptic ulcers that are perfectly benign can occur in the third portion of the duodenum. They are not common, but many of them have been recognized — some at operation, and some by careful x-ray examination — but they do not give the x-ray picture that is described here, in my experience.

Benign tumor, of course, can involve this portion of the duodenum, but the appearance described here does not suggest benign tumor to me. A very remote possibility, as far as I can see, is that of localized enteritis. The usual site of this disease is the terminal ileum, occasionally, it involves the jejunum rather than the ileum, and rarely is it sharply localized in the upper small bowel. This is extremely rare but can happen and might involve the area considered as the duodenum. I do not believe it was regional enteritis, so-called, but I suppose that is a remote possibility. It is also possible that it was one of the various granulomatous processes we have to think of from time to time, but I have no reason to do any more than mention the possibility.

I do not know that there is any connection between the clarinet playing and the symptoms. Perhaps it was a fortuitous affair rather than an occupational hazard.

I would like to look at the x-ray films before finally trying to decide in my own mind what the diagnostic possibility is.

There is obviously enlargement of the duodenum.

DR JAMES J. McCORT: We have the films made on admission to this hospital. The esophagus and stomach do not show any abnormality. Beginning at the pylorus the duodenum shows a considerable widening all the way around to the junction of the third and fourth portions. From that point on the lumen shows severe narrowing for a distance of 0.7 cm. The constriction is gradual so that it is somewhat funnel shaped. A definite shelf defect cannot be made out. Within the narrowed segment a normal mucosal pattern is not seen, and there are fine serrations that indicate small ulcerations. The film taken three hours after the barium was administered shows considerable barium remaining in the dilated proximal two thirds of the duodenum.

DR JONES: These two spot films are the most important ones, are they not?

DR McCORT: Yes.

DR JONES: I think the only thing to do is to go out on the extreme end of the limb. I think the pa-

tient had an adenocarcinoma of the duodenum, with a secondary inflammatory process, I think it was not duodenal ulcer, and I believe it was not lymphoma. I am not familiar with the roentgenologic picture of lymphoma. I see no reason for thinking he had it except as a possibility to be included in differential diagnosis.

DR McCORT: Does the absence of a shelf have any significance?

DR JONES: Do you mean to imply that if he had a shelf, you would be more interested in the diagnosis of cancer? I would go with that. The question that I cannot answer is how frequently one can show a shelf with a cancer. I do not know that.

DR McCORT: I think it is frequently found.

DR JONES: I am sure of that. But is it in half, two thirds or a quarter of the cases?

DR McCORT: I would say a high percentage.

DR JONES: In other words, you are putting a little pressure on me to say that this was an inflammatory process. The presence of ulceration would fit in with that idea. I should say that ulcer was a possibility here, and against that idea is the complete absence of anything that can be called a focal lesion. I have already said adenocarcinoma of the duodenojejunal junction. I might as well stick to it. There was no disease anywhere else in the adjacent portion as far as I can find. It was localized, and the important thing was to take it out. I believe a surgical exploration is the only reasonable approach. If this was a jejunitis or duodenojejunitis, an inflammatory process per se, it has to be determined by biopsy. And I think biopsy of living tissue has to be made on this to establish finally what should be done. I am willing to admit that it was perhaps an inflammatory process, but I am not good enough to make the diagnosis.

DR RICHARD H. SWEET: There are two questions I would like to ask Dr. Jones. It looks to me from the x-ray studies here as if the lesion was actually in the jejunum and not in the duodenum. Would that influence you in favor of a diagnosis of regional enteritis or some such inflammatory lesion rather than a malignant neoplasm?

DR JONES: Yes, I think so, but as the x-ray description was given it was stated that it was in the third and fourth portions of the duodenum.

DR SWEET: Yes, but it looks like the jejunum to me.

DR McCORT: I cannot answer that exactly. I think it is on the proximal side of the ligament of Treitz.

DR SWEET: I would be surprised if it is.

DR GORDON A. DONALDSON: Dr. Jones should be commended for "sticking his neck out" before seeing the x-ray films. I have the impression that after he actually saw them he thought of hedging a little bit.

DR JONES: I left it "on the end of the limb."

DR DONALDSON: This was a very interesting and unusual problem. The record is misleading in that

EDITH E. PARRIS, *Assistant Editor*

CASE 35171

PRESENTATION OF CASE

A thirty-year-old clarinet player entered the hospital because of epigastric pain and vomiting.

Twenty months before admission the patient developed what he called "indigestion and dyspepsia." There was no vomiting, food intolerance or melena. These symptoms persisted for six to eight months and then ceased spontaneously except for sporadic attacks. Three months previous to admission the symptoms became severe. Six weeks before entry a Graham test at another hospital was negative. A gastrointestinal series showed marked dilatation of the descending and proximal transverse duodenum. There was an area of constriction in the mid-transverse duodenum that extended for a distance of about 8 cm. to the ligament of Treitz. The jejunum distally was normal. After four hours there was approximately 50 per cent retention of barium proximal to the constriction. Operation was advised but was refused. Epigastric pain and "heartburn" became severe. There was almost nightly vomiting—at 2 to 3 a.m.—of bile-stained material, which relieved the pain. He developed constipation but no melena. Fried or fatty foods promptly caused vomiting so that he restricted his diet to boiled foods, especially eggs and cereals.

The past and family histories were noncontributory.

Physical examination showed a short, obese man in no distress. The heart and lungs were normal. The abdomen was not tender, and there were no masses or tenderness. There was a maculopapular dermatitis confined to the region of the right axilla.

The temperature, pulse and respirations were normal. The blood pressure was 120 systolic, 80 diastolic.

The hemoglobin was 14 gm. The white-cell count was 7700. The urine sediment contained an occasional pus cell. The serum protein was 6.5 gm., the chloride 97 milliequiv. per liter and the nonprotein nitrogen 23 mg. per 100 cc. A gastric analysis showed no free hydrochloric acid in the fasting specimen, 5 units after alcoholic test meal and 44

units after histamine. A gastrointestinal series showed the duodenum to be rather severely dilated from the pylorus to about the junction of the second and third portions of the duodenum. At that point the barium column presented a rounded, blunted extremity, with marked delay in the passage of barium through this region. There was considerable reflux, and back-and-forth motion occurred between the stomach and duodenum. After some delay the barium entered the third portion of the duodenum, outlining a severely narrow segment of somewhat irregular caliber about 7 cm. long. Small projections suggested areas of ulceration. The distal portion of the narrowed area was of greater caliber than the remainder. The rest of the small bowel was not unusual. After four hours a large amount of barium was present in the dilated duodenum.

On the third hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. CHESTER M. JONES: On the third hospital day an operation was performed, which probably should have been done some weeks before. The obvious thing is that there was partial obstruction of the duodenum. That was obvious from the two sets of x-ray studies, and there is no evidence of any other disease, at least, on the basis of history, physical findings, laboratory data or x-ray examination. We are told that a cholecystogram was normal, and the x-ray film taken six weeks before admission to this hospital, in general, was entirely comparable to that taken a day or so after admission here. It would be interesting to know whether there was any occult blood in the stools. There is no statement about that. The patient had no anemia so I assume that he had not been bleeding to any great degree, but it would be interesting to know if there was enough erosion to cause occult blood.

DR. BENJAMIN CASTLEMAN: No stool examination is recorded.

DR. JONES: He was here three days, and the x-ray studies were done on the first and second days. I do not believe there would have been a stool examination. The symptoms were those of partial obstruction. As far as I can see, the question when he came in was primarily one of making a decision—namely, to operate or not to operate. Some partial obstruction was demonstrated in the duodenum, and operation seemed the only logical approach to the problem. That is the only important part of the picture. Exact diagnosis is interesting, but whatever diagnosis had been entertained preoperatively would have made very little difference in what one decided to do.

Regarding the possibilities underlying this partial obstruction, I am going to make what I call an intelligent guess, I hope. But it seems to me that the x-ray description can do nothing more than suggest certain possibilities. He may have had pri-

Physical examination revealed a well developed and well nourished boy in whom positive findings were limited to the left lower extremity. There were definite tenderness and moderate swelling over the medial epicondyle. There were no palpable bony masses. The joint line was not tender, and there was no fluid. Twenty centimeters above the patella, the left thigh measured 33 cm and the right 36 cm in circumference. The left leg showed a permanent flexion contracture of 25°, with further flexion to 140°. There was full range of flexion 0° to 150° on the right.

The temperature, pulse and respirations were normal.

The urine was normal. The blood hemoglobin was 15.5 gm, the white-cell count was 7000, with 66 per cent neutrophils. The blood cholesterol was 197 mg, the calcium 9.9 mg, the phosphorus 4.9 mg, and the phosphatase 5.9 units per 100 cc. The sedimentation rate was 19 mm per hour. The blood Hinton test was negative, as was a skin tuberculin test.

A roentgenogram of the left knee revealed an area of rarefaction, measuring 1.3 by 3.0 cm, in the region of the medial aspect of the femoral epiphysis and apparently crossing the epiphyseal line. Around the lesion was a sclerotic margin. The joint space appeared intact, and the articular surfaces were smooth. The lesion appeared to lie somewhat posteriorly. Roentgenograms of the spine, pelvis and upper extremities were normal. A subsequent scanogram confirmed the previous impression of a lesion in the medial aspect of the distal end of the femur with dissolution of bone on both sides of the epiphyseal line.

On the seventh hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR GRANTLEY W. TAYLOR: This patient presented an essentially negative examination except for what appeared to be a defect at the distal end of the femur. It seems as if the radiologist logically should present it instead of me, but I will be glad to look at the pictures and hazard a guess.

DR STANLEY M. WYMAN: The lesion, as described, lies in the medial portion of the distal end of the femur in the epiphysis and crosses very slightly the epiphyseal line. In the lateral aspect there is slight sclerosis about the margins of the defect, and the defect is sharply defined, although slightly irregular in contour. The oblique view shows the defect crossing the epiphyseal line somewhat better. There is no evidence of periosteal reaction. There is a soft-tissue mass.

The bones are not decalcified, and no other evidence of bone disease is apparent.

DR TAYLOR: We can be as elaborate or simple as we choose to be. We can start off by running through the infections—Brodie's abscess, osteo-

myelitis—or gumma. There are reasons against all these diagnoses, which I do not need to go into. The boy was not sick and never had been. There was no apparent disturbance of any vital functions, and the blood Hinton test was negative. The more recently described, perhaps infectious, process, called eosinophilic granuloma, should be alluded to just long enough to say that I do not know much about the disease. It is discovered from time to time, but chiefly by the pathologist. We operate on one of these lesions hoping to find out what it is, and the pathologist says that it is an eosinophilic granuloma. I do not know that it has characteristics in the radiogram that would do more than possibly raise that diagnosis. We have the cystic lesions of bone,—bone cysts occurring in the younger age groups in the shaft, in the metaphyses of the shaft, near the epiphyseal line,—and as the patients grow older the lesion moves closer to the middle of the bone, and the epiphysis grows away from it. We have such cysts as are present in parathyroid disease or fibrous dysplasia (Albright's syndrome). This bears no relation to that. Specific films of the other bones were taken to find out whether there was disease in the bones elsewhere, and they were normal. Other conditions that we ought to consider are xanthoma and Gaucher's disease. We need not do more than allude to them and pass them by.

We come very quickly to the conclusion that this must have been a tumor, and when one arrives at that point the decision must be made whether it was benign or malignant and, if malignant, whether primary in the femur or metastatic. The history is brief, but the history in a bone tumor, a large part of it, is frequently silent. It is not until symptoms begin to develop that one can date the onset. This boy had minor trauma, which drew attention to the knee, but the tumor may have existed for a long time before the trauma. There was impairment of function sufficient to cause atrophy of the thigh muscles but not bone atrophy. There is a little thickening in the soft tissues adjacent to the lesion, suggesting that perhaps with disturbed mechanics there was a little edema in a periosteal structure but no effusion in the joint. Boys of this age do not often have metastatic neoplasm. If they do, there is likely to be a primary focus, which betrays itself after careful investigation. Finally, metastatic disease would not present a picture comparable to this in that this bone lesion, whatever it was, had progressed in orderly fashion, with a zone of concentration of bone, suggesting an encapsulating process. That zone of encapsulation would work very much against a primary malignant lesion of the bone, such as osteogenic sarcoma, Ewing's tumor or lymphoma.

It seems to me that we come rapidly to the conclusion that this was a benign tumor involving this part of the bone, and then we can recapitulate the common types of bone tumor. One of the most re-

one might picture the patient as being quite depleted. As a matter of fact, he was a healthy, slightly obese, well nourished young man. He had had three sets of radiologic studies, but they were never able to demonstrate the involved area here. It was not until he got to the Baker Memorial that it was possible to displace the stomach upward and the small bowel laterally so that this area showed up. The important point that Dr. Jones brought out was that he had to be explored for duodenal ob-

FIGURE 1

struction. I shall simply point out that at exploration Dr. Allen found this mass to be more extensive than shown by x-ray examination. It extended for 10 cm. into the jejunum and 10 cm. into the duodenum, centering at the ligament of Treitz. We thought first of carcinoma and rather than any side-tracking procedure, a resection and duodeno-jejunosomy posterior to the transverse colon were done. Examination of the remainder of the small bowel revealed it to be normal down to the terminal ileum.

CLINICAL DIAGNOSIS

Regional enteritis

DR. JONES'S DIAGNOSIS

Adenocarcinoma of duodenojejunal junction

ANATOMICAL DIAGNOSIS

Regional enteritis of duodenum

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: This is a portion of the resected specimen showing the lesion at one end (Fig. 1). I

do not think it is 20 cm. in length. Allowing for some contraction after removal, I do not believe the entire lesion measures more than 10 cm. It appears to be entirely within the duodenum. It will be noticed that the wall is very thick and edematous, and the mucosa in the lesion is ulcerated in several places. The intervening mucosa is raised in verrucous formation. The appearance in gross corresponds to what we see in the ileum in regional enteritis. Microscopically, in the regions of the ulcerations there is much purulent exudate. Deeper in the wall is granulation tissue and a more chronic inflammatory reaction. The nerves in the wall of the bowel seemed very prominent with the infiltrate surrounding them, and I wonder if the pain may not in some way have been related to the severe infiltration around the nerves in the muscle layer. The serosa also shows an inflammatory reaction. As far as I can make out, this is a nonspecific reaction. There are a few areas that show epithelioid cells and an occasional giant cell, which is seen in regional enteritis. I do not believe it is tuberculosis. We have some material in a guinea pig, but it is still too early to find out. If this was regional enteritis, it is the first time we have seen it localized to the duodenum. I believe we have had one case in which the disease spread from some other region to the duodenum. The regional lymph nodes were chronically inflamed and did not show any of the granulomas sometimes seen in regional enteritis. I suppose this film demonstrates the string sign seen in regional enteritis.

DR. JONES: Yes, but that could be an infiltrating process of any sort, and if it were a lymphoma, ulceration could still occur. As I have already stated, a few cases have been reported of enteritis involving this area, but it is most unusual. Resection, of course, was the obvious move.

DR. CASTLEMAN: The patient was discharged home, apparently well.

CASE 35172

PRESENTATION OF CASE

A thirteen-year-old boy was admitted to the hospital because of stiffness in the left knee.

Four months before admission the patient injured the medial aspect of the left knee while playing football. There was no swelling or ecchymosis, and the injury was not severe enough to cause him to leave the game. One month later he noted the onset of stiffness and inability to extend the leg fully. There was no pain at rest or at night. Pain located over the left medial epicondyle became present when he first started walking but after he had gone 100 yards or so it disappeared.

The past and family histories were essentially noncontributory.

Physical examination revealed a well developed and well nourished boy in whom positive findings were limited to the left lower extremity. There were definite tenderness and moderate swelling over the medial epicondyle. There were no palpable bony masses. The joint line was not tender, and there was no fluid. Twenty centimeters above the patella, the left thigh measured 33 cm and the right 36 cm in circumference. The left leg showed a permanent flexion contracture of 25°, with further flexion to 140°. There was full range of flexion 0° to 150° on the right.

The temperature, pulse and respirations were normal.

The urine was normal. The blood hemoglobin was 15.5 gm, the white-cell count was 7000, with 66 per cent neutrophils. The blood cholesterol was 197 mg, the calcium 9.9 mg, the phosphorus 4.9 mg, and the phosphatase 5.9 units per 100 cc. The sedimentation rate was 19 mm per hour. The blood Hinton test was negative, as was a skin tuberculin test.

A roentgenogram of the left knee revealed an area of rarefaction, measuring 1.3 by 3.0 cm, in the region of the medial aspect of the femoral epiphysis and apparently crossing the epiphyseal line. Around the lesion was a sclerotic margin. The joint space appeared intact, and the articular surfaces were smooth. The lesion appeared to lie somewhat posteriorly. Roentgenograms of the spine, pelvis and upper extremities were normal. A subsequent scanogram confirmed the previous impression of a lesion in the medial aspect of the distal end of the femur with dissolution of bone on both sides of the epiphyseal line.

On the seventh hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR GRANTLEY W. TAYLOR: This patient presented an essentially negative examination except for what appeared to be a defect at the distal end of the femur. It seems as if the radiologist logically should present it instead of me, but I will be glad to look at the pictures and hazard a guess.

DR STANLEY M. WYMAN: The lesion, as described, lies in the medial portion of the distal end of the femur in the epiphysis and crosses very slightly the epiphyseal line. In the lateral aspect there is slight sclerosis about the margins of the defect, and the defect is sharply defined, although slightly irregular in contour. The oblique view shows the defect crossing the epiphyseal line somewhat better. There is no evidence of periosteal reaction. There is a soft-tissue mass.

The bones are not decalcified, and no other evidence of bone disease is apparent.

DR TAYLOR: We can be as elaborate or simple as we choose to be. We can start off by running through the infections — Brodie's abscess, osteo-

myelitis — or gumma. There are reasons against all these diagnoses, which I do not need to go into. The boy was not sick and never had been. There was no apparent disturbance of any vital functions, and the blood Hinton test was negative. The more recently described, perhaps infectious, process, called eosinophilic granuloma, should be alluded to just long enough to say that I do not know much about the disease. It is discovered from time to time, but chiefly by the pathologist. We operate on one of these lesions hoping to find out what it is, and the pathologist says that it is an eosinophilic granuloma. I do not know that it has characteristics in the radiogram that would do more than possibly raise that diagnosis. We have the cystic lesions of bone, — bone cysts occurring in the younger age groups in the shaft, in the metaphyses of the shaft, near the epiphyseal line, — and as the patients grow older the lesion moves closer to the middle of the bone, and the epiphysis grows away from it. We have such cysts as are present in parathyroid disease or fibrous dysplasia (Albright's syndrome). This bears no relation to that. Specific films of the other bones were taken to find out whether there was disease in the bones elsewhere, and they were normal. Other conditions that we ought to consider are xanthoma and Gaucher's disease. We need not do more than allude to them and pass them by.

We come very quickly to the conclusion that this must have been a tumor, and when one arrives at that point the decision must be made whether it was benign or malignant and, if malignant, whether primary in the femur or metastatic. The history is brief, but the history in a bone tumor, a large part of it, is frequently silent. It is not until symptoms begin to develop that one can date the onset. This boy had minor trauma, which drew attention to the knee, but the tumor may have existed for a long time before the trauma. There was impairment of function sufficient to cause atrophy of the thigh muscles but not bone atrophy. There is a little thickening in the soft tissues adjacent to the lesion, suggesting that perhaps with disturbed mechanics there was a little edema in a periosteal structure but no effusion in the joint. Boys of this age do not often have metastatic neoplasm. If they do, there is likely to be a primary focus, which betrays itself after careful investigation. Finally, metastatic disease would not present a picture comparable to this in that this bone lesion, whatever it was, had progressed in orderly fashion, with a zone of concentration of bone, suggesting an encapsulating process. That zone of encapsulation would work very much against a primary malignant lesion of the bone, such as osteogenic sarcoma, Ewing's tumor or lymphoma.

It seems to me that we come rapidly to the conclusion that this was a benign tumor involving this part of the bone, and then we can recapitulate the common types of bone tumor. One of the most re-

cent accretions to this category is osteoid osteoma I do not recall ever seeing that condition in the epiphyses. Characteristically, there is a punched-out area of bone, with some condensation around it, and invariably a careful search discloses a small condensation in the center, a little grainlike focus that is apparently the crux of the problem and the removal of which is accompanied by relief of symptoms. Benign cysts I referred to earlier as being in the shaft of the bone. The giant-cell tumor, it seems to me, must be seriously considered. Giant-cell tumors, arranged in relation to the epiphyses of the long bone, grow over into all the nooks and crannies of the joint surface, leaving a thin rim of bone. They grow by expansion and usually preserve an intact overlying periosteum for a long period. The x-ray appearance of giant-cell tumor is apt to show more trabeculation, which helps to identify it in the roentgenogram. Chondromas, not the osteochondromatosis but simple chondromas, are likely to occur in relation to cartilaginous plate, such as epiphyseal plate. They are much more common in the small bones of the hands and feet, and occasionally occur in the ends of the long bones, and also in the ribs and in the vertebrae. It seems to me that we have to consider that seriously. The characteristic arrangement is apt to show coarse trabeculation of bone as supporting it. I have never seen hemangiomas in this location, which does not mean they may not occur. They are much more common in the small or compact bones like the vertebrae. The growth is progressive and expansive and does not, as a rule, start a zone of protective reaction ahead of the tumor. Finally, the nonossifying fibroma must be considered — fibroma of the bone, with which this picture is entirely consistent. I think, from the point of view of the surgeon, one arrives at the conclusion that this was a benign tumor of bone and leaves to his colleague, the pathologist, the decision exactly what sort of tumor it is. Sometimes the radiologists will tell us unequivocally that this is thus and so — a tumor. I believe that is an esoteric art that they acquire and are incapable of communicating to me, although I strive to follow them by implication and inference from the films. I think this was a benign tumor of bone, probably fibroma or chondroma.

DR TRACY B MALLORY: Have you any comment on the x-ray films, Dr Wyman?

DR WYMAN: I should say that Dr Taylor has done a great deal better than his x-ray colleagues in this diagnosis. We thought of chronic infection, benign tumor and eosinophilic granuloma.

CLINICAL DIAGNOSIS

Bone cyst

DR TAYLOR'S DIAGNOSIS

Benign tumor of bone fibroma or chondroma

ANATOMICAL DIAGNOSIS

Benign chondroblastoma of femur

PATHOLOGICAL DISCUSSION

DR MALLORY: I think this is an example of a type of tumor that was first clearly recognized by Dr Codman¹ of the staff of this hospital, some eighteen years ago, which he called at that time chondromatous giant-cell tumor of bone and noted that it most commonly occurred in the head of the humerus. He was able to discover 8 cases in that area, many of which had been erroneously described as osteogenic sarcoma. More recently, Jaffe and Lichtenstein² have found that tumors of this type occur in other bones besides the humerus, perhaps almost with equal frequency. They disagreed with Dr Codman in his interpretation that this was an atypical form of giant-cell tumor and gave it the name of benign chondroblastoma of bone. They pointed out a number of characteristic features that it is always seen in young persons, usually between thirteen and twenty years of age — this boy just falls in at the lower end of their age scale — that there is frequently, though not invariably, a history of trauma as there was here, and that the lesion is always found in the epiphysis, very close to the epiphyseal line, although in about a quarter of the cases it crosses the epiphyseal line as this one did. From the x-ray point of view it is characteristically surrounded by a dense line of condensation of bone, as in the case under discussion. Histologically, the tumor simulates benign giant-cell tumor, but there are always certain atypical features: one is that the number of large giant cells is frequently slight compared with the typical giant-cell tumor, that the tumor cells tend to lay down a slightly basophilic intercellular matrix, which faintly suggests cartilage. Calcification develops focally in this matrix, and the neighboring tumor cells become necrotic. Finally, the necrotic focus heals by organization with a peculiar type of hyaline fibrous tissue, which again resembles poorly formed cartilage. This particular tumor shows all these various features. Whether or not Jaffe and Lichtenstein are correct in their interpretation of the lesion as a chondroblastoma, they have described a clinical and pathological entity. This case is beyond doubt a characteristic example.

"CAULDRON BUBBLE"

PROPOSED legislation bearing on the extension of medical services has been augmented by the introduction in Congress on March 30 of S1456, the "Voluntary Health Insurance Bill." This bill, which was introduced by Senator Lister Hill of Alabama, co-author of the familiar Hill-Burton Act, bore the additional signatures of Senators George D. Aiken of Vermont, O'Connor of Maryland, Withers of Kentucky and Morse of Oregon.

Patterned to some degree after the Hospital Survey and Construction Act, the Voluntary Health Insurance Bill seeks to employ the same methods in financing hospital and medical care that the Hill-Burton Act uses in the construction of new hospitals and health centers.

The purpose of the bill is "to make a high quality of hospital and medical care available to all persons in each state by (a) strengthening and co-ordinating existing health resources within the State, (b) encouraging and stimulating voluntary enrollment in prepayment plans for hospital and medical care, with emphasis on employer participation and on making such protection available to persons in rural areas, and (c) providing protection to persons financially unable to pay all or part of subscription charges for prepayment of hospital and medical care." The services to be rendered are to be furnished in a hospital, not in excess of sixty days in any year.

The financing of the Plan would be similar to that of the Hospital Survey and Construction Act of 1946, through federal grants and a variable percentage of funds from state and local sources, giving a greater percentage of aid to low-income states.

It is important to note that the program would be entirely in the hands of the state agency acting in consultation with a state hospital and medical-care council, and regional hospital and medical-care authorities within the state. This method of administration is already in effect in many states to carry out the provisions of the Hill-Burton Act.

Persons unable to pay the costs of medical and hospital care would have it made available through Government-supported membership in nonprofit, prepayment health-insurance programs. Since these recipients would not be identified as the beneficiaries of governmental assistance, their anonymity would be safeguarded, they would be spared the "indignity of a means test."

The Voluntary Health Insurance Bill, whether or not it is enacted, represents a relatively conservative step down the road of socialization to which the whole world is committed. Such a step would have been bitterly opposed by all conservative elements ten years ago, and with reason. Today it is viewed with comparative equanimity. The times, the customs, the viewpoints of people change. The attitude of critics who today decry the conservatism of a decade ago shows in itself a reluctance to recognize progress in other camps than their own.

Dr. Channing Frothingham, of Boston, chairman of the Committee for the Nation's Health and

cent accretions to this category is osteoid osteoma. I do not recall ever seeing that condition in the epiphyses. Characteristically, there is a punched-out area of bone, with some condensation around it, and invariably a careful search discloses a small condensation in the center, a little grainlike focus that is apparently the crux of the problem and the removal of which is accompanied by relief of symptoms. Benign cysts I referred to earlier as being in the shaft of the bone. The giant-cell tumor, it seems to me, must be seriously considered. Giant-cell tumors, arranged in relation to the epiphyses of the long bone, grow over into all the nooks and crannies of the joint surface, leaving a thin rim of bone. They grow by expansion and usually preserve an intact overlying periosteum for a long period. The x-ray appearance of giant-cell tumor is apt to show more trabeculation, which helps to identify it in the roentgenogram. Chondromas, not the osteochondromatosis but simple chondromas, are likely to occur in relation to cartilaginous plate, such as epiphyseal plate. They are much more common in the small bones of the hands and feet, and occasionally occur in the ends of the long bones, and also in the ribs and in the vertebrae. It seems to me that we have to consider that seriously. The characteristic arrangement is apt to show coarse trabeculation of bone as supporting it. I have never seen hemangiomas in this location, which does not mean they may not occur. They are much more common in the small or compact bones like the vertebrae. The growth is progressive and expansive and does not, as a rule, start a zone of protective reaction ahead of the tumor. Finally, the nonossifying fibroma must be considered — fibroma of the bone, with which this picture is entirely consistent. I think, from the point of view of the surgeon, one arrives at the conclusion that this was a benign tumor of bone and leaves to his colleague, the pathologist, the decision exactly what sort of tumor it is. Sometimes the radiologists will tell us unequivocally that this is thus and so — a tumor. I believe that is an esoteric art that they acquire and are incapable of communicating to me, although I strive to follow them by implication and inference from the films. I think this was a benign tumor of bone, probably fibroma or chondroma.

DR. TRACY B. MALLORY: Have you any comment on the x-ray films, Dr. Wyman?

DR. WYMAN: I should say that Dr. Taylor has done a great deal better than his x-ray colleagues in this diagnosis. We thought of chronic infection, benign tumor and eosinophilic granuloma.

CLINICAL DIAGNOSIS

Bone cyst

DR. TAYLOR'S DIAGNOSIS

Benign tumor of bone fibroma or chondroma

ANATOMICAL DIAGNOSIS

Benign chondroblastoma of femur

PATHOLOGICAL DISCUSSION

DR. MALLORY: I think this is an example of a type of tumor that was first clearly recognized by Dr. Codman¹ of the staff of this hospital, some eighteen years ago, which he called at that time chondromatous giant-cell tumor of bone and noted that it most commonly occurred in the head of the humerus. He was able to discover 8 cases in that area, many of which had been erroneously described as osteogenic sarcoma. More recently, Jaffe and Lichtenstein² have found that tumors of this type occur in other bones besides the humerus, perhaps almost with equal frequency. They disagreed with Dr. Codman in his interpretation that this was an atypical form of giant-cell tumor and gave it the name of benign chondroblastoma of bone. They pointed out a number of characteristic features that it is always seen in young persons, usually between thirteen and twenty years of age — this boy just falls in at the lower end of their age scale — that there is frequently, though not invariably, a history of trauma as there was here, and that the lesion is always found in the epiphysis, very close to the epiphyseal line, although in about a quarter of the cases it crosses the epiphyseal line as this one did. From the x-ray point of view it is characteristically surrounded by a dense line of condensation of bone, as in the case under discussion. Histologically, the tumor simulates benign giant-cell tumor, but there are always certain atypical features. One is that the number of large giant cells is frequently slight compared with the typical giant-cell tumor, that the tumor cells tend to lay down a slightly basophilic, intercellular matrix, which faintly suggests cartilage. Calcification develops focally in this matrix, and the neighboring tumor cells become necrotic. Finally, the necrotic focus heals by organization with a peculiar type of hyaline fibrous tissue, which again resembles poorly formed cartilage. This particular tumor shows all these various features. Whether or not Jaffe and Lichtenstein are correct in their interpretation of the lesion as a chondroblastoma, they have described a clinical and pathological entity. This case is beyond doubt a characteristic example.

JOSEPH VON MERING (1849-1949)

FEBRUARY 28 marked the hundredth birthday anniversary of Joseph von Mering. He belonged to that group of German clinicians who like Naunyn, F von Müller and Minkowski were responsible to a high degree for the great progress in experimental pathology at the end of the nineteenth and the beginning of the twentieth century. He had an excellent medical education. Hoppe-Seyler introduced him to biochemistry, Ludwig was his teacher in physiology. He worked with Goltz on neurologic problems. He was Frerich's assistant in the medical clinic of the University of Berlin. Mering became privatdozent and assistant professor at Strassburg under Kussmaul and later director of the medical polyclinic and medical clinic of the university in Halle. There he died in 1908. His knowledge of medicine was remarkable. He taught pharmacology, legal medicine, laryngology and internal medicine. Twice he was offered a chair in pharmacology and was also nominated by the faculty of the University of Vienna as successor of Stricker in the post of professor of experimental pathology.

Mering's scientific work includes three main spheres: the investigations on diabetes mellitus, the connection between chemical constitution and effect of hypnotic drugs and the conditions of absorption in the stomach. In 1886 he discovered the phlorhizin diabetes, and in 1889 he published with Minkowski the first paper on experimental pancreatic diabetes. His experimental work on the constitution and effect of narcotics started with studies on chloral hydrate and was crowned with the discovery of veronal, which he made when working with Emil Fischer. His investigations on the physiology of absorption from the intestine yielded fundamental knowledge about the absorption of water, sugar, dextrin and peptones from the stomach.

In his textbook of internal medicine, which he edited with Krehl, he tried for the first time to apply the principles of the great encyclopedic handbooks to a short textbook, and he did it successfully, as the great number of editions of this textbook proves.

"EEG JOURNAL"

IN FEBRUARY of this year the medical journals of the world had the opportunity and the privilege of welcoming into their austere ranks the newest comer of them all — *Electroencephalography and Clinical Neurophysiology*. The official organ of the International Federation of EEG Societies, this quarterly international journal would represent almost the ultimate degree in specialization were it not for its broader scope. This breadth of interest allows it to include 'any aspect of the physiology of the nervous system or neuromuscular system which may contribute to progress in our understanding of the neural basis of behaviour'.

As stated at its masthead its purpose is threefold

to provide an official organ for the various EEG Societies being established throughout the world, to bring together in one publication selected studies of merit in the growing field of neurophysiology as applied to the understanding of human behaviour, both normal and abnormal, and to foster international co-operation and understanding among scientists with these common interests.

Any newcomer to the journalistic field — as well as the old-timers — must see to it that the saddle girth is tightened and the stirrups adjusted, for there may be a rough ride ahead. "The EEG Journal," however, has been launched under good auspices and with excellent backing. The editor is Herbert H. Jasper, of Montreal, the co-editor, W. Grey Walter, of Bristol, England, and the managing editor, Robert S. Schwab, of Boston. The editorial board is representative of the civilized world. The publication office is in the charge of Dr. Schwab at the Massachusetts General Hospital.

The first number is concerned largely with a symposium on the physiologic basis of epileptic discharge delivered at the annual meeting of the American Electroencephalographic Society in June, 1948. May success crown its continuing efforts!

a former president of the Massachusetts Medical Society, calls the Hill bill, according to *Washington Report on the Medical Sciences*, "either a fraud on the American people or a proposal to appropriate billions of dollars out of the Treasury without any assurance that it will provide adequate medical care."

Even as this issue of the *Journal* goes to press, Senators Taft of Ohio, Smith of New Jersey and Donnell of Missouri have introduced their own national health bill. This also calls for federal aid to states, instead of compulsory insurance.

It is anticipated that the next few months will witness considerable controversy over the Nation's health.

BOSTON LYING-IN HOSPITAL

THE function of the voluntary teaching hospital in making available special services that usually accompany the more recent advances in medical knowledge and technics has always been considered one of the major contributions that large medical centers can make to improve medical care. In these times when there is a great desire to change the mode of medical practice, it is well to examine the extent to which the teaching hospital is able to contribute to the medical services of a community, for one might question whether these services have been completely utilized under the present system. The availability of the services is often not adequately appreciated by either the practicing physicians or the neighboring hospitals. This idea is especially prevalent regarding the specialty hospital, for in the minds of the practicing physicians these institutions are capable of rendering only one type of medical service. Frequently, such attitudes are due to the fact that the teaching hospitals have not informed the medical community of the character and scope of the services that they have to offer.

A more co-operative effort between institutions in attempting to solve complicated medical problems should produce a wider distribution of medical care and should provide additional opportunity for the accumulation and dissemination of medical knowledge. The branch of medicine concerned with maternal and child health affords an excellent opportunity for such a co-operative effort.

During the past two decades a gratifying reduction in maternal mortality and morbidity has occurred,

with a parallel improvement in the mortality rate in the newborn. This result has been due in large measure to an increase in hospital facilities and in trained personnel. This has been reflected by an improved quality of prenatal care and the provision of the proper hospital surroundings to cope with the complicated obstetric emergency. These services must continue. However, a further reduction of maternal and fetal mortality and morbidity will depend on a more careful screening of the obstetric patient with chronic problems and to anticipate and provide the specialized care that she and her infant may demand. It is obvious that with this general improvement in the maternal mortality rate the chronic patient will contribute a greater percentage of the mortality of the future. In addition, many patients with other conditions such as infertility, premature labor, abortion, Rh sensitivity and certain gynecologic disorders related to pregnancy and those with possible labor dystocia should have available the benefits of specialized diagnostic and therapeutic aids to ensure the best in present-day medical care.

The Boston Lying-in Hospital has over the years developed special clinics devoted to these problems. Clinics are available for the supervision of the cardiac, diabetic, urologic and toxemic patient, as well as those with possible labor dystocia. Recent figures released by the Children's Bureau have shown that this hospital has developed a method of care that has produced the lowest mortality among premature infants of any large maternity hospital in the country. In this institution replacement transfusions for the treatment of infants with erythroblastosis was first carried out in New England.

Believing that the voluntary teaching hospital has an even greater future in aiding the distribution of medical care and knowledge, this institution has recently completed a successful campaign to obtain the funds necessary to create facilities for the provision of consultation services as well as additional space to be devoted for teaching and research. It is hoped that physicians throughout New England will utilize these consultation services for the benefit of their patients. It is believed that only in this manner can any teaching institution such as the Boston Lying-in Hospital fulfill its obligations to the medical welfare of the area that it serves.

JOSEPH VON MERING (1849-1949)

FEBRUARY 28 marked the hundredth birthday anniversary of Joseph von Mering. He belonged to that group of German clinicians who like Naunyn, von Müller and Minkowski were responsible to a high degree for the great progress in experimental pathology at the end of the nineteenth and the beginning of the twentieth century. He had an excellent medical education. Hoppe-Seyler introduced him to biochemistry, Ludwig was his teacher in physiology. He worked with Goltz on neurologic problems. He was Frerich's assistant in the medical clinic of the University of Berlin. Mering became privatdozent and assistant professor at Strassburg under Kussmaul and later director of the medical polyclinic and medical clinic of the university in Halle. There he died in 1908. His knowledge of medicine was remarkable. He taught pharmacology, legal medicine, laryngology and internal medicine. Twice he was offered a chair in pharmacology and was also nominated by the faculty of the University of Vienna as successor of Stricker in the post of professor of experimental pathology.

Mering's scientific work includes three main spheres: the investigations on diabetes mellitus, the connection between chemical constitution and effect of hypnotic drugs and the conditions of absorption in the stomach. In 1886 he discovered the phlorhizin diabetes, and in 1889 he published with Minkowski the first paper on experimental pancreatic diabetes. His experimental work on the constitution and effect of narcotics started with studies on chloral hydrate and was crowned with the discovery of veronal, which he made when working with Emil Fischer. His investigations on the physiology of absorption from the intestine yielded fundamental knowledge about the absorption of water, sugar, dextrin and peptones from the stomach.

In his textbook of internal medicine, which he edited with Krehl, he tried for the first time to apply the principles of the great encyclopedic handbooks to a short textbook, and he did it successfully. As the great number of editions of this textbook proves

"EEG JOURNAL"

IN FEBRUARY of this year the medical journals of the world had the opportunity and the privilege of welcoming into their austere ranks the newest comer of them all — *Electroencephalography and Clinical Neurophysiology*. The official organ of the International Federation of EEG Societies, this quarterly international journal would represent almost the ultimate degree in specialization were it not for its broader scope. This breadth of interest allows it to include "any aspect of the physiology of the nervous system or neuromuscular system which may contribute to progress in our understanding of the neural basis of behaviour."

As stated at its masthead its purpose is threefold

to provide an official organ for the various EEG Societies being established throughout the world, to bring together in one publication selected studies of merit in the growing field of neurophysiology as applied to the understanding of human behaviour, both normal and abnormal, and to foster international co-operation and understanding among scientists with these common interests

Any newcomer to the journalistic field — as well as the old-timers — must see to it that the saddle girth is tightened and the stirrups adjusted, for there may be a rough ride ahead. "The EEG Journal," however, has been launched under good auspices and with excellent backing. The editor is Herbert H. Jasper, of Montreal, the co-editor, W. Grey Walter, of Bristol, England, and the managing editor, Robert S. Schwab, of Boston. The editorial board is representative of the civilized world. The publication office is in the charge of Dr. Schwab at the Massachusetts General Hospital.

The first number is concerned largely with a symposium on the physiologic basis of epileptic discharge delivered at the annual meeting of the American Electroencephalographic Society in June, 1948. May success crown its continuing efforts!

MASSACHUSETTS MEDICAL SOCIETY

COMMENT

DEATHS

COBB — Oliver W Cobb, M D, of Northampton, died on April 6. He was in his ninety-first year.

Dr Cobb received his degree from University of Virginia Department of Medicine in 1897. He was a former president of Hampshire District Medical Society, councilor of the Massachusetts Medical Society and a member of the medical staff of Cooley-Dickinson Hospital. He was an affiliate fellow of the American Medical Association.

Two sons, five grandchildren and two great-grandchildren survive.

DRAKE — Richard A Drake, M D, of Marshfield, died on April 8. He was in his seventy-first year.

Dr Drake received his degree from Harvard Medical School in 1902. He was a member of the staff of Lawrence Memorial Hospital and was formerly city physician in Medford.

His widow and three daughters survive.

ROE — John C Roe, M D, of Pittsfield, died on March 13. He was in his sixtieth year.

Dr Roe received his degree from Georgetown University School of Medicine in 1915. He was chief of the surgical staff at Pittsfield Hospital and was formerly associate medical examiner of Berkshire District. He was a fellow of the American College of Surgeons and American Medical Association and was a member of the staffs of St Luke's and Hillcrest hospitals in Pittsfield, Fairview Hospital in Great Barrington and W B Plunkett Memorial Hospital in Adams.

His widow, four sons and three daughters survive.

NEW HAMPSHIRE MEDICAL SOCIETY

DEATH

ADAMS — Charles W Adams, M D, of Franklin, died on March 12. He was in his eighty-sixth year.

Dr Adams received his degree from Boston University School of Medicine in 1884. He was one of the founders of the Franklin Hospital and had served on the State Medical Board and Franklin Board of Health.

A son, two grandchildren and three great-grandchildren survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

COMMUNICABLE DISEASES IN MASSACHUSETTS FOR MARCH, 1949

RÉSUMÉ

DISEASE	MARCH 1949	MARCH 1948	SEVEN-YEAR MEDIAN
Chancroid	7	4	2*
Chicken pox	4026	2405	1793
Diphtheria	41	21	20
Dog bite	964	864	790
Dysentery bacillary	4	9	9
German measles	892	119	316
Gonorrhea	274	215	327
Granuloma inguinale	0	0	0*
Lymphogranuloma venereum	3	1	2*
Malaria	0	7	8
Measles	6550	4205	3245
Meningitis, meningococcal	8	6	21
Meningitis, Pfeiffer-bacillus	0	4	2
Meningitis, pneumococcal	4	2	0
Meningitis staphylococcal	0	0	0
Meningitis streptococcal	0	1	7
Meningitis undetermined	4	5	1575
Mumps	1788	2522	1575
Polio-myelitis	0	0	2
Salmonellosis	2	4	8
Scarlet fever	1215	703	1457
Syphilis	218	226	443
Tuberculosis pulmonary	180	227	230
Tuberculosis other forms	12	25	20
Typhoid fever	0	1	1
Undulant fever	7	4	4
Whooping cough	319	241	645

*Five-year median

Diseases above the seven-year median were chicken pox, diphtheria, German measles, measles, mumps and undulant fever.

Diseases below the seven-year median were bacillary dysentery, meningitis (all types), salmonellosis, scarlet fever and whooping cough.

For the sixth consecutive month chicken pox was at the highest level ever reported. German measles was at the highest it has been since the epidemic year 1943. The incidence of measles was the highest in March except for the record year 1934, when there were 9891 cases during the month. Only once since 1934 has diphtheria been higher for the month of March.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anthrax was reported from Newton, 1, Somerville, 1, total, 2.

Diphtheria was reported from Billerica, 1, Boston, 23, Brookline, 1, Chelsea, 1, Danvers, 2, East Brookfield, 5, Everett, 1, Fall River, 1, Malden, 1, Newton, 1, Revere, 1, Rockport, 1, Somerville, 1, Spencer, 1, total, 41.

Dysentery, amebic, was reported from Danvers, 1, total, 1. Dysentery, bacillary, was reported from Wrentham, 4, total, 4.

Encephalitis, infectious, was reported from Brockton, 1, Quincy, 2, total, 3.

Infectious hepatitis was reported from Boston, 2, Springfield, 1, Williamstown, 1, Worcester, 1, Wrentham, 3, total, 8.

Lymphocytic choriomeningitis was reported from Cambridge, 1, total, 1.

Meningitis, meningococcal, was reported from Cambridge, 2, Everett, 1, Fall River, 2, Hadley, 1, Lawrence, 1, Palmer, 1, total, 8.

Meningitis, pneumococcal, was reported from Lawrence, 1, Quincy, 1, Salem, 1, Worcester, 1, total, 4.

Meningitis, undetermined, was reported from Fall River, 1, Hanover, 1, Northbridge, 1, Randolph, 1, total, 4.

Salmonellosis was reported from Wellesley, 2, total, 2.

Septic sore throat was reported from Boston, 8, Lynn, 2, Swampscott, 1, Taunton, 1, Worcester, 8, total, 20.

Trichinosis was reported from Boston, 3, Cambridge, 1, Quincy, 1, Westwood, 1, total, 6.

Undulant fever was reported from Bridgewater, 1, Malden, 1, Newton, 1, Pembroke, 1, Sandwich, 1, Swansea, 1, Wilmington, 1, total, 7.

MISCELLANY

WOMAN'S AUXILIARY, SUFFOLK DISTRICT

At its annual meeting on April 7, the Woman's Auxiliary of the Suffolk District Medical Society elected the following officers and committee chairmen for 1949-1950: president, Mrs Joseph Garland, vice-president, Mrs Roger I Lee, secretary, Mrs J Martin Woodall, treasurer, Mrs Charles G Shedd, director for one year, Mrs Harvey A Kelly, director for two years, Mrs Donald Munro, and director for three years, Mrs Thomas H Lanman. The chairmen of the various committees are Mrs David J Calcechio (membership), Mrs Raymond A Dillon (program), Mrs Howard F Root (legislation), Mrs James P O'Hare (health education), Mrs Albert A Hornor (public relations) and Mrs Merrill C Sosman (hospitality).

CORRESPONDENCE

CONSULTATIVE SERVICE IN OBSTETRICS

To the Editor The following letter, which is being sent to the chief of staff of those community hospitals within a reasonable radius of Boston that have no formal obstetric service, is self-explanatory.

Dear Dr —

It is the desire of the Boston Lying-in Hospital to increase its medical service to physicians and their obstetric patients throughout New England. This letter is concerned with the possible need for and the desirability of establishing free medical consultation service at the Boston Lying-in Hospital for the complicated obstetric case, should the attending physician so desire it. We are now

in the process of improving the hospital's facilities. Special attention is being given to the enlarging of the outpatient department. This will allow for more adequate housing of the cardiac, diabetic, urologic, toxicologic, dystocia and Rh clinics, as well as many ancillary services. These clinics will be supervised by physicians who are eminent in their fields, and many are no doubt familiar to you. Naturally, since the hospital is a teaching institution, the resident staff will also be closely associated with the care of patients in these clinics.

To enhance the educational value of the institution to the community, we thought that members of your staff might be interested in the treatment of the complicated cases as they occur here at the hospital. It might be desirable to hold meetings from time to time at the hospital when certain obstetric topics would be discussed or a periodic review of the treatment of the complicated cases could be presented. We wish you would question your staff regarding the need for such consultation service and meetings. We would appreciate your opinion on these matters.

DUNCAN E. REIN, M.D.
Obstetrician-in-Chief

Boston Living-in Hospital

BOOK REVIEW

The Physicians of Essex County. By Russell L. Jackson. With a foreword by Harold Bowditch, M.D. 8°, cloth, 152 pp., with 12 illustrations and frontispiece. Salem, Massachusetts: The Essex Institute, 1948.

In the Essex Institute in Salem, Massachusetts, is a vast collection of material on doctors who were born in or who subsequently lived in Essex County. Much has found its way into print in the last eighty-four years in the Essex Institute Historical Collections, but a greater amount remains unpublished in papers, diaries and memoirs. The present director of the Institute has cast a wide net to catch the vital facts about the County physicians, many without medical degrees, others ministers of the Gospel, who practiced their art from the early seventeenth century to 1840. The list is a long one, has been carefully compiled, with appropriate references to sources of information. Most of the notices are short, — only a few lines, — but others of more famous personages comprise even a page or more. A few illustrations accompany the text, unfortunately without reference to their source. The brief biographic notes are listed alphabetically, but there is also an extensive index. Mr. Jackson has produced a sound, biographic study, gracefully acknowledged in the Introduction by Dr. Harold Bowditch, long a devoted student of medical history.

NOTICES

ANNOUNCEMENTS

Dr. Charles Djerf announces the opening of his office at 1200 Hancock Street, Quincy, for the practice of pediatrics.

Dr. Walter J. McDonough announces the opening of his office for the practice of diseases of the skin at 270 Commonwealth Avenue, Boston.

JOHN T. BOTTOMLEY MEDICAL SOCIETY

A meeting of the John T. Bottomley Medical Society will be held in the auditorium of the Carney Hospital on May 2 from 11:30 a.m. to 1:00 p.m. Dr. Herbert G. Finn will speak on the subject "Treatment of Cancer of the Skin." Drs. Morris Shapiro and Robert Grandfield will lead the discussion.

Physicians and medical students are cordially invited.

SUFFOLK DISTRICT MEDICAL SOCIETY

The annual meeting of the Suffolk District Medical Society will be held in Ware Hall, Boston Medical Library, 8 Fenway, Boston, on Wednesday, May 4, at 4:30 p.m.

There will be a meeting of the councilors of Suffolk District Medical Society on the same day and place at 3:30 p.m.

AGENDA

- Call to order by the President
- Reports of committees
- Consideration of an annual assessment
- Unfinished business
- Blue Shield and Blue Cross Affairs
Charles G. Hayden, M.D.
- Report of Massachusetts Medical Society Affairs
H. Quimby Gallupe, M.D.
- Such other business as may properly be brought before the Society
- Adjournment

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children, will be held in the classroom of the Nurses' Residence on Thursday, May 5, at 7:15 p.m. Dr. Edward L. Young will speak on the subject "Liver Abscesses as Complication of Biliary Surgery." Dr. Gulh. Lindh Muller will be chairman.

MASSACHUSETTS GENERAL HOSPITAL

A research meeting will be held in the Bigelow Amphitheater of the Massachusetts General Hospital on Friday, May 6, at 4 p.m.

PROGRAM

- New Drugs in the Treatment of Parkinson's Disease
Dr. Robert Schwab
- The Pathologic Distribution of Water and Electrolytes in Patients after Duodenal Ulcer
Dr. Oliver Cope

BOSTON UNIVERSITY SCHOOL OF MEDICINE ALUMNI ASSOCIATION

The seventy-fifth annual reunion of Boston University School of Medicine Alumni Association will be held in the auditorium of the School of Medicine, 80 East Concord Street, Boston, on Friday, May 6.

The morning session, which will be held from 10:30 a.m. to 12:30 p.m., will be as follows:

- Some Problems Concerned with the Diagnosis and the Course of Prolonged Fever
Samuel Leard, M.D. (1942)
- Pharmacologic Approach to the Treatment of Neurogenic Disorders
Frederick F. Youlman, M.D. (1939)
- Melography — Indications and Significance
John D. Camp, M.D. (1922), assistant director, Section of Roentgenology, Mayo Clinic, Rochester, Minnesota
- Hormonal Alteration of Carcinoma of the Breast
Ira T. Nathanson, M.D.
- Seminoma of the Testicle Followed by Adenocarcinoma of the Breast
Presentation of case
Frank E. Barton, M.D. (1924)

Luncheon will be served at 1:00 p.m. in the main dining room, eighth floor, Evans Memorial Building, 65 East Newton Street (price, 75 cents). Luncheon tickets will be available at the School of Medicine Auditorium.

The afternoon session, which will be held from 2 to 4 p.m., will be as follows:

- Stump the Experts — Round-Table Discussion
Moderator, Samuel Vose, M.D.
- Chester S. Keefer, M.D. (Medicine)
- Reginald H. Smithwick, M.D. (Surgery)
- Leighton F. Johnson, M.D. (Otolaryngology)
- William Malamud, M.D. (Psychiatry)
- Joseph M. Foley, M.D. (Neurology)
- Donald G. Anderson, M.D. (Education, American Medical Association)
- Louis G. Howard, M.D. (Orthopedics)

Newer Antibiotic Agents, with Emphasis on Aureomycin and Chloromycetin William Hewitt, M D
 Pharmacologic Tests and Diagnosis of Tumor of the Adrenal Gland Causing Paroxysmal Hypertension William E R Greer, M D (1943)

HARVARD MEDICAL SOCIETY

A meeting of the Harvard Medical Society will be held in the amphitheater of Building D, Harvard Medical School, on Tuesday, May 10, at 8 00 p m The following program will be presented by the Department of Pharmacology, Harvard Medical School

Plasma Prostugmine Levels and Cholinesterase Inhibition in Dogs and Myasthenic Patients Avram Goldstein
 Iodide Excretion in Dog and Man Douglas S Riggs and John B Stanbury
 Effect of Cardiac Glycosides on Cardiac Tissue Metabolism Albert Wollenberger
 Action of Pure Veratrum Alkaloids in Human Hypertension Edward Meilman and Otto Krayer
 Antagonists to the Cardioaccelerator Action of Epinephrine Otto Krayer

NEW ENGLAND SOCIETY OF ANESTHESIOLOGISTS

A meeting of the New England Society of Anesthesiologists will be held in the auditorium of Building A, Boston University School of Medicine, 80 East Concord Street, Boston, on Tuesday, May 10, at 8 p m The scientific program will be as follows

Heart Disease and Anesthesia Dr S Gilman
 Subarachnoid Ephedrine Drs E Marchand and S Gilman
 Some Observations on Anesthesia in Uremia Dr A Abrams

Physicians and medical students are invited

NORFOLK DISTRICT MEDICAL SOCIETY

The annual meeting of the Norfolk District Medical Society will be held at the Hotel Kenmore, Boston, on Wednesday, May 11

PROGRAM

5 15 p m Business meeting Embassy Room
 6 00 p m President's Reception Social Hour
 7 00 p m Annual Dinner Crystal Ball Room
 Acceptance Speech W Richard Ohler, M D, incoming president
 Greetings from the Massachusetts Medical Society Daniel B Reardon, M D, president
 Remarks on Woman's Auxiliary Mrs James J Hepburn, president
 Erwin D Canham, editor of the *Christian Science Monitor*, will speak on "The Role of the Press in the Present World Crisis"

SOUTH BOSTON MEDICAL SOCIETY

The annual dinner of the South Boston Medical Society will be held at the Harvard Club of Boston on Wednesday, May 11, at 6 30 p m The speaker will be Dr Norman Welch

HARVARD SCHOOL OF PUBLIC HEALTH

The Harvard School of Public Health announces that the Cutter Lecture on Preventive Medicine, initiated in 1917, will be held in Amphitheater D of the Harvard Medical School on Wednesday, May 11, 1949, at 5 p m Dr James C Spence, professor of child health, University of Durham, England, will speak on "Preventive Medicine The role of parents in child health" The medical profession, medical and public-health students and others interested are cordially invited to attend

MASSACHUSETTS SOCIETY OF EXAMINING PHYSICIANS

A meeting of the Massachusetts Society of Examining Physicians will be held at the Harvard Club, Boston, on Wednesday, May 11, at 7 p m Dr Donald Munro will speak on the subject "Total Rehabilitation of the Paraplegic Patient," with a film presentation

AMERICAN ORTHOPAEDIC ASSOCIATION

The sixty-second annual meeting of the American Orthopaedic Association will be held at the Broadmoor, Colorado Springs, Colorado, on May 18, 19, 20 and 21, under the presidency of Dr Ralph K Ghormley

The orthopedic surgeons of Denver, with Drs Robert G Packard and Atha Thomas as chairmen, have planned a clinical day in Denver on May 17 All members of the Association and their guests are invited Those planning to attend are requested to notify Dr Packard or Dr Thomas in advance, so that adequate arrangements may be made

SAMUEL D GROSS PRIZE

Essays will be received in competition for the Samuel D Gross Prize of \$1500 until January 1, 1950 The conditions annexed by the testator are the prize "shall be awarded every five years to the writer of the best original essay, not exceeding one hundred and fifty printed pages, octavo, in length, illustrative of some subject in Surgical Pathology, or Surgical Practice founded upon original investigations, the candidates for the prize to be American citizens" It is expressly stipulated that the competitor who receives the prize shall publish his essay in book form, and that he shall deposit one copy of the work in the Samuel D Gross Library of the Philadelphia Academy of Surgery, and that on the title page it shall be stated that the essay was awarded the Samuel D Gross Prize of the Philadelphia Academy of Surgery

The essays, which must be written by a single author in the English language, should be sent to the Trustees of the Samuel D Gross Prize of the Philadelphia Academy of Surgery

(Notices concluded on page xiii)

A DECADE'S EXPERIENCE IN THE OPERATION OF A GROUP MEDICAL-CARE ORGANIZATION*

SEYMOUR ETKIN, M.A.

WASHINGTON, D. C.

THE National Health Assembly, which met last summer in Washington, D. C., reached agreement on everything except the question of national compulsory health insurance. Among the subjects agreed on was the proposal that voluntary prepayment was a sound method for financing health services.

Ten years ago such an agreement would have been impossible. At that time a storm raged within and without the medical profession over the question of prepaid health programs. The focal point of the storm was Group Health Association of Washington, D. C., a medical-care organization operating on the principles of group medical practice and the prepaid method of financing. Ten years ago programs of the type represented by Group Health Association were attacked as being forerunners of "socialized medicine." Today these programs are generally supported by all who are concerned with bringing medical care of the highest standard within the reach of all.

This article is a description and an analysis of the experience of Group Health Association from 1938 through 1947. In many respects the record is notable. Yet it is not without its shortcomings. No honest student of social welfare can afford to minimize them. It is my opinion that an honest appraisal of this experience will provide guidance to future changes in the organization of medical programs.

When the Association was organized in 1937, predictions concerning its future were of two kinds. One camp predicted that it would rapidly fold up and that its doctors would become outcast members of the medical profession. The other prophesied that this prepaid type of medical care would sweep the nation's capital because of its low-cost provisions and ensnare all the physicians in a monster octopus of regimentation and bureaucracy.

Actually, neither has happened. The Association is a respectable community organization attracting respectable residents of the Washington area to membership. Its physicians are accorded the same privileges in hospitals as other doctors in the District of Columbia and surrounding area. They have similar social status. They teach at the local universities. They are members in good standing in the District of Columbia Medical Society and the American Medical Association. Many of them have private practices, devoting only part of their time to Group Health Association member patients.

OPERATION OF MEDICAL SERVICE

The medical-service plan operates in this manner: members purchase a membership certificate and pay monthly dues. In return, with certain limitations and exceptions, members have a "blank check" on the medical services by Group Health. These services include diagnosis and treatment of ailments, major and minor surgical operations, use of facilities such as x-ray and laboratory procedures, and physical therapy. Members may avail themselves of physical checkups and other preventive care. Child care and obstetric service are provided. Eye examinations are given. Members may purchase lenses and frames through the Association at a reduced cost, and they may obtain prescriptions, drugs, vitamins and other pharmaceutical supplies at the pharmacies at a saving.

There are two types of membership: full service and nonhospitalization. Those who have full service pay larger monthly dues than those who have nonhospitalization memberships. Full-service members are eligible to receive hospitalization when necessary for sixty days in any calendar year, or in any one illness or condition, or continuous period of hospitalization. This includes a semiprivate room, general nursing, use of the operating or delivery room, services of the anesthetist, dressings and most medications, routine laboratory examinations, nursing care, emergency-room facilities and the use of an ambulance as requested by the attending physician.

*Nothing in this article is to be construed as an official pronouncement of the Bureau of the Census.

†Economist, Bureau of the Census, United States Department of Commerce; formerly member of administrative staff, Group Health Association.

A nonhospitalization member is entitled to all the services except the hospital services mentioned above

Changes in Benefits

Over the course of the Association's history, two divergent trends in the scope of benefits under its service program have appeared. One is toward more and more restrictions and limitations, and the other is toward greater liberalization of its program.

Restrictive trend When the first set of by-laws was adopted on March 22, 1937, there were relatively few restrictions on service. Only two impor-

The first set of by-laws restricted house calls within a radius of ten miles of the center of the District of Columbia. At the present time the radius is fifteen miles.

Other examples of liberalization of the service program are night clinics (tried for a time but discontinued), delivery service of pharmacy supplies, night telephone service, discount of 5 per cent for a year's prepayment of dues and 2 per cent for six months' prepayment, routine physical examinations encouraged, service to refugee children without cost, early infant-care classes and prenatal classes (not in operation at the present time), members drafted

TABLE 1 *Partial List, Showing Development of Restrictions on Services Provided by Group Health Association*

EFFECTIVE DATE	RESTRICTION	SOURCE
1937	Medical service not to include treatment of industrial accidents; operations on the brain or nervous system; mental cases; tuberculosis; drug or alcohol addiction.	<i>Minutes</i> , Board of Trustees, April 6, 1937
	Members to pay for the following items: medicines, drugs or surgical appliances; radium and deep x-ray treatments; oxygen tanks; tents or materials; blood transfusions.	
1938	\$1.00 charge for first house call in any illness. \$25.00 charge in maternity cases.	<i>GHA News Letter</i> , September 1938
June 1, 1939	Members to pay \$1.50 for x-ray film and material.	<i>Minutes</i> , Board of Trustees, May 24, 1939
August 1, 1939	Members with ailments or physical conditions requiring treatment, present at date of admission, to reimburse Association at cost for service rendered in connection with treatment.	<i>Minutes</i> , Board of Trustees, July 24, 1939
1939	During first 10 months of service, members to reimburse Association for cost of services including hospitalization connected with ailments present at admission; confinement and elective operations.	<i>Minutes of Special Membership Meeting</i> , November 21, 1939
September 3, 1940	Additional services not covered: plastic surgery; correction of deformities and birthmarks; psychiatric treatment and chiropody.	<i>Minutes</i> , Board of Trustees, September 9, 1940
August 1, 1941	Charge for obstetric care increased to \$50.00*.	<i>Minutes</i> , Board of Trustees, June 23, 1941
January 1, 1948	Those who have all services at cost except clinic consultations and routine laboratory services and all those 60 years of age or over admitted after January 1, 1948, are now restricted for all services — no exceptions — dues to apply against cost†.	Personal communication from Hospitalization Secretary, March 3, 1948

*At the present time this additional charge for obstetric care is \$100.00.

†Interestingly enough, the suggestion was made as early as 1939 that elderly dependents be required to pay for all services at cost (*Minutes*, Board of Trustees, September 18, 1939).

tant restrictions were embodied in the first set of by-laws. If a member became ill outside the Washington area, the Association reimbursed the member for expenses only up to the amount that would have been incurred had the member resided in the Washington area, and if a member's sickness was caused by a third person and the third person was required by law to pay for the member's sickness, the Association was entitled to reimbursement for the medical service furnished to the member.

As the Association developed, a gradual but ever-growing set of restrictions was adopted. Table 1 presents a partial list showing the development of these restrictions.

Liberalization trend On the other hand, there have been many examples of a liberalization in the service program. The first set of by-laws restricted membership to Government employees. In 1946 other employees became eligible to join on a group basis, and in 1947 they became eligible to join on an individual basis.

into military service could suspend membership, racial barriers dropped, and Negroes accepted for membership, health education forums (continued for a time but not in operation at the present time except for a series of psychiatric counseling forums on a fee basis), availability of optical service for the purchase of eyeglasses and frames at reduced cost, waiting period for service removed, and availability of child-guidance service.

MEMBERSHIP ELIGIBILITY

At the present time membership is open to all residents of the District of Columbia and vicinity. There are no restrictions concerning sex, race, occupation or place of employment. Up until January 1, 1948, there were no age restrictions, but on that date the restriction was imposed as noted in Table 1.

Participants may join on an individual basis or as part of a group.

Individual Enrollment

Individual applicants pay a \$2 00 application fee. This fee covers the expense involved in processing the application and in making laboratory tests such as urinalysis and blood tests.

Group Enrollment

No application fees are paid in a group enrollment. A group consists of employees of a single employer, or persons in one administrative unit of a business or Government agency or persons in one building or office. The percentage of those who must join to obtain group benefits varies according to the size of the basic unit.

Whether a person joins on an individual basis or with a group, a \$10 fee must be paid. This is the membership-certificate fee and gives the member voting and participating privileges in the organization. The \$10 membership fee covers all persons in a family unit unless more than one person desires to take out a membership certificate. The fee, which is the member's contribution toward the cost of the facilities and equipment purchased by the Association, is not refundable, but members who leave the Association may transfer their membership certificate under certain circumstances.

Through the membership certificate members have an equal share in ownership, and through an-

employees were permitted to join on a group basis. In February, 1947, any resident of the District of Columbia and vicinity was permitted to join on either a group or an individual basis.

By expansion of the promotion department and through an aggressive membership drive, large gains in membership were recorded in 1947. The most notable of these gains was due to the signing of contracts between Group Health Association and the Food and Agriculture Organization, the International Bank for Reconstruction and Development

TABLE 3 Rates of Accession and Secession in Membership, August, 1946, Through September, 1947

GROWTH IN MEMBERSHIP AND MEMBERSHIP TURNOVER

Table 2 shows the gradual rise in membership during the first ten years of operation. During the early years, the growth was fairly steady. During World War II, members were permitted to add dependents but new applications for membership were not accepted because of the difficulty in obtaining additional physicians and auxiliary medical personnel for the staff. When World War II ended, membership rolls were again opened and nongovernmental

and the International Monetary Fund. Under these agreements, the Association enrolled the employees of these agencies as group members.

Increase in membership through admission of new applicants has been retarded by the withdrawal of members who resign or suspend the membership of a dependent for one reason or another. For instance, during the fourteen months from August, 1946, to September, 1947, for every 7 new participants added, about 3 old participants withdrew. (The actual figures are 3.47 new participants as against 1.63 withdrawn participants and are derived from Table 3.) According to Miss Dorothy Sharrow, administrative assistant to the executive director, about 90 per cent of those who withdraw give as reasons the fact that they are moving away from the city. However, the extent to which other factors have caused members to withdraw or suspend membership is analyzed below.

MEMBERSHIP CHARACTERISTICS

Family Status

By types of family unit, the largest proportion of memberships consisted of member, spouse and one or more children (Table 4).

A comprehensive survey made in 1942 showed that at that time approximately a third of the participants were in the "member only" category, another third comprising the "member and spouse only" group.²

In 1947 the average number of participants in each membership was 2.6.¹ In 1942 it had been 2.3.²

Though the average size of family unit has increased from 1942 to 1947, the families* are small, compared to those in an urban population.

Other important features of the 1942 survey showed that participants, compared to an urban

TABLE 4 *Distribution by Types of Family Unit, March, 1947**

TYPE OF MEMBERSHIP	PERCENTAGE

Member only	27.1
Member and spouse only	19.5
Other (all types of family units, including adult dependents)	7.7

*Based on Number and Composition of Group Health Membership.¹

population group, consist of a larger proportion who are married and a smaller proportion widowed or divorced.²

Age of Participant

A sample study of the ages of members was made in 1947 by examination of the entrance age of every fifth member participant who joined between May, 1944, and July, 1946. The ages at time of entrance are presented in Table 5, which shows that over

TABLE 5 *Entrance Age of Sample Group*

AGE	NO. OF MEMBERS	PERCENTAGE OF TOTAL
Newborn infants	27	6
0-4 years	66	14
5-20 years	59	12
21-44 years	289	61
45-59 years	29	6
60 and over	4	1
Total	474	

90 per cent of new member participants were under 45 years of age at the time of the study.

The more comprehensive study made in 1942 showed, by actual count, that half the members were between 20 and 34 years of age and only an eighth 50 years old or over. The median age for all participants was 29.7 years, the median age for male participants being 30.1 and that for female participants 29.3.²

*All members of a family are not always included as a member's dependent for service, but it is my impression that the number of dependents who are not listed is very small.

DUES AND FEES

The cost of monthly dues depends on the type of membership and the size of the member's family. The present rates are shown in Table 6.

Limitations and Exceptions Under Dues System

Obstetric care. When obtaining prenatal, delivery and post-partum care, the member pays the first \$100 toward the hospital bill when both parents have been listed for membership for ten months prior to expected delivery. When obstetric service is obtained in cases in which delivery is expected before ten months of continuous membership, the member meets the entire hospital bill and pays to the Association an additional \$75.00.

Cost of Materials

The expenses of materials, such as x-ray films, serums, eyeglasses and lenses, are paid by members. These are usually purchased from the Association's pharmacies or Optical Department. There are special charges for electrocardiograph materials, basal-metabolic-test materials, x-ray therapy, phys-

TABLE 6 *Cost of Dues*

PARTICIPANT	MONTHLY DUES	
	WITH HOSPITALIZATION	WITHOUT HOSPITALIZATION
Member	\$3.00	\$3.00
Adult dependent	3.50	3.00
Child dependent (for each of first three children — no charge for more than three children)	2.25	2.00

ical therapy and laboratory test materials. Some of these material charges appear to be actually service charges — for example, x-ray and physical therapy. A charge of \$1.00 is placed on each x-ray and physical-therapy treatment rendered, "to compensate for heavy wear on expensive equipment," according to the *Minutes* of the Board of Trustees (July 8, 1947). If these are actually service charges the principle of removing barriers to medical care is being violated because service charges are apt to constitute "hesitation fees" — that is, fees that cause participants to neglect medical attention because of additional costs involved.

Restricted services. On the basis of laboratory tests, medical histories and physical examinations, certain types of medical conditions existing prior to membership are determined. Members who join on an individual basis (nongroup) may be restricted for services under the monthly dues for specific conditions present at time of admission. Service for these restricted conditions is given on a cost basis.

Limitations of Service

There is some evidence that the present rates of dues and other fees are so high that the Associa-

tion is attracting only people with the highest family incomes

In 1939 the median salary of members was \$2700, and 53 per cent of the members had salaries under \$3000 per year. A survey for 1946 indicated that the median family income was about \$5600.

The original purpose of GHA was to provide the best type of medical care to those who usually could not afford it. What is needed is a comprehensive study to determine whether the program has become "selective" in its operation.

QUALITY OF MEDICAL SERVICE

In his report at the annual membership meeting in February, 1947, former president Harry J. Becker stated:

We have nearly completed the recruitment for the medical care organization which a year ago was largely a dream on paper. We are happy to report that we have been able to recruit professional staff to meet substantially the medical care requirements for our membership. For the first time in a long while we have as many general physicians as are necessary to maintain our medical standards. Medical judgment will support my statement that the members of Group Health are today enjoying a better quality of medical care than can be purchased on either a prepaid or fee-for-service basis elsewhere in Washington. We have available to any member of the Washington community the most completely equipped and staffed out-patient service in Washington utilizing the principle of the group practice of medicine.

It is beyond the scope of this article to pass medical judgment on the caliber of the Association's medical staff. However, one method of appraising the quality of the medical care program is by considering member reaction to the program.

A survey made in the summer of 1947 indicated that the three aspects of the program most appreciated by the members were the competence of the medical staff, the prepayment features of paying for medical care, which afforded insurance against large medical bills, and the scope of service available.

However, member reaction to the program has often been negative. A study of the records of separation for four selected months (Table 7) indicated that from 4 to 20 per cent of those who are separated in any one month are separated because of dissatisfaction with the service. It is also possible that there are among those who give no reason for requesting separation members who are dissatisfied with the service but who prefer not to state their reasons. (On the other hand, the administrative assistant to the executive director has stated that 90 per cent of current separations are due to the fact that participants are leaving the Washington metropolitan area.)

Unsatisfactory service does not always lead to the stage where the member requests separation. For the ten months from June, 1946, through March, 1947, the Complaints and Suggestions Committee

received 54 complaint letters and 16 letters suggesting ways of improving the service.

Complaints and suggestions are usually received by the Association in writing to assure accurate transmittal of the members' view.* They are routed to the executive director, who consults interested parties, gets other information as needed and takes such action as he considers to be the best interests of the Association. The Complaints and Suggestions Committee at its monthly meetings reviews the papers, searching for factors that may have been overlooked. The purpose is to determine the essen-

cial nature of the complaint and find underlying causes.

Many items of criticism and suggestions for improving the service were received in a recent survey. Most of all, members wanted the Association to expand its services to include dental care, a psychiatric program and other medical facilities not now provided on a prepaid basis. The two greatest limitations on the program, according to member opinion, are its telephone service and its appointment scheduling.

A survey made in 1942² revealed the following:

The turnover of membership which occurred prior to 1942 affected primarily the younger group. The older members showed a greater degree of stability. Almost two thirds [of the participants] who were 50 years old or over on January 1, 1942 joined the organization before

*Obviously not all complaints are reduced to writing and many complaints never reach the organization.

January 1, 1939, whereas only 38% of the present membership as a whole joined before that date. Less than 5% of the members who joined in 1941 were 50 years old or over, but 20% of the present membership who joined before 1939 are in that age group now.

INFANT AND MATERNAL MORTALITY AND GENERAL DEATH RATES

Infant Death Rate

A reliable barometer of the health of any segment of the population is the infant mortality rate of

TABLE 8 Infant Mortality, Group Health Association and White Population of the District of Columbia, 1937-1946 *

*Figures for Group Health Association supplied by Statistical Department Group Health Association and figures for the District of Columbia by Health Department District of Columbia.

†No data available for Group Health Association.

‡The standard error of this arithmetic mean is 2.734. "Knowledge of this standard deviation or standard error" says Mills "enables us to set limits within which it is highly likely that the true mean lies."

the group. This index is the number of infant deaths per thousand live births. An infant death is a death occurring when the child is less than one year of age and does not include stillbirths.

According to Sir Arthur Newsholme, an outstanding British authority on public health, "Infant mortality is the most sensitive index we possess of social welfare. If babies were well-born and well-cared for, their mortality would be negligible."

Dr. George C. Ruhland, health officer for the District of Columbia, terms infant mortality "the most delicate indicator of the health mindedness of a community and the nation."

Data on infant mortality for babies born to members are available and are reproduced in Table 8, compared to the infant mortality rates for the white population in the District of Columbia.

Since the composition of the Association is almost entirely white, it was believed that a more valid comparison would result by the use of infant mortality figures for the white population in the District of Columbia rather than the general (Negro and white) average.*

*It is generally agreed that there is a great disparity in the relative health level of Negroes and whites. The life expectancy of Negroes is approximately ten to twelve years shorter than that of whites; approximately three times as many Negro males and four times as many females proportionately die of tuberculosis. The death rate from heart disease is also considerably greater among Negroes than among whites.

From Table 8 it will be seen that for every year for which data have been recorded (only data missing are those from November 1, 1937, the date of initial operation of the Group Health Association, to December 31, 1938), the Association's infant mortality rate is lower than that for the white population of the District of Columbia.

Taken by themselves, the infant mortality rates appear remarkably low. From 1939 to 1946, the average was 14.2 deaths per thousand live births per year (standard error of deviation 2.734) as compared with an average of 32.9 infant deaths per thousand live births for the white population of the District of Columbia during the same period. It would be still more remarkable, however, if the results were less striking in view of the fact that the family incomes of members are probably higher than those of the "average" white family in the District of Columbia.

Adequate incomes make possible healthful living, provide proper diets for expectant mothers and per-

mit needed rest for pregnant women. The relation between economic factors and health has often been stated but rarely more effectively than in a recent radio broadcast.

What is health? It's not the great operation. It's not the surgeon and his sterile rubber gloves. It's not a test tube full of vitamins. Vitamins, yes. But not in test tubes. In people. Health is day to day living, the food you eat, the clothes you wear, the house you live in. The size of the town in which you're born. The kind of water supply and sewage disposal. Is the road to your house good enough so the doctor can get there on a rainy day? Health is the number of dollars a week your father earns. Health is the teacher in the fourth grade who sees you squinting and tells your mother. Health is love and understanding when you're an infant. All these things. Many more. You can't solve it with a quick dramatic operation.

I do not wish to belittle the competence of the Association's obstetric staff or the adequacy of the prenatal, delivery and postnatal care given to members. However, since members use the same hospital facilities as other white persons in the community, and since Group Health Association obstetricians and pediatricians are not supermen, the remarkable difference between infant mortality rates shown in Table 8 can be partially ascribed to

the suspected high family income levels of members mentioned above and the fact that, with very few exceptions, births occurred in the hospitals rather than in homes

This last factor was a greater influence in explaining the difference in infant mortality rates in the early years of operation from those in recent years. The proportion of hospital deliveries of white mothers in the District of Columbia has been steadily increasing during the past decade. In 1937, 95.1 per cent of births for the white population occurred in hospitals, in 1946, 99 per cent of these births occurred in hospitals.

Maternal Death Rates

The maternal death rate is another index of general health effectiveness in a community.

About 2000 babies have been born to Group Health Association mothers in the last ten years without a maternal death. For the white population in the District of Columbia, maternal death rates per thousand live births are shown in Table 9.

General Mortality Rates

Table 10 shows the general mortality rates for Group Health Association members from 1938 to

TABLE 10 *Mortality for Group Health Association Members, 1938-1946*

*Computed by use of two-year moving averages with exception of figure for year 1946. In 1946 the number of members is an average of the membership levels at the end of each month of that year.

†Five (5) deaths in 1938 omitted from total.

1946. For purposes of comparison the mortality rates for the District of Columbia for all causes, all colors, and those for all causes in the white population are listed in Table 11. It will be seen that the death rates among Association participants are lower than those for the District of Columbia for

every year for which statistics of Group Health Association mortality are available.

As shown in Table 10, the average mortality rate for the years 1939-1946 for Group Health Association members is 2.72 per thousand population. However, when specific death rates* are applied to the composition of the membership for 1942 (the only year for which the composition of membership by sex and age is available), it is found that the expected death rate is 6.57.

In other words, part of the low death rate is explained by the fact that, on the basis of the com-

*Source: Department of Health, Washington D C

position of its participants as of January 1, 1942, its members are relatively young, women preponderate, and the participants are predominantly white.

However, in view of the extraordinarily low death rate over a period of years, it may be concluded that factors other than age, sex and race are responsible. What these factors are and to what extent they influenced the mortality rate are not definitely known. It can only be surmised that these factors include the relatively high socioeconomic levels of participating families and the arrangement under which members obtain their medical care.

*A specific death rate is one for a selected population group usually based on race, sex and age.

ciated with leg pains, a heart murmur was noted, and his pulse was said to have been unusually slow, but no exact details were obtainable. Through school and college he led a very active life. He was an ardent tennis player and participated in all types of sports.

In 1939 the patient was rejected for the Navy because of an elevated blood pressure. Consequently he was examined at the Massachusetts General Hospital Out-Patient Department (U No 223487). Examination at that time showed a regular cardiac rate at 70, systolic and diastolic murmurs at the base and apex of the heart, and a blood pressure of 180/65 in both arms whereas in the legs the systolic pressure was 140. Diagnosis was deferred, and the patient was sent for chest x-ray films, which were reported as showing hypertrophy of the left ventricle without evident rib changes (November 15, 1939). The patient never returned for follow-up examination.

In 1943, when he again attempted to enlist in the Navy, he was told that his blood pressure was 230/80 and that he had coarctation of the aorta. He remained entirely asymptomatic and led an active life until May, 1946. At that time, while working under considerable pressure, he first experienced a blackout, during which he had a mild generalized convulsion and became unconscious for about a minute. This type of episode was repeated on frequent occasions in subsequent weeks. An electroencephalogram taken on suspicion of epilepsy was stated to have been normal.

In July an electrocardiogram was reported as showing complete heart block, and it was believed that the seizures were of the Adams-Stokes type. Treatment with ephedrine and atropine was followed by a temporary decrease in the number of attacks.

In August, because of blackouts increasing in frequency up to several an hour, as well as "brownouts," consisting of weakness and faintness without convulsive movements or loss of consciousness, the patient was referred to us*. He denied joint pains, symptoms of infection, dyspnea, chest pain or any other symptomatology.

The family history indicated that his father and mother were both living and well, two siblings were in excellent health. He had been married for 5 years and had a 2-year-old child, his wife and child were well.

Physical examination revealed a thin but fairly well developed man appearing tense and concerned over his condition but not acutely ill. The neck vessels showed a vigorous collapsing type of arterial pulsations but no abnormal venous fullness. The cardiac apical beat was forceful and felt in the fifth interspace 1 cm outside the midclavicular line. There was a harsh Grade II to III systolic murmur at the base, heard loudest in the second left interspace, but radiating all over the precordium, especially toward the lower sternal areas. The murmur radiated into the neck vessels and was heard loudly over the upper dorsal spine. Also at the base there was a high-pitched, Grade II, blowing diastolic murmur heard equally to the right and left of the sternum in the second interspaces and radiating down the sternal borders. The aortic second sound was greater than the pulmonary second sound. The first sound at the apex was forceful but variable in intensity, and a Grade II systolic murmur was heard in this area, together with a rather loud third sound. No thrill was made out. Definite intercostal pulsations were felt in the posterior axillary line. The lungs were clear and resonant. The abdomen was not remarkable. The liver and spleen were not felt. The femoral and dorsalis pedis pulsations were palpable but definitely reduced.

The pulse rate at the time of examination was 48 and somewhat irregular. The temperature was normal. The blood pressure in both arms was 200/60. The systolic blood pressure in the legs was 100, and the diastolic was questionable at 70.

During the examination the patient had no blackouts. An electrocardiogram made at the time showed varying degrees of heart block ranging from complete dissociation to simple first-degree block with a varying PR prolongation. The basic pattern was the same as that shown in Figure 1.

The patient was admitted to the Winchester Hospital for further observation and treatment. Routine blood and urine studies were not remarkable. A blood Hinton test was negative. Three blood cultures were negative. Electrocardiograms on various occasions showed normal sinus

rhythm at a rate of 90 with a PR interval of 0.22 second as demonstrated in Figure 1A, and again, complete auriculoventricular dissociation with a ventricular rate of 45, as in Figure 1B. Unfortunately, no tracing was obtained during an attack. X-ray studies of the heart showed prominence of the left ventricle, with unusually vigorous contractions. The aortic knob was small. The left auricle was not remarkable. The transverse diameter of the heart measured 13.9 cm, as compared with an internal chest diameter of 28.2 cm. The lung fields were normal. There was slight but

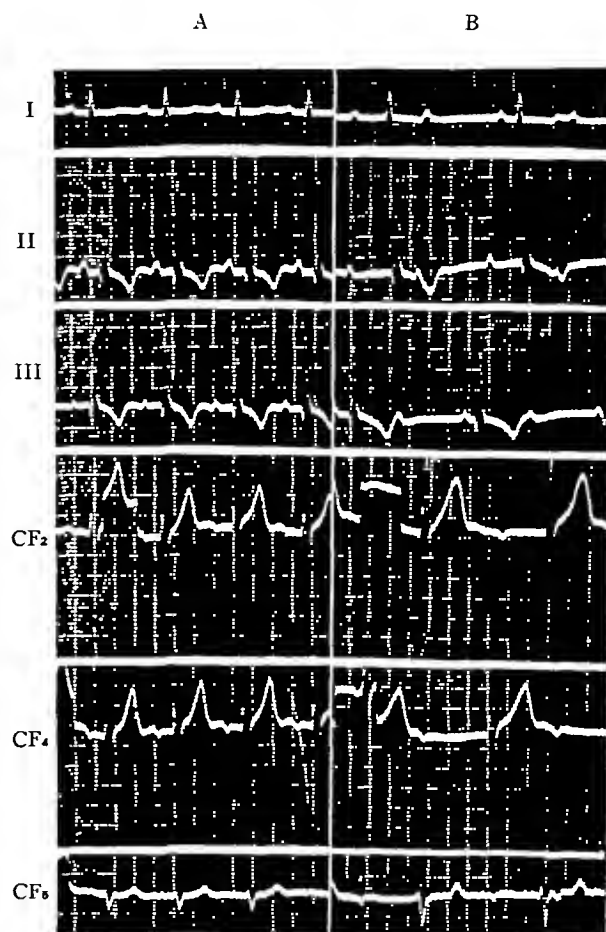

FIGURE 1 Electrocardiograms in a Case of Coarctation of the Aorta

A shows regular sinus rhythm at a rate of 90, with a PR interval of 0.22 second, the T waves are low and upright in Lead I, inverted in Leads 2 and 3, with sagging ST segments and 1.5-mm Q waves and prominent T waves in Leads CF₂ and CF₄, with relatively low R and deep S waves. The R wave is very low in Lead CF₆, with upright T waves. B shows complete auriculoventricular dissociation, with a ventricular rate of 45 and an auricular rate of 90.

definite notching of the ribs. The temperature remained normal. The blood pressure in the arms varied from 190/50 to 210/60. Two milligrams of epinephrine in oil was given intramuscularly twice daily, and 0.65 mg of atropine by mouth thrice daily. There was continued shifting in the heart rate from about 90 to about 40, several times daily. At intervals the patient had mild "brownouts," but none of the blackouts.

After a week of hospitalization he was discharged on ephedrine sulfate, 48 mg three times daily, and atropine sulfate, 0.65 mg four times daily by mouth. The first week at home he had two mild blackouts, but subsequent to this he had

COARCTATION OF THE AORTA ASSOCIATED WITH ADAMS-STOKES SYNDROME, COMPLETE HEART BLOCK AND BICUSPID CALCAREOUS AORTIC VALVE

Report of a Case

RICHARD J. CLARK, M.D.,* AND HARLAN I. FIRMINGER, M.D.†

WINCHESTER, MASSACHUSETTS, AND BETHESDA, MARYLAND

TO OUR knowledge coarctation of the aorta in association with complete heart block and Adams-Stokes syndrome has not previously been reported. The patient in the case reported below was first observed while having attacks of Adams-Stokes syndrome. Examination revealed signs characteristic of coarctation of the aorta. Varying degrees of heart block were manifest and subsequently became complete. Post-mortem examination showed, in addition to coarctation, a calcified bicuspid aortic valve. The cause of the heart block prompted considerable debate prior to death.

REVIEW OF THE LITERATURE

Coarctation of the aorta has been very thoroughly discussed in its clinical and pathological aspects. Virtually all autopsied cases in the literature were assembled by Abbott¹ up to 1928, and subsequent cases over two years of age up to 1946 by Reifenshtein, Levine and Gross.² From these reviews it may be observed that bicuspid aortic valves are of such frequent occurrence as to be almost considered a part of the coarctation syndrome, in the first report they were found in 25 per cent of 183 cases¹, in the second this anomaly was present in 42 per cent of 104 cases.² It is emphasized that these bicuspid valves are a vulnerable focus for subacute bacterial endocarditis and other types of valvulitis. Among the patients living to adult age, the development of a calcareous aortic valve is not unusual, Reifenshtein et al.² described 11 cases of "calcific aortic stenosis" among 93 patients, in which fairly complete valvular descriptions were available.

The subject of complete heart block in younger age groups has recently been discussed by Crawford and Di Gregorio,³ who itemize various possible causes and review the literature of complete heart block due to congenital heart disease. The following criteria have been set up for congenital heart block: proof by graphic methods, knowledge of a slow pulse at an early age, signs of congenital heart disease, and absence of a history of infection or other factors that might produce heart block. Fifty cases have been reported in which complete heart block has appeared to be of congenital origin. Yater et al.^{4, 5} have reviewed and reported the greater number of these. The associated congenital lesions have included ventricular septal defects as the most

common (26 out of 44 cases),⁴ patent ductus arteriosus, auricular septal defects, pulmonary stenosis, transposition of the great vessels, common aorta and pulmonary artery, and cor triatriatum triloculare.

Waldman⁶ reported a case of patent ductus arteriosus with transient heart block and mild Adams-Stokes attacks. This was the first such case of congenital heart disease in which a cardiogram was obtained during an attack. Faessler⁷ reported 8 cases of Adams-Stokes syndrome with congenital heart disease, 6 patients having complete block between attacks, of these, 6 cases were diagnosed as ventricular septal defects, 1 as a patent ductus, and 1 as a persistent foramen ovale. Waldman⁶ points out that heart block in congenital heart disease may be present as a part of the congenital defect or may be acquired and superimposed upon the congenital deformity. Prior to post-mortem examination it might have been argued that the case reported below could fit into the former category, but subsequently the latter explanation appeared probable.

Complete heart block in calcareous aortic stenosis has recently been reviewed by Warshawsky and Abramson.⁸ They report a case in a fifty-two-year-old patient with rheumatic heart disease manifested by aortic stenosis and insufficiency, showing calcific extension from the aortic valve into the membranous portion of the interventricular septum. Dry and Willius,⁹ in a study of calcareous aortic stenosis, found 1 case, out of 63 examined post mortem, that showed complete heart block with a nodular excrescence of calcium extending from the mitral cusp of the aortic valve in such a manner as to involve the bundle of His. In their series of 85 cases with marked clinical evidence of calcareous aortic stenosis, 2 showed complete heart block, and 5 others, delayed auriculoventricular conduction. In a study of 22 cases of calcific aortic stenosis, Reich¹⁰ found 1 case of rheumatic etiology that showed complete heart block and left-bundle-branch block. Boas¹¹ reported 2 out of 6 cases of aortic stenosis that showed complete heart block. Cohen et al.,¹² in an analysis of 9 cases of calcareous aortic stenosis, described 1 with complete heart block.

CASE REPORT

L. A. M., a 31-year-old married schoolteacher was first seen by one of us (R. J. C.) in August, 1946. He was considered to have been normal at the time of birth. He had had a vague illness at the age of 10 for about 10 days, asso-

*Assistant physician Massachusetts General Hospital, assistant cardiologist Boston Lying-in Hospital, cardiologist, Winchester Hospital.

†Pathologist National Institute of Health, United States Public Health Service, formerly resident pathologist Massachusetts General Hospital.

The lung sections showed small, patchy areas of atelectasis, and the alveolar walls appeared slightly thickened. Frequent areas of large confluent alveoli containing septal remnants with bulbous tips were present.

There was moderate sclerosis of the small arteries within the substance of the brain, especially in the gray matter. In the white matter, in addition, there were scattered phagocytes containing brown hemosiderin pigment in the perivascular spaces of some of these vessels.

The pathological diagnoses were coarctation of the aorta, bicuspid aortic valve, calcific aortic valve with stenosis and insufficiency, cardiac hypertrophy and dilatation, auriculo-ventricular block, complete, clinical, interstitial fibrosis of the myocardium in the region of the bundle of His, fibrous pericardial adhesion, acute passive congestion of the liver, spleen and intestines, peripheral edema of the lower extremities, and pulmonary emphysema.

DISCUSSION

There was little doubt from the first that this patient suffered primarily from coarctation of the aorta and heart block. The chief problem was the interpretation of the murmurs and the explanation of the cause of the heart block.

In the present day of surgical correction for coarctation, the interpretation of murmurs becomes increasingly important as an indication of possible complicating lesions. The classic murmur of coarctation is described as a basal systolic murmur of slight to moderate intensity, with radiation to the upper dorsal spine. However, numerous variations have been reported, from complete absence of murmurs to a systolic murmur heard only posteriorly. The presence of associated diastolic murmurs at the base has been mentioned in various articles. Reifenstein et al.² stated that diastolic murmurs were present in 20 of their 104 cases, in each of which, where the valves were described, there was either aortic-valve disease or a patent ductus arteriosus. In a clinical series of 40 cases of coarctation observed by one of us (R. J. C.),¹⁴ basal diastolic murmurs were heard in 14, and an additional 5 showed this finding on phonocardiography, giving a total of 47 per cent. Reifenstein and his associates² found bicuspid aortic valves in 42 per cent of their series. It has been suggested that in the presence of coarctation with high pressure in the proximal aorta, bicuspid aortic valves may give rise to a diastolic murmur. Although this relation has not been proved, the correlations are suggestive. Rheumatic valvular disease in association with coarctation is not unusual, being present in 20.4 per cent of the series reported by Reifenstein et al.² Apical murmurs may be secondary to the coarctation or due to separate mitral-valve disease.

In the case under discussion there was a suggestive history of rheumatic fever at the age of ten. We first considered that accompanying rheumatic aortic valvulitis might account for the basal diastolic murmur, but because of the frequency of associated bicuspid aortic valves this diagnosis was also postulated. The basal systolic murmur was considered as arising from the coarctation. The murmur radiated into the neck, which is not uncommon in this

condition. The aortic second sound was present and no thrill was made out. For these reasons a clinical diagnosis of aortic stenosis was not made.

Because of the heart block and the moderately loud systolic murmur along the sternum, the possibility of an accompanying ventricular septal defect was strongly entertained. This case and others in the literature suggest that the diagnosis may be made too often because of the presence of heart block.

The basic electrocardiographic pattern with the inverted T waves and small Q waves in Leads 2 and 3, as well as the high T waves in the chest leads, raised the question of coronary-artery disease, either congenital or acquired, as a factor in the heart block. There was no suggestion of coronary-artery pain, the T waves were not typical of coronary thrombosis, and patterns over a period of observation showed no significant change. It was thought more likely, and confirmed subsequently at autopsy, that this tracing represented left ventricular strain in a vertically placed heart.*

The degree of hypertension that developed in the last six to eight months of life is unusual in coarctation and probably in part a factor of compensation for the complete heart block. This appeared in spite of marked aortic stenosis. It is interesting that the patient complained of none of the symptoms usually referable to hypertension, possibly because of the low diastolic level associated with aortic insufficiency.

Treatment of this case was symptomatic and general. Surgical plastic repair was briefly considered, but it was thought that the obvious complications, together with the patient's age, were absolute contraindications. Sympathectomy was also discussed but dismissed, again because of the patient's condition and because of relatively unfavorable results in other less complicated cases.¹⁴ This case demonstrated the value of epinephrine in acute phases of Adams-Stokes syndrome and the fact that such acute phases usually subside over a period of time with the clearing of block or establishment of fixed complete block.

The post-mortem examination although explaining much of the clinical picture, also provided other problems, one was the explanation of the unusual aortic valve. Lewis and Grant,¹⁴ in their study of congenital bicuspid aortic valves, found that the annulus fibrosus failed to break through the aortic media normally. Koletsky,¹⁵ in a study of 18 cases described two types, in one group there was a simple bicuspid valve, and in the other there was a rudimentary congenital ridge showing some attempt to form three cusps. The case under discussion seemed to fit into the latter class. The only questionable point was the superficial position of the annulus

*It is of interest that we have recently observed 2 other cases in young men at the Massachusetts General Hospital with coarctation showing almost the identical pattern.

only "brownouts" occurring with shifts in pulse rate from 80 to 40, which occurred off and on once or twice daily. In September he resumed teaching. In late October his heart was remaining in complete block most of the time. By mid-November his rhythm settled into permanent block at a rate of 40, and he was quite symptom free. During the winter, spring and summer he led an active life, often walking 5 miles a day. His blood pressure in the arms gradually increased up to 290/50. The heart size increased 4 cm in the transverse diameter. Complete heart block with a ventricular rate of 40 persisted. Apart from some increase in nervous irritability he felt well.

On November 16, 1947, the patient got up feeling as usual. He had flown to New York City on the previous day to attend a football game. In midmorning he remarked that

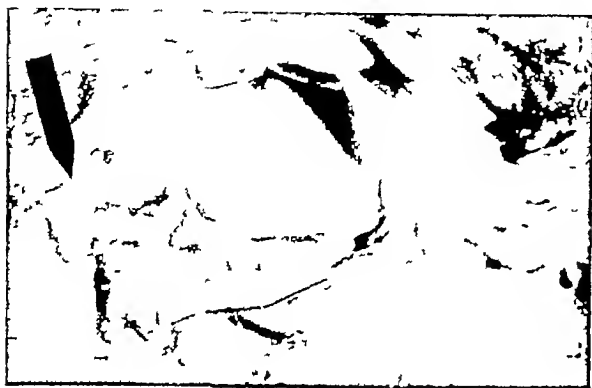

FIGURE 2 Gross Specimen of the Aortic Valve

The arrow indicates the rudimentary ridge between two coronary cusps, the right coronary cusp is on the left, and most of the leaf is on the right of the plate. (Note Y-shaped calcific mass below.)

his heart felt as though it were "going to be jumpy," and he took a dose of atropine. He seemed nervously irritable. On returning from church he sat down to read the paper. He suddenly put the paper down and stated that he felt smothered, his eyes rolled upward, and he took several short gasps, became pallid and apparently expired within 2 or 3 minutes.

Post-mortem examination revealed a well developed man, 5 feet, 7 inches, in height and weighing about 150 pounds. He appeared at least 5 years younger than his actual age of 32. Slight edema was evident in the lower legs and ankles.

Examination of the thoracic organs showed light and doughy lungs. The pericardial cavity contained about 20 cc of clear, yellow fluid. There was a fibrous adhesion at the apex of the heart between the visceral and the parietal pericardium occupying an area 1.5 cm in diameter. The heart was enlarged and weighed 630 gm. The left ventricle was markedly elongated, the distance from the mitral ring to the apex of the left ventricle was 10.2 cm, compared to 6.7 cm for the distance from the tricuspid ring to the apex of the right ventricle. The wall of the left ventricle was thickened to 21 mm at the mitral valve, but it tapered to only 4 mm in thickness at the apex. The right ventricle appeared slightly dilated, and the wall measured 4 mm in thickness. The foramen ovale was closed, and there were no interventricular or interauricular defects.

The aortic ring measured 7 cm in diameter. The valve was bicuspid, sclerotic and stenotic, the cusps being stiff and thickened, with rolled edges. There was considerable calcification, especially at the bases of the common coronary cusps and extending into the aortic wall in the sinuses of Valsalva. In addition, a rough, yellow, inverted Y-shaped, hard, verrucous, calcific mass extended down over the left ventricular endocardium from the right coronary cusp. This mass was superficial and did not impinge on the underlying myocardium.

The two coronary cusps were equally small and confluent, with a rudimentary ridge instead of a commissure between them (Fig. 2). Together these cusps measured only slightly

more in transverse diameter than the opposing noncoronary cusp. The rudimentary septum partially dividing the small coronary cusps was smooth and hemispherical and projected 2 mm above the sinus wall. This ridge ran vertically and joined the aorta much lower than the other two commissures, which showed no interadherence between the cusps. In the anterior leaflet of the mitral valve just below the noncoronary cusp there was a rough, atheromatous plaque, which measured 1.5 cm in diameter. The remainder of the mitral valve, together with the pulmonary and tricuspid valves, was entirely normal.

The stiffness of the "double" aortic cusp and the absence of the normal commissure left the coronary orifices completely unprotected, however, the coronary arteries contained only minimal atherosclerotic changes. The right coronary artery had two ostia. The ascending aorta was fairly narrow, measuring 6 cm in circumference. More striking, however, was the marked narrowing just beyond the origin of the left subclavian artery at the point of junction with a very prominent ligamentum arteriosum, which measured 0.6 cm in thickness and 1.0 cm in length (Fig. 3). Here the aorta measured 0.5 cm in diameter for almost 1 cm. Internally, there was a small channel measuring 0.2 cm in diameter through this narrowed portion.

Beyond the point of narrowing the descending portion measured 3.7 cm in circumference. The innominate, left common carotid and left subclavian arteries were almost twice the normal caliber. Similarly, the intercostal arteries were two or three times the normal caliber, and a small linking with associated notching of the ribs was noted laterally in the chest wall. There was thickening of the walls of the larger arteries at the base of the brain, but no atheromatous

FIGURE 3 Gross Specimen of the Great Vessels, Showing Marked Narrowing of the Aorta Just Beyond the Prominent Ligamentum Arteriosum

plaques. The remainder of the organs were not especially noteworthy.

Several microscopical sections of the myocardium through the interventricular septum just below the aortic valve in the region of the bundle of His failed to reveal the bundle but showed considerable interstitial fibrosis and coarse myocardial fibers with no inflammatory infiltration. An increase in interstitial fibrous tissue was also noted in the myocardium at the base of the mitral valve. This did not extend into the valve leaflet, nor were similar foci found elsewhere in the myocardium.

Sections taken horizontally through the origin of the abdominal commissure from the aorta and stained for elastic tissue revealed the annulus fibrosus superficial to the media, in the same relation as a normal commissure (Lewis and Grant¹⁹). However, a coronal section taken through the rudimentary ridge just before it joined the aortic cusps and stained for elastic tissue revealed a single delicate elastic lamina running immediately beneath the endocardium, without evidence of fibrosis or inflammation.

BALLISTOCARDIOGRAMS IN COARCTATION OF THE AORTA*

Observations before and after Operation

HERBERT R. BROWN, JR., M.D.,† MARVIN J. HOFFMAN, M.D.,‡ AND VINCENT DELALLA, JR., M.D.‡

ROCHESTER, NEW YORK

THE recent interest in coarctation of the aorta can be attributed to the development of a surgical treatment eliminating the stenotic area.¹⁻³ In recent years the number of reported cases has steadily increased. This apparent increased incidence probably represents a new awareness leading to a much more frequent diagnosis of a condition that was formerly a medical curiosity. The incidence of coarctation as given by Levine⁴ is 0.05 per cent of the population.

In large measure the diagnosis depends first upon thinking of the possibility of this condition and

cerebrovascular accidents are often present terminally.

Early in the course of the disease the symptoms are scant, and clinical findings more important. One should routinely feel for abdominal and femoral pulsations, which are characteristically diminished or absent in coarctation of the aorta. When this

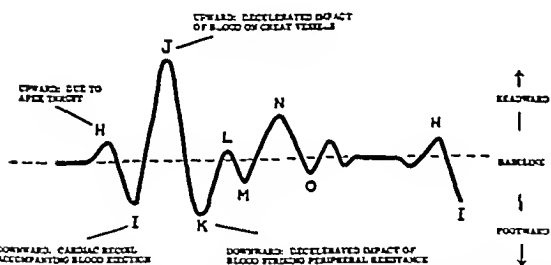

FIGURE 1 Drawing of the Normal Ballistocardiographic Wave Pattern, with a Brief Explanation of the Most Significant Waves

secondly on a few additional procedures indicated to aid in establishing a diagnosis. Coarctation of the aorta must be suspected if a diagnosis of hypertension, rheumatic heart disease or congenital heart disease is made, particularly in young persons.

The patient with coarctation is frequently without complaint. When symptoms are present they can be attributed to impaired circulatory dynamics resulting in an increased pressure above the stenosis. Headache and dyspnea are the two most common symptoms.⁵ On occasion, palpitation, epistaxis, visual disturbances, vertigo, dizziness, intermittent claudication or angina pectoris may be attributed to this abnormality. Symptoms of heart failure or of

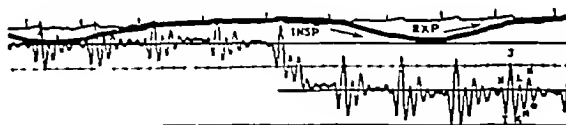

FIGURE 2 Representative Normal Ballistocardiographic Tracing

Note the regularity and definitiveness of the pattern. Simultaneously recorded with the ballistocardiogram are respirations (the heavy undulating line) and the electrocardiogram. The distance between two heavy time lines is 0.2 second, and that between two fine lines 0.04 second.

abnormality is suspected the blood pressures should be determined in the lower as well as the upper extremities to detect a reversal of the normal relation.

Other clinical features are the demonstration of a collateral circulation, usually over the thoracic, scapular and clavicular areas, the presence of one or more cardiovascular murmurs, roentgenographic evidence, particularly that of rib erosion, and characteristic differences in direct intra-arterial radial and

FIGURE 3 Ballistocardiographic Tracing of a Patient with Hypertension, Demonstrating Deep JK Strokes. This is a common finding in hypertension.

femoral pulsations where the femoral pulse is delayed both in the onset and in attaining its maximum height.⁶

It is the purpose of this paper to add another laboratory measurement that is characteristic of aortic coarctation — namely the ballistocardiogram. Obtaining ballistocardiographic records requires

fibrosus at the origin of the congenital ridge. In almost all of Koletsky's cases the elastic strands of the media remained superficial to the annulus until well out in the ridge. In some the annulus fibrosus then became superficial.

Furthermore, the complete lack of inflammatory or degenerative changes in the coronal section through the rudimentary ridge seemed incompatible with acquired fusion as described by Sohval and Gross.¹⁶ This evidence strongly favored the congenital origin of the ridge.

Transverse sections just below the aortic valve through the interventricular septum revealed only dense interstitial fibrosis, and the bundle of His was not identified. This seems to provide an anatomic explanation of the complete heart block. On the other hand, the etiology of this fibrosis remains open to considerable question.

Though the gross picture was compatible with, but not strongly suggestive of, rheumatic endocarditis and aortic valvulitis, no definite microscopical proof of this diagnosis was found. The possibility that the interstitial fibrosis was rheumatic in origin could not be ruled out, however, the lack of other foci of interstitial fibrosis elsewhere in the myocardium and the absence of additional rheumatic stigmas suggested that the local fibrosis was the result of local myocardial strain as in a case (No 7) described by Cohen et al.,¹² which also showed interstitial fibrosis and complete heart block associated with calcareous aortic stenosis without rheumatic heart disease.

The second problem raised by the autopsy was the actual cause of death. Sudden unexplained death in cases of calcific aortic stenosis is not uncommon. Though this case did not show such severe stenosis as the usual fatal cases, the final episode was similar. The lack of any evident anatomic explanation and the known serious disturbance in the cardiac conduction system led us to attribute death in this case to sudden ventricular standstill or fibrillation.

SUMMARY

A case of coarctation of the aorta associated with Adams-Stokes syndrome, complete heart block and a calcareous stenotic bicuspid aortic valve is presented, with post-mortem findings and a brief review of the pertinent literature.

The heart block appeared to be related to the calcific aortic valve and interstitial fibrosis in the region of the bundle of His.

This is believed to be the first case of coarctation of the aorta with Adams-Stokes syndrome and complete heart block reported.

but a few minutes and is without discomfort to the patient. The apparatus used is an electronic device that permits simultaneous recording of the electrocardiogram, ballistocardiogram and respirations.⁷

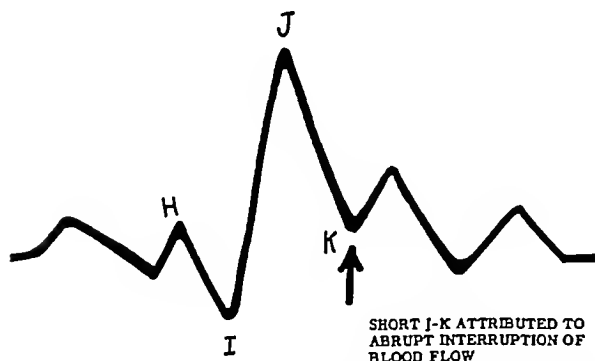

FIGURE 4 Drawing of the Typical Ballistocardiographic Wave Pattern in Coarctation of the Aorta, Characterized by a Short JK Stroke

The ballistocardiogram itself constitutes a simple means of visualizing mechanical circulatory function. Figure 1 is a wave pattern as originally designated by Starr,⁸ with a brief explanation of the sig-

the decelerated impact of blood as it strikes the major peripheral arterial resistance. As would be expected, typical hypertension is normally characterized by a deep JK stroke⁹ (Fig. 3). The coarctation, although hypertension is present in the upper extremities, offers an early obstruction to the flow of blood through the aorta, and, again, as would be expected, this early and abrupt interruption results in an abnormally short JK stroke (Fig. 4), during and after which blood flows to the lower parts of the body primarily through the well-developed collateral circulation. This was originally mentioned by Hamilton.¹⁰

To date ballistocardiograms have been obtained in 6 consecutive cases in which the diagnosis was firmly established, and the short JK stroke was clearly demonstrated in all (Fig. 5 and 6). If the above postulation is correct, surgical removal of the coarctation should restore normal circulatory dynamics, with a resultant typically normal JK stroke. In 1 of these 6 cases of coarctation preoperative and postoperative records that completely support the above conclusion (Fig. 7) were obtained.

The case history of this patient was as follows:

A N., an 11-year-old boy, had been under a physician's care since the age of $4\frac{1}{2}$ years, when hypertension associated with a harsh precordial systolic murmur had been discovered. These findings had persisted during the ensuing

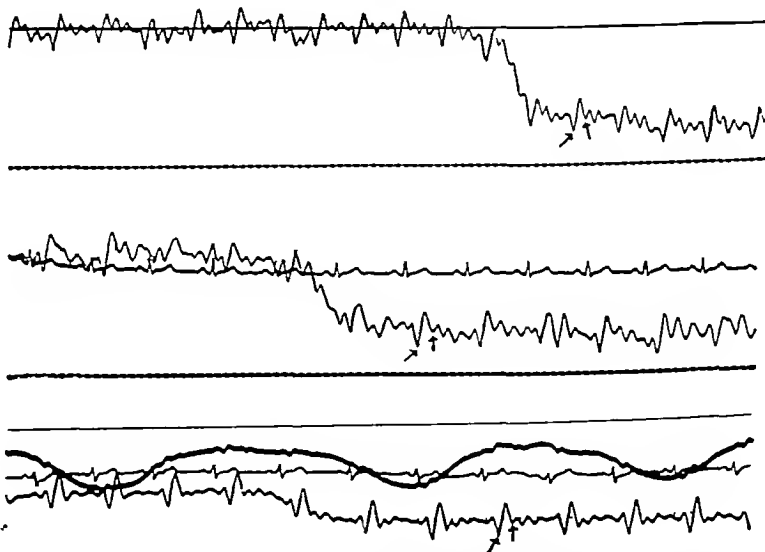

FIGURE 5 Ballistocardiographic Records of 3 Patients with Coarctation of the Aorta in Whom the Diagnosis Was Well Established. Each of these tracings demonstrates the pathognomonic finding of a short JK stroke.

nificance of each individual wave. Figure 2 is a representative normal tracing. In coarctation the K-wave variation constitutes the single purpose of this paper. The JK stroke normally represents

years. His only complaints were dyspnea on running, rare headaches and occasional bouts of mild epistaxis. No history of coma, convulsions, paralysis, eyesight abnormalities or genitourinary complaints was elicited. The patient was finally re-examined 1 year before operation in the hospital.

legs were not obtainable. A bounding radial pulse was noted, with capillary pulsations visible in the fingers. By contrast

pable. The lungs were clear. No collateral vessels were noted in the usual locations.

Examination of the blood showed a red-cell count of 4,390,000, with a hemoglobin of 12 gm., and a white-cell count of 10,000, with a normal blood smear, a blood Wassermann test and a urine examination were negative. A urea clearance test was 65 per cent and 70 per cent of normal, the blood urea nitrogen was 14.2 mg per 100 cc, and an intravenous pyelogram was normal. A roentgenogram of the chest revealed a prominent left ventricle, but no suggestive notching of the ribs. Fluoroscopy showed definite and marked pulsations toward the neck of the vessels on both sides of the mediastinum. There was no accentuation of the ascending aorta. An electrocardiogram showed a PR interval of 0.15 second, borderline right-axis deviation, a deep S wave in Lead I and a diphaseic R wave in Lead 3.

On March 15, 1947, the preoperative ballistocardiogram was recorded. One year later, surgical correction was successfully accomplished by Dr R. E. Gross in Boston. At operation a point of narrowing was found about 1.5 cm. below the aortic arch. At this site the aorta had a tiny lumen, no more than 3 mm. in diameter. The narrowed portion of the aorta was removed, and by means of an end-to-end anastomosis the lumen of the aorta was restored to normal size. The patient's general condition was good during and after surgery, and he enjoyed an uninterrupted convalescence.

He has been well since operation. A ballistocardiogram taken on October 2 was entirely normal. The blood pressures at this time were recorded as 118/70 in the left arm and 124/60 in the right arm. Pressures in the legs were 140/60 in both, with a restoration of good pulsations in the abdominal aorta and femoral arteries. The heart murmurs, however, have persisted as before.

SUMMARY

Six consecutive cases of definitely established coarctation of the aorta showed the characteristic ballistocardiographic abnormality of a shortened JK stroke. This demonstrates the usefulness of the ballistocardiogram as a diagnostic agent in suspected cases of aortic coarctation.

In the normal ballistocardiogram there is a full and uninterrupted downward JK stroke, which represents the decelerated impact of ejected blood as it strikes the major peripheral arterial resistance. The abrupt and early interruption of the flow of blood because of the coarctation, then, is the cause of the shortened JK stroke. Surgical correction of this abnormality should restore normal dynamics and produce a normal ballistocardiogram.

The case history and preoperative and postoperative ballistocardiographic tracings of a patient with this condition are presented.

PRESENT-DAY STATUS OF FENESTRATION SURGERY*

LEIGHTON F. JOHNSON, M.D.,† AND HECTOR SILVA, M.D.‡

BOSTON

THE purpose of this paper is to present a study of the results of fenestration surgery, based on our ten years' experience at the Boston University School of Medicine and Massachusetts Memorial Hospitals, on observations made at various other clinics visited and, finally, on the current literature.

In any discussion of fenestration surgery it should be remembered that the first practical, considerable operation for the relief of deafness from otosclerosis was devised by Dr. Julius Lempert. It is also interesting to observe that the major changes in the evolution of this work have emanated from him. However difficult the birth of fenestration surgery may have been, its value is now generally recognized, and its future secure.

The etiology of otosclerosis is still unknown. There is, however, an immense amount of research being carried on to determine the etiologic factors,

and it appears probable that a plausible explanation for this pathologic phenomenon will soon be described. Such observers as Kobrak, Hallowell Davis, Stacey Guild, Dorothy Wolf and Weaver, working in the allied fields of histopathology, physiology and electronics, have greatly extended otologic concepts, and aural mysticism is beginning to give way to aural realism.

The pathology of otosclerosis is complex and not clearly understood. It is known that the process may appear anywhere in the bony capsule of the labyrinth. It is also known that eighth-nerve deterioration is part of the complex picture of otosclerosis, and no explanation for this phenomenon has thus far appeared. The whole subject is teeming with challenging, unsolved problems. So far, there is insufficient evidence to prove that fenestration of the labyrinth halts the progressive degenerative changes of the eighth nerve. The question whether a successful fenestration operation gives a respite from deafness for ten or fifteen years or whether it is a permanent cure cannot be answered today. Deaf-

*Presented at the annual meeting of the American College of Surgeons, Los Angeles, California, October 21, 1948.

†Professor of otolaryngology, Boston University School of Medicine, chief Otolaryngology Service, Massachusetts Memorial Hospitals.

‡Resident in otolaryngology, Massachusetts Memorial Hospitals.

ened persons, however, are anxious to avail themselves of the possibility of social and economic rehabilitation even if the permanency of the operation is still in question

The selection of cases suitable for fenestration is an exacting responsibility and plays a most important part in the success or failure of this work. To hope to restore hearing to the practical threshold, which is considered to be the 30-decibel level, presupposes a nerve response by bone conduction of 30 or better by audiometric examination and a differential between the air and bone audiogram of at least 25 decibels. This differential between the air and bone response is referred to as the cochlear potential. The tuning forks continue to be invaluable in the diagnosis of otosclerosis and in the selection of suitable cases for operation.

It is true that certain patients with an audiometric nerve response in one or more frequencies below 30 decibels improve remarkably after operation. In many such cases both the patient and operator are conscious of the probability of failure, and occasionally there is a gratifying result. However, we consider the favorable response too infrequent to justify the procedure except in rare cases.

The principle behind the fenestration operation is a delightfully simple one. In brief, the oval window has been invaded by the otosclerotic process, thereby partially or completely shutting out the air-borne sound waves from the labyrinth. The operation calls for the construction of a new window into the labyrinth through which the sound waves may pass. The execution of this simple principle to the ultimate goal of restored hearing is, however, complex and highly technical.

The technic of the fenestration operation is familiar to all. Its evolution embraces two main eras. During the first period, in which the window was made in the external horizontal canal, the incus was left in situ. The immediate results of this operation were spectacular, however, within the first year two thirds of the cases had bony closure of the fistula, and the hearing dropped to the preoperative level. In the present era the fistula is made in the surgical dome of the vestibule, and the incus is removed. This new window has been named the *novalis*. In this location a much larger fistula can be made, and the selection of this site by Lempert doubtless saved fenestration surgery from the discard.

Innumerable attempts have been made to influence the osteogenic reaction around the fistula by a wide variety of procedures ranging from the gold burr, various obturators and cartilaginous stopples to the lead burr. Lempert has proved by experiments on monkeys that the lead burr definitely inhibits osteogenesis. It is now our practice to use the lead burr routinely. The present technic of preparing the fistula by removal of the lid in one piece obviates the production of much bone dust

and thereby lessens the likelihood of bone regeneration.

All aspects of the fenestration operation must be performed with technical finesse, but it is the fistula that requires meticulous endeavor, and success or failure largely hinges on this aspect of the operation.

We believe that progress has been too rapid in the endeavor to handle the difficult problems connected with osteogenesis and fistula patency. Certain procedures that appeared sound from the standpoints of physiology and physics have sharply reduced the percentage of successes—for example, the cartilaginous stopple and the use of the dental excavators. Most operations in which the stopple was employed did not bring the hearing acuity to the practical threshold. The use of the dental excavators stimulated the endosteal layer, with resulting untoward osteogenesis. We are convinced that the present cupola technic of Lempert or the double line procedure of House will give a sharply increased percentage of success in cases reported one or two years hence.

The causes of failure of the fenestration operation include improper selection of cases and bony closure of the fistula. The incidence of bony closure when the fistula is made in the surgical dome of the vestibule by the cupola or twin line technic and properly treated with lead has been reduced to approximately 10 per cent. It should be emphasized that the flap should undergo most careful scrutiny under magnification for the presence of bony spicules. Obviously, if a bony spicule is attached to the under-surface of the flap and the spicule falls over the fenestra, early closure is certain. Revisions when bony closure has reduced the hearing to the preoperative level are far more successful today than in the era of the fistula in the external horizontal canal.

Aseptic labyrinthitis continues to be a possible source of failure. However, with penicillin given routinely for five days, its incidence has been greatly curtailed. Great care must be exercised in irrigation so that the membranous labyrinth is not traumatized while bone dust is being washed away from the endosteum, any instrumentation calls for meticulous effort to avoid trauma to the labyrinth.

Thermal changes to the labyrinth by excessive heat caused by the polishing burr or an irrigation solution that is too warm must be zealously guarded against.

There must be complete hemostasis at the time the labyrinth is opened.

The anesthesia for the fenestration operation seems to vary with each clinic. The following is the anesthetic procedure in use at the Massachusetts Memorial Hospitals.

Preoperative medication should be adequate to provide a good night's sleep and to present the patient in the operating room quite drowsy and euphoric. 2 gm of phenobarbital at bedtime, the

dosage being repeated if necessary for sleep, 2 gm of phenobarbital by mouth at 6 a m, 2 to 6 gm of neonal by mouth at 6 30, 5 to 8 mg of morphine sulfate subcutaneously at 7, and 5 to 8 mg of morphine sulfate and 0.6 mg of atropine sulfate subcutaneously at 7 30

On arrival in the operating room at 7 45, a needle is inserted in a vein, preferably of the lower extremity, and an infusion of dextrose in water is started. The pharynx is sprayed with 2 per cent pontocaine. Sodium nembutal, in a dosage ade-

quate to induce sleep, is injected into the tubing (50 to 150 mg is usually sufficient). A continuous infusion of 0.4 per cent pentothal sodium is started about five minutes before incision by the insertion of a needle through the tubing so that the solution runs in through the needle previously placed. When the patient is sufficiently relaxed, a Guedel oropharyngeal airway is placed and oxygen is run in through a catheter threaded through this during operation. The total dose of pentothal sodium is usually 1 gm or less, and rarely is as much as 1.5 gm.

This anesthesia, in the hands of the Anesthesia Service, has proved safe and satisfactory.

Postoperatively, each patient receives 300,000 units of penicillin daily. Pyribenzamine, in amounts of 50 mg, is given four times a day. This is administered empirically in the hope that its antihistaminic action may prove beneficial in thwarting the possibility of chemical labyrinthitis. The cavity is packed with either paraffin gauze or small sea sponges. We have been using the sea sponges for some time, since they are easy to apply and remove, and are successful in firmly attaching the flap to the bony surface. The packs are removed on the fifth day under careful aseptic technic, and the patient leaves the hospital on the tenth day. Office dressings are done once or twice a week thereafter until the cavity is dry and epidermatized.

Throughout our entire series we have had no mortality and no injury to the facial nerve. There have been no untoward complications such as lateral sinus thrombosis and intracranial disease. The complications have been limited to local allergic reaction to the sulfonamides, a few cases of persistent aural discharge requiring considerable time and patience to dry up, a case of acute otitis media after operation, with spontaneous rupture (with

large doses of penicillin the middle ear became dry, and the perforation healed with no ultimate damage to the improved hearing), and 4 cases of atresia of the external auditory meatus, requiring excision of scar tissue.

The results of fenestration surgery may be divided into four groups as follows: patients who show a postoperative hearing level of 30 decibels or better for the vital frequencies of 512, 1024 and 2048; patients whose postoperative hearing level is not sustained at the 30-decibel level but in whom definite gain in hearing acuity has taken place; patients whose hearing remains at the preoperative level; and those whose hearing has become worse after operation.

Table 1 shows our record at the Massachusetts Memorial Hospitals with the novovalis operation from 1942 to 1946. Any skillful operator can have an immediate record of at least 80 per cent successes, but at least one year should transpire before the permanency of the hearing can be accurately evaluated. It should be mentioned that this list includes 4 cases in which the stopple was employed, none of which reached the practical threshold. Many of the patients listed as improved are perfectly rehabilitated, but since their audiograms do not show the practical threshold of 30 decibels, they are labeled only as improved. Nearly all in this group had practical hearing immediately after operation, but in the year and a half since then, 14 per cent

TABLE 1 *Results of Novovalis Fenestration Operation in 151 Cases, 1942-1946*

RESULT	PERCENTAGE OF CASES
Practical hearing	60.0
Improved hearing	26.0
Preoperative hearing level	13.0
Hearing worse after revision	0.88

TABLE 2 *Results in the Experimental Group (Diminished Bone Conduction), 1942-1946*

RESULT	PERCENTAGE OF CASES
Practical hearing	31
Improved hearing	18
Preoperative hearing level	51
Hearing worse	0

have fallen to the preoperative level. Many are suitable for revision.

The second group comprises 32 experimental cases in which one or more of the vital frequencies were below the 30-decibel level by bone conduction (Table 2).

CONCLUSIONS

We believe that no patients with otosclerotic deafness have experienced restored practical hearing except by the Lempert fenestration operation. Several thousand patients today have been socially and economically rehabilitated by this means. In skilled and trained hands the surgical hazards are minimal. The likelihood that further impairment in hearing will result from operation is less than 1 per cent.

The record of the last two years gives every promise of substantial improvement in the per-

centage of patients who have had no mortality and no injury to the facial nerve. There have been no untoward complications such as lateral sinus thrombosis and intracranial disease. The complications have been limited to local allergic reaction to the sulfonamides, a few cases of persistent aural discharge requiring considerable time and patience to dry up, a case of acute otitis media after operation, with spontaneous rupture (with

centage of practical hearing, because of the improved fistula technic

The work is new and should be approached only by those with broad otologic training and an investigative temperament

In the transition from surgical procedures for infections to operation and study for the alleviation of deafness otology has emerged increased in stature and achieved an enviable position among the surgical specialties

MEDICAL PROGRESS

ORAL SURGERY (Continued)

KURT H. THOMA, M.D.*

BOSTON

DENTOALVEOLAR SURGERY

Dentoalveolar surgery, which includes the extraction of teeth (exodontia), probably occupies a large part of the time of most oral surgeons

The technic of tooth extraction has been perfected. Teeth judged to be complicated on x-ray examination because of exostosis of the roots or anatomic deformity are excised by an open procedure that allows clear vision and prevents laceration of the soft tissue and fracturing of the surrounding alveolar bone.^{51 52}

Much more attention has recently been devoted to the correction of deformities and preparation of the alveolar ridge for the construction of satisfactory dentures.^{53 54} Deformities such as maxillary protrusion are eliminated by alveolectomy. Bony exostoses and hyperplasia of the gums are excised. Irregularities caused by trauma when the teeth are extracted are eliminated to produce an even ridge, and in cases of atrophy of the alveolar process, knife-edge ridges should be made smooth,⁵⁵ whereas in other cases an operation for ridge extension is indicated.^{56 57}

New methods have been developed during the last two decades for the removal of unerupted and impacted third molars. An odontectomy⁵⁸ is performed if the tooth is impacted. This includes tooth division to preserve the bone, large parts of which formerly had to be removed to dislodge the tooth *in toto*. Pell and Gregory⁵⁹ report their findings on the basis of a ten-year study and recommend tooth sectioning highly because of the small amount of operative trauma, which reduces the postoperative discomfort.

It is generally believed that the removal of these malposed teeth can be more easily performed in young persons, and others have gone so far as to recommend prophylactic odontectomy^{60 61} to prevent the crowding and disalignment of anterior teeth. Such malocclusion is caused by pressure of

the third molars in their attempt to erupt. Other reasons for the early removal of these teeth are, according to Gunter,⁶² the following: their eruption may be accompanied by pain and infection of the investing structures (pericoronal infection), they are often hypoplastic and susceptible to dental caries, their repair, if decay is present, is difficult and inadequate, and they tend to disturb the alignment of other teeth. In addition should be mentioned obscure, referred pain, which may radiate to other branches of the fifth nerve or may even involve other nerves of the face and head.⁶³ There is no room in the modern dental arch for third molars, and few of them ever become functional teeth.

The patient's general health and resistance should be considered in case of multiple extraction of infected teeth, and the dentist should consult with the patient's physician.⁶⁴ This is especially true in cases of diabetes and cardiac, thyroid and renal diseases. Most patients with such diseases should be hospitalized, properly prepared and premedicated, and given the protection of antibiotic therapy before and during the operation and also post-operatively. Kane⁶⁵ points out that the danger of bacteremia during the extraction of infected teeth should always be kept in mind. The risk of bacterial shower is present not only in apical abscesses but also in periodontal infection. O'Kell and Elliott⁶⁶ have recovered *Streptococcus viridans* from the blood stream in 75 per cent of 40 patients suffering from marked pyorrhea. Barnfield,⁶⁷ studying autopsy records of 92 cases of subacute bacterial endocarditis, found in 6 a relation between the disease and extraction. Of 40 reported cases supposedly precipitated by dental extraction, in 15 there was convincing evidence, whereas in 10 others the relation seemed probable. Kane⁶⁸ believes that oral surgeons may do much to prevent the occurrence of subacute endocarditis by giving patients with heart murmurs prophylactic penicillin, which is superior to the sulfonamides in preventing transient bacteremia. Pressman and Bender⁶⁹ report an incidence of bacteremia as high as 80 per cent after

*Emeritus professor of oral surgery and Charles A. Brackett, Professor of Oral Pathology, Harvard University; lecturer in oral surgery, Graduate School of Medicine, University of Pennsylvania; member, Board of Consultation, Massachusetts General Hospital.

tooth extraction The American Heart Association⁶⁹ has urgently recommended that dentists take advantage of the prophylactic effect of penicillin when extracting teeth for patients with rheumatic heart disease

Patients with a hemorrhagic diathesis require special consideration Hemorrhage following tooth extraction has always been feared though lately great progress has been made in its prevention In many cases, local causes are present, such as fractured alveolar process and lacerations of the gingiva If bleeding is due to systemic disease, a more serious situation exists, and general as well as local therapy is indicated The patient should first of all be hospitalized, and a thorough blood study should be made The following treatment has been recommended⁷⁰

In ascorbic acid deficiency, which is generally recognized because it produces a typical scorbutic gingivitis besides the well known general signs, spontaneous hemorrhages occur in the mouth from the bluish-purple, bloated gums Patients should receive 500 mg of ascorbic acid per day with vitamin P (citric) to decrease the capillary fragility

In thrombocytopenic purpura, splenectomy may almost immediately cause a marked increase in the platelet count, and fresh blood transfusions are valuable In cases of secondary purpura that are not improved by splenectomy in addition to transfusions, the use of moccasin venom has been recommended⁷¹

In cases of pernicious anemia, liver therapy is indicated, in cases of hemorrhage associated with obstructive jaundice, vitamin K with bile salts should be given In the leukemias, blood transfusions to decrease the danger of hemorrhage in preparation for necessary tooth extraction, which should be avoided if possible, are considered helpful In hemophilia, a cure cannot be expected, but in anticipation of tooth extraction, or if the patient has started to bleed spontaneously, transfusions of fresh blood (twelve to twenty-four hours old) are recommended to reduce the coagulation time Small amounts of blood (50 to 100 cc) will reduce the coagulation time markedly Such transfusions should be repeated frequently until the danger of hemorrhage has passed They should be given preoperatively, during the operation and postoperatively

Lewis and his associates⁷² reported that normal plasma contains a substance that is absent in hemophilic plasma and is a subfraction of the active globulin fraction with which it is associated In the Plasma Fractionation Laboratory of the Department of Physical Chemistry, Harvard Medical School, an antihemophilic globulin, Fraction I, of normal blood plasma has been developed for intravenous administration and is provided by the Red Cross without charge It will reduce the coagula-

tion time to about fifteen to thirty minutes after one or two intravenous injections of the content of two vials containing 200 mg each, diluted in 5 cc. of sterile water The tooth extractions should be performed as soon as the clotting time has been reduced to safe ranges, and it is recommended that all the teeth that have to be extracted be removed at one sitting The reduction of the clotting time persists for about four hours, after which it slowly rises to its previous high level The injection may be repeated until the wound has healed completely This treatment, however, has not been found to give uniformly good results, and blood transfusions may have to be given as well It is believed by some hematologists that there is another factor lacking in hemophilia, such as a serum activator, that has not been discovered as yet

Other patients may have a predisposition to hemorrhage that is not so easily recognized Among these are patients with prothrombinopenia, which may arise from lack of vitamin K because of dietary deficiency, faulty absorption due to lack of bile salts (obstructive jaundice, biliary fistula and sprue) or severe infection and liver damage Here should be mentioned the effect of the prolonged use of acetylsalicylic acid, which may decrease the prothrombin Prothrombinopenia may be corrected in such cases by the administration of vitamin K Cahn⁷³ recommends that 1 mg of vitamin K be prescribed to every 0.38 gm of aspirin, if the drug is taken constantly

There is also recognized nonhemophilic hereditary hemorrhage, which occurs in patients with perfectly normal hematologic findings, except the bleeding time, which is prolonged They suffer from prolonged bleeding after injuries, especially the extraction of teeth In some the tourniquet test is positive whereas the platelet count and coagulation times are normal Offspring of either sex may inherit the disease Levy⁷⁴ recently reported 4 such cases with prolonged bleeding after extraction of teeth

Local Treatment of Hemorrhage

Before the local treatment is described, it should be pointed out that patients with or without hemorrhagic diathesis who have been bleeding excessively become dehydrated Fluids should be forced by mouth or given intravenously, or blood should be given if the hemoglobin and red-cell count are low⁷⁵

After the extraction of teeth, meticulous care should be taken to arrest all bleeding from soft-tissue wounds Often suturing is indicated A sterile pack of gauze may be applied between the jaws It is placed on the bleeding socket or on an oozing wound that has been sutured, until the clot has formed Excessive bleeding from a tooth socket may be dealt with by the placing of thrombin or

oxidized cellulose into the alveolus, as described below

In case of secondary hemorrhage after tooth extraction the socket should be debrided, all old clot removed, and a pressure pack applied. The patient should be placed in a semi-Fowler position if in bed, or should be directed to sit in a chair rather than to lie down, to decrease the blood pressure in the head. Cold compresses applied to the region or to the neck are often useful. Rinsing the mouth should be prohibited.

Various drugs have been recommended for local application. Epinephrine in 1:1000 solution is generally employed during operation. The use of ferric subsulfate powder pressed into a socket with iodoform gauze and left for several days has given good results, although the black precipitate is objectionable. In patients with hemorrhagic diseases the bleeding may be arrested by the local application of fresh raw meat, fresh blood or cephalin. Beef or rabbit globulin can be applied on gauze into the socket, and has been recommended as a great aid in such bleeding after tooth extraction. Today, oxidized cellulose⁷⁶ may be left in the wound permanently, avoiding the danger of new hemorrhage, which is always feared when a medicated gauze pack is being removed. I have found thrombodont cones,* which contain 1 unit of thrombin and 1 mg of tyrothricin, extremely effective; they are ideal for use in the mouth because they contain an antibiotic that is effective against gram-positive and some gram-negative organisms found in the oral cavity. One to three are placed into a tooth socket, or if the bleeding occurs at the gingival margin, they can be crushed to a powder and held in place by an intermaxillary pack. These local measures are of great help whether or not general medication and blood transfusions are used.

ODONTOGENIC INFECTIONS

Focal Infection

Chronic dental abscesses and periodontal diseases as foci of infection played an important role three decades ago. Today focal infection is not heard of so much in this country, although abroad papers on this subject are making up a considerable part of the literature. This may be due to the great clean-up that followed the denunciation of septic dentistry by William Hunter in his famous inauguration lecture at McGill.⁷⁷ The American dentist was quick to change his attitude toward the retention of all teeth whether good or bad as long as they were asymptomatic, and discarded practices that led to the formation of abscesses. When it is deemed advisable to retain a tooth in spite of an infected pulp, root-canal therapy is undertaken. Bacterial tests are made during the treatment of

the root canals, which are not filled until they are free of infection.⁷⁸

Reimann and Havens⁷⁹ concluded that the field of focal infection has been definitely narrowed from former concepts. Several sobering articles have appeared to discourage those who believe that all ills can be cured by the extraction of teeth, and it has been pointed out that the removal of a focus of infection presents more prophylactic than therapeutic potentialities.⁸⁰ However, the theory of focal infection should not be entirely discredited since there are still occasional cases in which there is a good probability of the relation of infected teeth to the systemic disorder of the patient. Kravitz⁸¹ believes that, of all foci of infection, those of the teeth are most closely related to the eye. Slocumb et al.,⁸² of the Mayo Clinic, discussing the effect of the removal of foci of infection in heart disease, chronic infectious arthritis and glomerulonephritis (conditions representative of those in which removal of foci of infection has been said to be of clinical benefit), state that in heart disease focal infection can be considered to be a factor only in an occasional case of coronary thrombosis or acute pericarditis. However, they lay stress on the importance of protecting patients by means of chemotherapy when septic tonsils and badly infected teeth are removed in the presence of an old valvular lesion. As previously mentioned, bacteremia following dental extractions may become the starting point for acute bacterial endocarditis. In chronic infectious arthritis, the authors recommend eradication of a definite focus if present after the progression of symptoms is under control. Chronic glomerulonephritis is considered to be caused by repeated and continued toxic assaults on the kidneys originating in acute and chronic foci of infection. Patients with chronic nephritis, intermittent suffering and exacerbations have more than 80 per cent evidence of chronic infections about the roots of teeth, tonsils or sinuses, and clearing up such foci not only shortens the convalescent period of the acute episode but also prevents further damage to the kidney. Ensign⁸³ points out that infected pockets in periodontal disease are an important focus, and the mobility of the teeth aids toxic absorption, "the tooth acting as a piston pumping bacteria into an area of rich capillary supply."

Acute Alveolar Abscesses

These inflammations and their sequelae, deep infections involving the fascial planes around the jaws, have been accompanied with very serious complications. Keefe⁸⁴ called attention to the fact that three periods of disease may be distinguished: that in which the initial lesion develops, that of extension to the fascial spaces, and that of serious complications through embolism, pyemia and septicemia. Haymaker,⁸⁵ of the Army Institute of Path-

*Available from L. D. Caulk Company, Milford, Delaware.

tooth extraction. The American Heart Association⁶⁹ has urgently recommended that dentists take advantage of the prophylactic effect of penicillin when extracting teeth for patients with rheumatic heart disease.

Patients with a hemorrhagic diathesis require special consideration. Hemorrhage following tooth extraction has always been feared though lately great progress has been made in its prevention. In many cases, local causes are present, such as fractured alveolar process and lacerations of the gingiva. If bleeding is due to systemic disease, a more serious situation exists, and general as well as local therapy is indicated. The patient should first of all be hospitalized, and a thorough blood study should be made. The following treatment has been recommended.⁷⁰

In ascorbic acid deficiency, which is generally recognized because it produces a typical scorbutic gingivitis besides the well known general signs, spontaneous hemorrhages occur in the mouth from the bluish-purple, bloated gums. Patients should receive 500 mg of ascorbic acid per day with vitamin P (citrin) to decrease the capillary fragility.

In thrombocytopenic purpura, splenectomy may almost immediately cause a marked increase in the platelet count, and fresh blood transfusions are valuable. In cases of secondary purpura that are not improved by splenectomy in addition to transfusions, the use of moccasin venom has been recommended.⁷¹

In cases of pernicious anemia, liver therapy is indicated, in cases of hemorrhage associated with obstructive jaundice, vitamin K with bile salts should be given. In the leukemias, blood transfusions to decrease the danger of hemorrhage in preparation for necessary tooth extraction, which should be avoided if possible, are considered helpful. In hemophilia, a cure cannot be expected, but in anticipation of tooth extraction, or if the patient has started to bleed spontaneously, transfusions of fresh blood (twelve to twenty-four hours old) are recommended to reduce the coagulation time. Small amounts of blood (50 to 100 cc) will reduce the coagulation time markedly. Such transfusions should be repeated frequently until the danger of hemorrhage has passed. They should be given preoperatively, during the operation and postoperatively.

Lewis and his associates⁷² reported that normal plasma contains a substance that is absent in hemophilic plasma and is a subfraction of the active globulin fraction with which it is associated. In the Plasma Fractionation Laboratory of the Department of Physical Chemistry, Harvard Medical School, an antihemophilic globulin, Fraction I, of normal blood plasma has been developed for intravenous administration and is provided by the Red Cross without charge. It will reduce the coagula-

tion time to about fifteen to thirty minutes after one or two intravenous injections of the content of two vials containing 200 mg each, diluted in 5 cc. of sterile water. The tooth extractions should be performed as soon as the clotting time has been reduced to safe ranges, and it is recommended that all the teeth that have to be extracted be removed at one sitting. The reduction of the clotting time persists for about four hours, after which it slowly rises to its previous high level. The injection may be repeated until the wound has healed completely. This treatment, however, has not been found to give uniformly good results, and blood transfusions may have to be given as well. It is believed by some hematologists that there is another factor lacking in hemophilia, such as a serum activator, that has not been discovered as yet.

Other patients may have a predisposition to hemorrhage that is not so easily recognized. Among these are patients with prothrombinopenia, which may arise from lack of vitamin K because of dietary deficiency, faulty absorption due to lack of bile salts (obstructive jaundice, biliary fistula and sprue) or severe infection and liver damage. Here should be mentioned the effect of the prolonged use of acetylsalicylic acid, which may decrease the prothrombin. Prothrombinopenia may be corrected in such cases by the administration of vitamin K. Cahn⁷³ recommends that 1 mg of vitamin K be prescribed to every 0.38 gm of aspirin, if the drug is taken constantly.

There is also recognized nonhemophilic hereditary hemorrhage, which occurs in patients with perfectly normal hematologic findings, except the bleeding time, which is prolonged. They suffer from prolonged bleeding after injuries, especially the extraction of teeth. In some the tourniquet test is positive whereas the platelet count and coagulation times are normal. Offspring of either sex may inherit the disease. Levy⁷⁴ recently reported 4 such cases with prolonged bleeding after extraction of teeth.

Local Treatment of Hemorrhage

Before the local treatment is described, it should be pointed out that patients with or without hemorrhagic diathesis who have been bleeding excessively become dehydrated. Fluids should be forced by mouth or given intravenously, or blood should be given if the hemoglobin and red-cell count are low.⁷⁵

After the extraction of teeth, meticulous care should be taken to arrest all bleeding from soft-tissue wounds. Often suturing is indicated. A sterile pack of gauze may be applied between the jaws. It is placed on the bleeding socket or on an oozing wound that has been sutured, until the clot has formed. Excessive bleeding from a tooth socket may be dealt with by the placing of thrombin or

oxidized cellulose into the alveolus, as described below

In case of secondary hemorrhage after tooth extraction the socket should be debrided, all old clot removed, and a pressure pack applied. The patient should be placed in a semi-Fowler position if in bed, or should be directed to sit in a chair rather than to lie down, to decrease the blood pressure in the head. Cold compresses applied to the region or to the neck are often useful. Rinsing the mouth should be prohibited.

Various drugs have been recommended for local application. Epinephrine in 1:1000 solution is generally employed during operation. The use of ferric subsulfate powder pressed into a socket with iodoform gauze and left for several days has given good results, although the black precipitate is objectionable. In patients with hemorrhagic diseases the bleeding may be arrested by the local application of fresh raw meat, fresh blood or cephalin. Beef or rabbit globulin can be applied on gauze into the socket, and has been recommended as a great aid in such bleeding after tooth extraction. Today, oxidized cellulose⁷⁶ may be left in the wound permanently, avoiding the danger of new hemorrhage, which is always feared when a medicated gauze pack is being removed. I have found thrombodont cones,* which contain 1 unit of thrombin and 1 mg of tyrothricin, extremely effective; they are ideal for use in the mouth because they contain an antibiotic that is effective against gram-positive and some gram-negative organisms found in the oral cavity. One to three are placed into a tooth socket, or if the bleeding occurs at the gingival margin, they can be crushed to a powder and held in place by an intermaxillary pack. These local measures are of great help whether or not general medication and blood transfusions are used.

ODONTOGENIC INFECTIONS

Focal Infection

Chronic dental abscesses and periodontal diseases as foci of infection played an important role three decades ago. Today focal infection is not heard of so much in this country, although abroad papers on this subject are making up a considerable part of the literature. This may be due to the great clean-up that followed the denunciation of septic dentistry by William Hunter in his famous inauguration lecture at McGill.⁷⁷ The American dentist was quick to change his attitude toward the retention of all teeth whether good or bad as long as they were asymptomatic, and discarded practices that led to the formation of abscesses. When it is deemed advisable to retain a tooth in spite of an infected pulp, root-canal therapy is undertaken. Bacterial tests are made during the treatment of

the root canals, which are not filled until they are free of infection.⁷⁸

Reimann and Havens⁷⁹ concluded that the field of focal infection has been definitely narrowed from former concepts. Several sobering articles have appeared to discourage those who believe that all ills can be cured by the extraction of teeth, and it has been pointed out that the removal of a focus of infection presents more prophylactic than therapeutic potentialities.⁸⁰ However, the theory of focal infection should not be entirely discredited since there are still occasional cases in which there is a good probability of the relation of infected teeth to the systemic disorder of the patient. Kravitz⁸¹ believes that, of all foci of infection, those of the teeth are most closely related to the eye. Slocumb et al.,⁸² of the Mayo Clinic, discussing the effect of the removal of foci of infection in heart disease, chronic infectious arthritis and glomerulonephritis (conditions representative of those in which removal of foci of infection has been said to be of clinical benefit), state that in heart disease focal infection can be considered to be a factor only in an occasional case of coronary thrombosis or acute pericarditis. However, they lay stress on the importance of protecting patients by means of chemotherapy when septic tonsils and badly infected teeth are removed in the presence of an old valvular lesion. As previously mentioned, bacteremia following dental extractions may become the starting point for acute bacterial endocarditis. In chronic infectious arthritis, the authors recommend eradication of a definite focus if present after the progression of symptoms is under control. Chronic glomerulonephritis is considered to be caused by repeated and continued toxic assaults on the kidneys originating in acute and chronic foci of infection. Patients with chronic nephritis, intermittent suffering and exacerbations have more than 80 per cent evidence of chronic infections about the roots of teeth, tonsils or sinuses, and clearing up such foci not only shortens the convalescent period of the acute episode but also prevents further damage to the kidney. Ensign⁸³ points out that infected pockets in periodontal disease are an important focus, and the mobility of the teeth aids toxic absorption, "the tooth acting as a piston pumping bacteria into an area of rich capillary supply."

Acute Alveolar Abscesses

These inflammations and their sequelae, deep infections involving the fascial planes around the jaws, have been accompanied with very serious complications. Keefe⁸⁴ called attention to the fact that three periods of disease may be distinguished: that in which the initial lesion develops, that of extension to the fascial spaces, and that of serious complications through embolism, pyemia and septicemia. Haymaker,⁸⁵ of the Army Institute of Path-

*Available from L. D. Caulk Company, Milford, Delaware.

ology, has described 27 cases of fatal intracranial complications of dental infection. Direct spread was more often caused by maxillary than by mandibular teeth, whereas in hematogenous infection the reverse was true. Osteomyelitis of the sphenoid bone occurred in 8 cases, brain abscess in 7, cavernous-sinus thrombosis in 9, infraorbital abscesses in 6, and intraorbital abscesses in 3. Hargraves⁸⁶ stresses the need for early and adequate treatment to reduce the mortality by preventing such complications.

The best treatment of acute dentoalveolar abscesses is prompt extraction of the tooth, under the protection of antibiotic therapy. A culture should be taken to establish the penicillin sensitivity of the organisms. Swelling of the face and early cellulitis generally require no treatment besides continuation of parenteral administration of the antibiotic.⁸⁷ In advanced cases when submaxillary, submental, sublingual, parapharyngeal, masseter, parotid and infratemporal abscesses or their complications have already developed, removal of the original focus (tooth) will not afford sufficient drainage, and the antibiotic treatment will not be effective without operative interference.⁸⁷ Incision and drainage should be resorted to, and great care should be taken to open deep accessory abscesses. Since penicillin has come into use, complications are less frequent and less likely to have a fatal result. An example is a case reported by Wiesenfeld and Philipps⁸⁸ of a patient with thrombophlebitis of a cavernous sinus developing after tooth extraction in spite of adequate sulfadiazine administration, who made a dramatic recovery after the administration of penicillin (150,000 units a day). Ludwig's angina also has a much better prognosis, since penicillin has given striking results in early cases with and without incision.⁸⁹

Bacteriologic examination is of great importance since mixed infections are very common in the mouth. Colon bacilli, gram-negative organisms and especially the fusospirochetal organisms are frequently found accompanying infections by the streptococcus or staphylococcus, and in some cases the use of streptomycin is therefore indicated. Actinomycosis frequently yields to penicillin therapy. Nichols and Herrell⁹⁰ reported cures in 24 out of 26 cervicofacial cases. They recommend the administration of 500,000 units daily for six weeks.

OSTEOMYELITIS OF THE JAWS

The treatment of osteomyelitis of the jaws, which may be caused by dental infections and septic fracture, occasionally by furunculosis⁹¹ and through hematogenous transportation of bacteria,⁹²⁻⁹³ has also undergone a considerable change since the advent of chemotherapy.

Infantile Osteomyelitis of the Maxilla

This condition has a better outlook. Intramuscular injections of penicillin, 80,000 to 800,000

units a day, are recommended and, if an intraoral fistula is present, should be supplemented with penicillin irrigations.⁹⁴ Schenk⁹⁵ described 5 patients all of whom recovered in spite of a mortality of 20 to 50 per cent. He recommended that penicillin should be administered promptly, and a minimum of 800,000 units should be given over a long period. Sometimes, penicillin combined with sulfonamide is recommended in mixed infections.

Osteomyelitis of the Jaws in Adults

This inflammation occurs in an acute fulminating form and the more frequent subacute and chronic types. The former is often aborted if penicillin treatment is instituted even before x-ray evidence of bone changes can be demonstrated.⁹⁶ In most of the subacute and chronic cases the use of antibiotics and the removal of the cause do not result in resolution without operative interference to eliminate pus and necrotic tissue since patients frequently do not seek treatment until extensive suppuration and bone necrosis have occurred.⁸⁷ Various operative procedures performed under antibiotic therapy are recommended,⁹⁷ including surgical drainage, sequestrectomy and saucerization, fixation in pathologic fracture and very rarely excision of the affected segment of bone. Sequestrectomy is simple if an intraoral approach is possible, frequently, however, the sequestrum is encased or inaccessible, and an extraoral sequestrectomy is recommended.⁹⁸ This is combined with careful débridement and saucerization of the bone defect. Excision (condylectomy) is especially indicated if the infection is restricted to the condyloid process, which occurs as a complication of an infratemporal abscess, since osteomyelitis here generally causes partial or complete ankylosis of the mandibular joint.⁹⁹ In any of these procedures intramuscular administration of antibiotics should be supplemented by local instillation of a solution of 1000 to 5000 units of penicillin per cubic centimeter into the involved area, as recommended by Smith-Petersen, Larson and Cochran.¹⁰⁰ A rubber catheter sutured to the margin of the incision gives satisfactory results and allows primary closure of the wound.

The determination of the bacteria causing the infection is recommended in each case, with their sensitivity to specific antibiotics. Although staphylococci and streptococci are the common bacteria found, Vincent's organism, colon bacilli and many other aerobic and anaerobic organisms may be encountered. It is well to have a serologic test because syphilis occasionally simulates pyogenic osteomyelitis,¹⁰¹ and in the localized form tuberculosis should be kept in mind.¹⁰² Pathological examination of the excised tissue establishes the diagnosis.

Good postoperative care is of great importance in osteomyelitis. This includes a liquid diet high in protein, caloric and vitamin content. The adminis-

tration of fluids and electrolytes is indicated, and the use of blood transfusions to improve the patient's general resistance aids the recovery

Irradiation Osteomyelitis

Necrosis of the jaw, as well as a slowly progressing sclerosing type of osteomyelitis, is produced by heavy irradiation for the treatment of cancer. The resorptive and regenerative power of the bone is destroyed. Watson and Scarborough¹⁰² reported on 235 cases of osteonecrosis found in a group of 1819 patients with cancer of whom 12 died free of cancer as a direct result of jaw infection. Colby¹⁰⁴ makes a statement with which I thoroughly agree — namely, that radical dental treatment is indicated before irradiation, all remaining teeth being extracted. Irradiated patients on the other hand should have no operative procedures on the irradiated jaw for years. If teeth remain, proper hygienic conditions should be maintained, and extremely conservative dental treatment is imperative. The use and construction of protective prostheses containing lead shields has been described by Ackerman¹⁰⁵. They are used to protect the regions of the jaw that are not to be irradiated.

FRACTURES OF THE MAXILLA AND MANDIBLE

Great progress was made in the treatment of fractures of the jaws during World War I, but there were certain limitations, which were only recently overcome with the advent of the use of antibiotics. Simplified methods of fixation that require less technical work (dental splints) have been developed,¹⁰⁶ assuring more rapid results with less discomfort to the patient. This refers particularly to transosseous wiring and skeletal fixation.

Transosseous Wiring

While the use of open reduction with internal wiring fixation has been discouraged in the past, Gordon¹⁰⁷ reported the use of this method for 7 malar, 2 maxillary and 15 mandibular fractures. Adams¹⁰⁸ described a method of fixation for maxillary fractures by wiring the fractured parts to neighboring unfractured bony structures to avoid uncomfortable extraoral appliances such as headbands and plaster caps. The prophylactic use of penicillin and of stainless steel or tantalum wire, which are biologically inert, probably plays a great part in the recent success with these methods. It is, however, important not to rely on the wires for the immobilization of jaw fractures. The wire should serve only to hold the fragments in the reduced position so that they cannot be displaced by muscle pull. The fracture should be fixed by immobilization of the mandible.¹⁰⁹

Indications for transosseous wiring are mandibular fractures at the angle of the jaw with upward or lateral displacement of the posterior segment,

fractures through an unerupted third molar, which should be removed, and comminuted fractures with small displaced segments.

Transfixation with Steinmann Pins

This method is hazardous because it easily causes injury to the inferior alveolar nerve and vessels, resulting in anesthesia of the lip and intraosseous hematoma. However, it is useful¹¹⁰ in fractures of the symphysis, as well as for craniomandibular fixation. This method and others eliminating the use of headbands and plaster caps were described by Thoma.¹¹¹

Skeletal Pin and Clamp Fixation

Numerous advantages are claimed for this method. Winter,¹¹² in a report on 36 cases, stated that skeletal fixation made early and prompt reduction possible, since it required a minimum of complicated equipment and therefore could be applied in dressing stations, field hospitals, evacuation hospitals or on shipboard. Of first importance in war surgery, he stated, was the fact that with this method the soldier with a mandibular fracture may be transported after the fracture has been reduced without danger to his life from sea or air sickness. Secondly, because the bone is immobilized but the joint is free, moderate function is possible, which is a great advantage not only because it provides better nourishment for the patient, eliminating the preparation of liquid diets, but also because it favors healing. Haynes¹¹³ pointed out that callus formation may be expected earlier because it is known that the use of a bone increases the inflowing calcium and counteracts the atrophy that occurs from disuse. Other writers pointed out additional advantages. Mowlem et al.¹¹⁴ stated that the method facilitated oral hygiene, simplified feeding and prevented stiffness of the joint and muscles. Griffin¹¹⁵ added that drainage, inspection and irrigation were easily made in compound fractures and fractures with extensive wounds. Gillies¹¹⁶ stressed the perfect control of the fragments into which the pins were inserted and the easy anatomic positioning.

The indications for the use of skeletal fixations were set down by Waldron.¹¹⁷ He recommends the method for badly displaced fractures of the edentulous mandible, particularly when they are comminuted, fractures behind the angle of the jaw, when the posterior fragment becomes difficult to maintain in reduced position, multiple fractures involving both the upper and the lower jaw, when other methods are not satisfactory because of the loss of teeth, comminuted fractures of the mandible with destruction of a section, and cases in which facilities for construction of dental splints are not available.

Thoma¹¹⁸ found skeletal fixation unsatisfactory for cases of fractures at the angle of the jaw, pins will not hold well or last, because the bone in this

part of the mandible is very thin. He developed a peripheral bone clamp that can be placed around the jaw through a suitable incision in the skin, which is closed. Only the pin protrudes through the skin and serves as an attachment for the connecting bars of the fracture appliance fastened to half pins inserted in the anterior fragment.

Bradford and Wilson,¹¹² discussing skeletal fixation, give two good rules to prevent misuse or abuse of the method: the apparatus should be applied only by an experienced surgeon who thoroughly understands the principles of its use and who has carefully studied its mechanism, and the procedure should not be used routinely but should be applied only in cases in which treatment by simple, conservative methods seems to be inadequate.

Fractures of the Mandibular Condyle

These fractures, treated in the past by immobilization of the mandible without any attempt at reduction, have not given such uniformly good results as some of the proponents of conservative treatment suggest. In cases of gross displacement or fracture dislocation this treatment frequently results in deformity, functional debility and malocclusion with deviation on opening of the mouth, and ankylosis may occur.¹²⁰⁻¹²² A method of education and wiring fixation is recommended to prevent these deformities.¹²³ If they do occur, condylectomy will have to be resorted to to give relief.¹²¹

In conclusion, it may be said that the treatment of jaw fractures requires a great deal of experience with a variety of methods old and new. In a discussion of the history of the treatment of jaw fractures¹²³ some of the principles regarded as essential have been set forth and discussed. These are as follows: treatment of the patient, attention to soft-tissue wounds, carefully performed clinical and x-ray examination, determination of the type and exact location of the fracture, prevention and treatment of infection, temporary immobilization if adequate treatment has to be delayed, choice of the correct type of anesthesia, attention to proper reduction, selection of the best method of fixation and immobilization, and proper attention to after-care.

DISEASES OF THE MANDIBULAR JOINT

Arthrosis

Various intra-articular changes may occur in the temporomandibular joint owing either to major trauma causing injury to the meniscus or to trauma resulting from functional disturbances,¹²⁴ some of which are distinctly associated with occlusal abnormalities of the teeth. Other diseases that cause similar symptoms are the rheumatoid, hypertrophic and infectious forms of arthritis, which produce degenerative changes similar to those produced in

other joints of the body, and ankylosis of the jaw may result.

Bellinger¹²⁵ describes the symptomatology as follows: the symptoms are usually preceded by a history of a snapping sound in the joint, which may occur at the beginning or termination of the opening movement and is directly related to the meniscus. It indicates hypermobility and excessive excursion. In addition, more or less profound and palpable tenderness, pain and restriction of motion may develop. Extirpation of the meniscus effects immediate cessation of the symptoms.

Other symptoms, reflex in nature, may be experienced. These are generally spoken of as the "Costen syndrome." Besides the noise in the joint during mastication, the patient complains of various forms of neuralgia, such as headaches about the vertex and occiput, pain behind the ear or in the mouth and jaws and a burning sensation or pain in the tongue. Wright¹²⁶ pointed out that deafness may occur, vertigo and tinnitus (noises, buzzing and roaring) may be present, according to Goodfriend.¹²⁷ The dental signs are unusual attrition or loss of or incorrect replacement of the posterior teeth.

The treatment in many cases may be conservative, consisting of resting the jaw and the use of heat. Rest may consist of the omission of food that requires force to masticate, or intermaxillary wiring for complete immobilization. Heat may be applied by means of flaxseed poultices or diathermy. In some cases restoration of the occlusion or wearing of a splint to open the bite and distracting the joint surfaces give good results.¹²⁵ Operative treatment consists of injection of a sclerosing solution, meniscectomy and condylectomy or osteoarthrotomy.

Injection

Injection of the joint space with a sclerosing solution (sodium psylliate or synasol) is recommended by Schultz¹²⁹ for hypermobility, but not if the patient has acute symptoms, limited motion and pain. Clicking, grating and popping have been controlled in six to twenty-four hours.

Meniscectomy

Meniscectomy is indicated in recurrent dislocation, fracture or tear of the meniscus due to trauma, partial erosion of the meniscus in traumatic arthritis, blocking of the condyle and noise and cracking not relieved by conservative treatment.¹³⁰ Boman¹³¹ reported 58 cases of treatment by excision of the meniscus.

Condylectomy and Osteoarthrotomy

These operations are used in more serious disease of the mandibular joint, destruction of the joint surfaces with resulting pain, as in various forms of arthritis, in partial ankylosis caused by traumatic

arthritis, malunion of condylar fracture, rheumatoid arthritis, osteomyelitis of the condyle and hypertrophy (osteoma) of the condyle and true ankylosis. The causes of ankylosis⁹⁹ are birth trauma, rheumatoid arthritis, including Marie-Strümpell disease, suppurative arthritis, osteomyelitis of the condyle and fracture of the condyle with hemarthrosis.

Dingman¹³² and Thoma⁹⁹ prefer osteoarthrotomy to arthroplasty since there is less chance of recurrence because of the large separation of the condylectomized ramus from the glenoid fossa or temporal bone (1.5 to 2.0 cm). Hickey¹³³ has experimented with oxidized cellulose (oxycel), which he packs into the space not only because it controls the bleeding but also because it is said to interfere considerably with bone repair.¹³⁴

(To be concluded)

part of the mandible is very thin. He developed a peripheral bone clamp that can be placed around the jaw through a suitable incision in the skin, which is closed. Only the pin protrudes through the skin and serves as an attachment for the connecting bars of the fracture appliance fastened to half pins inserted in the anterior fragment.

Bradford and Wilson,¹¹⁹ discussing skeletal fixation, give two good rules to prevent misuse or abuse of the method: the apparatus should be applied only by an experienced surgeon who thoroughly understands the principles of its use and who has carefully studied its mechanism, and the procedure should not be used routinely but should be applied only in cases in which treatment by simple, conservative methods seems to be inadequate.

Fractures of the Mandibular Condyle

These fractures, treated in the past by immobilization of the mandible without any attempt at reduction, have not given such uniformly good results as some of the proponents of conservative treatment suggest. In cases of gross displacement or fracture dislocation this treatment frequently results in deformity, functional debility and malocclusion, with deviation on opening of the mouth, and even ankylosis may occur.¹²⁰⁻¹²² A method of open reduction and wiring fixation is recommended to prevent these deformities.¹²² If they do occur, condylectomy will have to be resorted to to give relief.¹²¹

In conclusion, it may be said that the treatment of jaw fractures requires a great deal of experience with a variety of methods old and new. In a discussion of the history of the treatment of jaw fractures¹²³ some of the principles regarded as essential have been set forth and discussed. These are as follows: treatment of the patient, attention to soft-tissue wounds, carefully performed clinical and x-ray examination, determination of the type and exact location of the fracture, prevention and treatment of infection, temporary immobilization if adequate treatment has to be delayed, choice of the correct type of anesthesia, attention to proper reduction, selection of the best method of fixation and immobilization, and proper attention to after-care.

DISEASES OF THE MANDIBULAR JOINT

Arthrosis

Various intra-articular changes may occur in the temporomandibular joint owing either to major trauma causing injury to the meniscus or to trauma resulting from functional disturbances,¹²⁴ some of which are distinctly associated with occlusal abnormalities of the teeth. Other diseases that cause similar symptoms are the rheumatoid, hypertrophic and infectious forms of arthritis, which produce degenerative changes similar to those produced in

other joints of the body, and ankylosis of the jaw may result.

Bellinger¹²⁵ describes the symptomatology as follows: the symptoms are usually preceded by a history of a snapping sound in the joint, which may occur at the beginning or termination of the opening movement and is directly related to the meniscus. It indicates hypermobility and excessive excursion. In addition, more or less profound and palpable tenderness, pain and restriction of motion may develop. Extirpation of the meniscus effects immediate cessation of the symptoms.

Other symptoms, reflex in nature, may be experienced. These are generally spoken of as the "Costen syndrome." Besides the noise in the joint during mastication, the patient complains of various forms of neuralgia, such as headaches about the vertex and occiput, pain behind the ear or in the mouth and jaws and a burning sensation or pain in the tongue. Wright¹²⁶ pointed out that deafness may occur, vertigo and tinnitus (noises, buzzing and roaring) may be present, according to Goodfriend.¹²⁷ The dental signs are unusual attrition or loss of or incorrect replacement of the posterior teeth.

The treatment in many cases may be conservative, consisting of resting the jaw and the use of heat. Rest may consist of the omission of food that requires force to masticate, or intermaxillary wiring for complete immobilization. Heat may be applied by means of flaxseed poultices or diathermy. In some cases restoration of the occlusion or wearing of a splint to open the bite and distracting the joint surfaces give good results.¹²⁸ Operative treatment consists of injection of a sclerosing solution, menisectomy and condylectomy or osteoarthrotomy.

Injection

Injection of the joint space with a sclerosing solution (sodium psyllate or synasol) is recommended by Schultz¹²⁹ for hypermobility, but not if the patient has acute symptoms, limited motion and pain. Clicking, grating and popping have been controlled in six to twenty-four hours.

Menisectomy

Menisectomy is indicated in recurrent dislocation, fracture or tear of the meniscus due to trauma, partial erosion of the meniscus in traumatic arthritis, blocking of the condyle and noise and cracking not relieved by conservative treatment.¹³⁰ Boman¹³¹ reported 58 cases of treatment by excision of the meniscus.

Condylectomy and Osteoarthrotomy

These operations are used in more serious disease of the mandibular joint, destruction of the joint surfaces with resulting pain, as in various forms of arthritis, in partial ankylosis caused by traumatic

was slightly elevated, and the hemoglobin was essentially normal. The sedimentation rate was elevated and indicated that infection was present. The calcium and phosphorus were normal, as was the phosphatase. May we see the x-ray films?

DR STANLEY M WYMAN: The lesion, I think, is readily seen on this view of the pelvis, which shows both upper femurs. The left femoral shaft, just below the lesser trochanter, shows an area of marked cortical, possibly some periosteal, thickening with a focus, perhaps 1.5 cm., of sharply defined rarefaction (Fig 1). This is better seen on slightly more exposed films and is shown in both projections. This view shows what was called a periosteal calcification, apparently separated from the tendon, at least, in part. There is no definite evidence from these films of any focus of increased density within the ovoid rarefaction. There is no evidence of ray formation and no evidence of a soft-tissue mass.

DR DALAND: The severity of the symptoms was not very great apparently at this time, and after staying in the hospital for ten days and carried only on aspirin, she was sent home. It must have been believed that there was nothing suggesting a tumor at this time, or I think she would not have been allowed to go home. In looking at these films we see a heaping up of calcification by periosteal replacement of bone, which does not look like tumor formation. One would think that if a Ewing tumor were present, we might get a heaping up here of the so-called onion-skin appearance. We would also have a soft-tissue mass, and the appearance of the bone would be unlike this. We would not expect to find a hole in the bone.

She was sent home and returned eight months later. In the interval she continued to go to school, so that the pain could not have been very severe. The pain persisted in the medial aspect of the upper third of the thigh and was more constant at rest, disappearing on activity. The symptoms recurred regularly at 2 a.m. and were entirely relieved by aspirin. This type of pain at night is rather typical of bone pain. We find it in joint disease as well. The classic story of the child with a tuberculous hip or knee is that of a patient who is fairly comfortable in the daytime but has pain at night. In this case there is nothing else to suggest a joint condition. At night there is complete relaxation of muscles, but the patient moves in bed and awakens with severe spasm that brings on pain.

We have, then, a girl with a low-grade condition, pain over a period of eighteen months plus eight months, a little over two years. During that time she was able to carry on and go to school, and the pain did not increase a great deal. Have we the films of the last admission?

DR WYMAN: We have only the films of the first admission. The others have disappeared, unfortunately. There was essentially no change, however

DR DALAND: The duration and type of pain pretty much rule out neoplastic disease in the early examinations. We know that she had an elevated sedimentation rate. It was indicated at one time that she had a considerable degree of infection somewhere. The normal calcium, phosphorus and phosphatase help rule out any type of cystic disease from hyperparathyroidism. The appearance of this lesion was not that of a solitary bone cyst. That is usually a central, medullary condition running down the canal and not showing an overgrowth

FIGURE 1

of bone like this, unless there has been a fracture. We do have evidence of a good deal of periosteal proliferation and overgrowth, but more important is the area that was hollow in the center of the reactive bone. This is the sort of thing that one gets in a bone abscess or Brodie's abscess. In Brodie's abscess the pain is low grade and may continue for a number of months without being severe enough to call for any operative treatment. It is rather unusual to find it in the femur. It is much more common in the tibia but is occasionally found in the fibula. This is the age at which one is pretty apt to find a Brodie abscess, anywhere between twelve and twenty—it is rarely seen in adults. I think we can

BENJAMIN CASTLEMAN, M D, *Associate Editor*

EDITH E PARRIS, *Assistant Editor*

CASE 35181

PRESENTATION OF CASE

First admission A fourteen-year-old girl entered the hospital complaining of pain in the left hip for eighteen months

Ten months before admission the patient had an attack of "streptococcal sore throat" and was confined to bed for two weeks. During this period she noticed an intermittent, dull ache in the left hip, present usually at night. After getting up, the pattern of symptom-free days and pain at night persisted. The pain was relieved by aspirin. The sedimentation rate was at first normal and later found to be elevated.

Physical examination demonstrated no abnormalities except for tenderness over the left femur anteriorly at the level of the lesser trochanter. There was no limitation of hip motion.

The temperature, pulse and respirations were normal. The blood pressure was 105 systolic, 70 diastolic.

Examination of the blood disclosed a white-cell count of 10,800, with 68 per cent neutrophils, and a hemoglobin of 13.8 gm per 100 cc. The urine was normal. The erythrocyte sedimentation rate was 30 mm in one hour. The blood calcium was 9.1 mg, the phosphorus 3.9 mg and the alkaline phosphatase 3.1 units per 100 cc. A blood Hinton test was negative.

X-ray study revealed a dense area of periosteal new-bone formation associated with the medial anterior aspect of the proximal femoral shaft (Fig 1). This periosteal new bone was in part differentiated from the course of the bone. In the lateral view a circular zone of rarefaction was observed in the cortex at about the midportion of the area of new-bone formation.

The patient received aspirin on several nights for relief of pain, and was discharged ten days after admission.

Second admission (eight months later) In the interval she continued to go to school. The pain persisted in the medial aspect of the upper third of the left thigh, more constant at rest and disappearing on activity. It recurred regularly at 2 a.m. and was entirely relieved by aspirin. She took up to 8 aspirin tablets daily. There was no recorded temperature elevation at home.

On physical examination the findings were unchanged from those on the previous admission. In the left thigh, about 9 cm below the anterior superior spine and 1.2 cm medially, was an area of deep tenderness, measuring 5 by 5 cm. No mass was palpable. The range of motion of the joint was full. There was 1.2 cm of measurable atrophy of the left thigh, 15 cm above the patella.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR ERNEST M DALAND This was a low-grade type of pain. Apparently it had been that for a number of months. We are told that it started eighteen months previously and that ten months before admission the patient had a streptococcal infection. We know nothing about what happened at the onset of this disease eighteen months before admission, but at one time apparently she did have an infection that laid her up in bed for two weeks. The sedimentation rate was found to be normal, and as time went on it was elevated. She had definite tenderness over the upper femur. The temperature was normal when recorded. The white-cell count

tion and was given oral fluids and insulin. On the day before entry another physician aspirated some material from the right eye.

For approximately sixteen years the patient had mild polyuria and polydipsia but refused to see a physician. For five to ten years she had occasional ulcers on the lower legs that occurred on the slightest trauma and were very slow to heal. In the two years before admission she had intermittent pain and injection of the right eye, with decreased vision and marked photophobia.

The patient's mother had diabetes for many years. Her father and two brothers died of carcinoma. One sister had a "lump" removed from a breast. The patient's husband was in a tuberculosis sanatorium fifteen and again eight years previously, each time for approximately a year.

Physical examination revealed an obese, critically ill woman. The right conjunctiva was injected, the globe was prominent, and the eye was very tender. The skin was hot and dry. There were a few necrotic lesions on the toes that looked like small areas of gangrene underlying old calluses. Examination of the chest was unsatisfactory owing to poor cooperation, but nothing significant was found. The heart was not enlarged, and a Grade II to III, harsh, high-pitched systolic murmur was heard over the entire precordium, loudest at the apex and toward the sternum. No diastolic murmur was heard. The sounds were of good quality. The abdomen was huge, with a thick panniculus. The dorsalis pedis and the posterior tibial arterial pulsations were not felt. There were scarred and pigmented areas over the lower extremities.

The temperature was 103.6°F, and the pulse 100. The blood pressure was 140 systolic, 70 diastolic.

The urine had a specific gravity of 1.026 and gave a + test for albumin. The white-cell count was 24,900, with 91 per cent neutrophils. The hemoglobin was 16 gm. The blood sugar was 279 mg. and the nonprotein nitrogen 39 mg. per 100 cc. and the carbon dioxide 27 milliequiv. per liter. An x-ray film of the chest showed increased vascular markings throughout both lung fields. At the right apex there was a rounded area of increased density. The aorta was somewhat tortuous. The heart appeared to be somewhat enlarged, with left ventricular prominence. The spinal fluid contained 5 lymphocytes and 210 red cells per cubic millimeter. The protein was 45 mg. per 100 cc. The gold-sol curve showed elevation in the mid-zone to a maximum of 2. A blood culture taken on admission grew out beta-hemolytic streptococci in both flasks.

The patient received 1,500,000 units of penicillin a day. On the first day of hospitalization she received a total of 90 units of insulin. The temperature dropped to normal, but the fasting blood sugar remained elevated to 346 mg. per 100 cc. The chemosis in the right eye increased and the process

was thought to be a hemorrhagic glaucoma. The ocular tension was 37 as compared to 20 in the left eye. She had immature cataracts in the left eye. She continued to have a fever of 100°F to 101°F and a white-cell count varying from 18,000 to a maximum of 27,000. The sensorium cleared somewhat. She received, in addition to the regular injection of penicillin, 25,000 units of penicillin subconjunctivally. There was questionable change in the quality of the heart sounds. On the seventh hospital day it was noted that she was icteric. A Grade I, apical, high-pitched systolic murmur was present, together with a short, high-pitched, coarse systolic sound, best heard in the third left intercostal space but audible at the apex. This second sound was faint and followed shortly by another coarse, high-pitched sound similar to the one following the first sound. There was a questionable, low-pitched mid-diastolic murmur heard at the apex. There was no edema, rash or petechiae, and the spleen could not be palpated. An electrocardiogram showed partial auriculoventricular block, with a PR interval of 0.25 second. The ST segment was slightly elevated in Leads 1, 2 and 3 and V₄, and the voltage was slightly low. On the eleventh hospital day auricular fibrillation was noted. There was a change in the quality of the heart murmurs, a definite low-pitched, rumbling diastolic murmur now being present. The heart rhythm later became more regular, with occasional ectopic beats. The temperature remained nearly normal, though the white-cell count was very much elevated. The icterus became more evident. On the twelfth hospital day she lapsed into coma, breathing became shallow, the blood pressure was unobtainable, and she died.

DIFFERENTIAL DIAGNOSIS

DR. W. WILSON SCHIER: The first significant statement in the history is that this patient was admitted to the hospital because of a fever. Presumably we are dealing with an infectious process from this point on. The low-back pain is mentioned frequently as a cardinal symptom, but my opinion is that this was associated with septicemia. She was acutely ill for ten days preceding hospital admission, and two days before admission she was found to have sugar and acetone in the urine, for which she was given fluids by mouth and injections of insulin.

From the data given I think we are justified in making a diagnosis of diabetes mellitus. This metabolic defect led to a complicated series of events. She apparently suffered from occasional ulcers on the lower legs which were a product of poor circulation. It was noted that arterial pulsations in the posterior tibial and dorsalis pedis arteries could not be felt—consistent with atheromatous degeneration. The character of the walls of the vessels was not commented on. These areas of ulceration

rule out any type of tumor here I am pretty certain it is infection At some time she may have had a low-grade osteomyelitis, and this may have been a residuum of it The other thing that she might have had was a subperiosteal hematoma, the result of some trauma, although we have no note of such trauma That would give a heaping up of periosteum like this, but probably would not cause the central hollow in the bone My opinion is that this was a Brodie abscess

DR WYMAN Would Dr Daland consider the possibility of osteoid osteoma, whatever that is?

DR DALAND Yes

DR ROBERT S PALMER What is it?

DR WYMAN I do not know

DR JACOB LERMAN Were the indications for operation at the second admission any greater than those at the first admission?

DR TRACY B MALLORY No, except that she had not improved, and it was obvious that the lesion would not clear up of its own accord

CLINICAL DIAGNOSIS

Osteoid osteoma

DR DALAND'S DIAGNOSIS

Brodie's abscess of femur

ANATOMICAL DIAGNOSIS

Osteoid osteoma of femur

PATHOLOGICAL DISCUSSION

DR MALLORY This lesion was explored as is so generally necessary in establishing a diagnosis of a bone lesion The area of thickening of the periosteum just below the lesser trochanter was found The cortical bone underlying this area of periosteum was chiseled out, and in the center of the cortical bone a little focus was found, which is shown in this picture (Fig 2) On the right is the external surface of the cortex, showing irregular thickening beneath the area of periosteal proliferation In the picture on the left we see the cavity lying within the excised piece of cortical bone This cavity was filled with a tumor-like mass of material that was rather firm, although distinctly softer than the surrounding cortical bone Microscopically it was typical of so-called osteoid osteoma It consisted of interlacing trabeculae of imperfectly calcified osteoid material, and there was the usual increased density of the surrounding cortical bone Exactly what this lesion was is doubtful as may have been guessed from the questions already asked Jaffe,* who first described the lesion in 1935, considers it to be a neoplasm of benign character, an unusual feature for neoplasm, however, is that these tumors appear to be entirely self-limited as to growth In spite of the fact that this had been present two

years and under observation many months between the first and second examinations, there was no increase in size during that time That is characteristic of similar lesions kept under observation for even longer periods So, if it was a neoplasm, it was one that is incapable of growth beyond a certain very definite and relatively small limit of size They always lie in the cortical bone In this case a narrow recognizable shell of cortical bone separated the lesion from the medullary cavity, and it was not necessary to enter the medullary cavity to remove

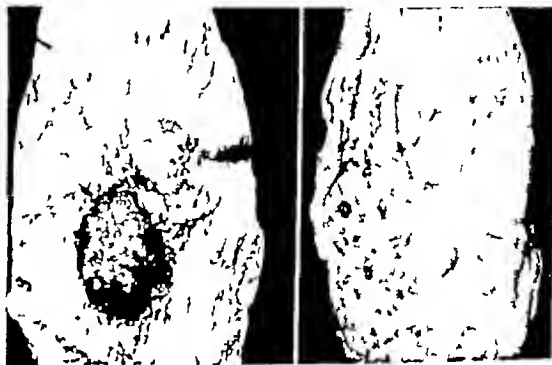

FIGURE 2

the lesion Very persistent pain is extremely characteristic of all examples of the lesion Sometimes the pain is more severe than that in this case and may be resistant to much stronger therapy than aspirin

CASE 35182

PRESENTATION OF CASE

A forty-eight-year-old married woman was admitted to the hospital because of pain in the right eye and fever

Ten days prior to admission the patient began to complain of low-back pain Two days after this, the pain having subsided, she became nauseated and vomited while riding in a train On the following day, seven days before admission, she complained again of low-back pain and was found to have a temperature of 104°F She refused to see a doctor, though she did take three penicillin tablets, which had been left for another patient The fever allegedly subsided but returned She continued to have a high temperature and low-back pain until three days before entry, when the right eye became inflamed Two days before admission, despite her objections, a physician was called He found her to be quite ill, tested some urine and found it to contain sugar and acetone She refused hospitaliza-

*Jaffe H L Osteoid-osteoma benign osteoblastic tumor composed of osteoid and atypical bone Arch Surg 31 709-728 1935

at all. Old rheumatic heart disease need not be postulated and the only evidence for a congenital lesion is the description of the murmur heard on admission, which could be consistent with an interventricular septal defect. Were there any evidences of embolic phenomena occurring in the kidney—red cells in particular? The urine is mentioned as showing only albumin. Both focal and diffuse nephritis may be associated with acute endocarditis.

DR MALLORY No red cells were observed in four specimens examined.

DR SCHIER I wonder if anyone would discuss the electrocardiographic changes?

DR JOHN W. HURST The electrocardiogram showed a partial heart block, the PR interval was 0.27 second, the ST segment was slightly elevated in Leads 1, 2, 3 and V_4 with low voltage. I reported that as consistent with myocarditis if pericarditis could be ruled out. It looked more like myocarditis than coronary-artery disease.

DR SCHIER The electrocardiographic changes are consistent both with severe infection and coronary-artery disease or rheumatic fever. The changing rhythm might occur with all of these, particularly the last two. With coronary-artery disease I would expect the ST segments to be depressed. Pericarditis associated with endocarditis and myocarditis would be more apt to cause elevation of the ST segments.

It is said that the patient died in icterus, although none was noted on admission. This seems most likely to have been a result of overwhelming sepsis of the liver from infected emboli. Without further clinical and laboratory evidence I cannot rule out cholelithiasis, pancreatitis and hepatitis. There is no mention of cardiac failure, which could cause jaundice, or evidence of large free emboli. Hemochromatosis is unlikely without the finding of pigmentation. Liver disease usually precedes diabetes by months, and I mention it only in passing.

In summary, my diagnoses are diabetes mellitus, acute endocarditis involving the aortic and mitral valves, septicemia, atheromatous arteriosclerosis, hemorrhagic glaucoma of the right eye and possible cardiac enlargement, with terminal hepatitis.

DR RICHARD CLARK What type of endocarditis? Do you mean acute bacterial endocarditis?

DR SCHIER Yes, acute bacterial—I cannot rule out rheumatic.

DR CLARK Would the appearance of the murmurs in addition to the prolonged PR interval indicating myocarditis together with the ST segments and sounds suggestive of pericarditis as well, fit better with activation of an acute rheumatic process, along with bacterial endocarditis? It is not infrequently seen in combination.

DR SCHIER I do not know.

DR HURST One point that might be brought up concerns the diastolic murmur which you thought might be aortic. Perhaps you were misled by the description in the protocol. That murmur was not of the high-pitched type heard in aortic regurgitation; it sounded more like the scratching of pericarditis. The really changing murmur was at the mitral area rather than the aortic.

DR SCHIER That would change my opinion of the aortic lesion and would be more consistent with a mitral valvulitis.

DR MEANS I think that Dr. Schier has covered nearly everything and I believe our line of thought ran similarly to his. I think he quite properly stressed the changing character of the auscultatory findings in the heart. They changed during observation quite strikingly, and there was one period, I am not sure it got into the record, when there was a most amazing phenomenon. There was only one heart sound, a loud clear sound and nothing else, and that, as well as the septic fever, made us all think that something fairly active must be going on in the heart. We considered the possibility of some kind of pyemic process with pus formation in various places. I do not want to say too much about that because I am vague about our ideas, whether they were before autopsy or after autopsy, but we were concerned about why penicillin did not have more effect. We wondered if it was because she had pus that it could not reach.

This woman was an interesting one from the point of view of personality. She had a strong anti-doctor complex, and we thought that a good deal of her pitiable condition might have been prevented if she had consulted a doctor twenty years previously. The obesity was tremendous and had a good deal to do with the diabetes. She neglected the infections and so forth.

DR ALFRED KRAVES Did the blood cultures become negative after treatment started?

DR MEANS I cannot remember, I think they did.

tion were a likely portal of entry for the subsequent infection. Buerger's disease is described as occurring rarely in women, and its first sign may be migrating phlebitis. It is much more reasonable to assume that the defective circulation was associated with this patient's diabetic state. She had three penicillin tablets preceding admission, and the remote possibility that a refractory organism resulted from this is only mentioned to condemn inadequate medication. She had gangrene of the toes, which is a common complication of untreated mild diabetes.

Is there anything in the record indicating the nature of the aspirated fluid from the right eye?

DR JAMES H. MEANS: I do not know. She was sent to the Eye and Ear Infirmary.

DR SCHIER: I do not know what to make of the eye lesion — I shall accept the diagnosis of hemorrhagic glaucoma. In the absence of other embolic processes it seems barely possible that she had a mycotic aneurysm of the optic artery to account for her symptoms in the right eye. She had had symptoms in the eye, however, during the two years preceding admission to the hospital, which would be consistent with glaucoma.

I now come to the portion of the discussion that offers richer speculative material. The heart initially was described as not being enlarged on physical examination, but a harsh high-pitched systolic murmur was heard over the entire precordium, loudest at the apex and at the sternum. My inclination is to explain the murmur by dilatation of the left ventricle, although old rheumatic fever cannot be dismissed. In addition to the murmur she had a high temperature, and a blood culture grew beta-hemolytic streptococci. The infection was not overwhelming enough to depress the bone-marrow function, for the white-cell count initially was 24,900, with 91 per cent neutrophils. The heart is described on x-ray examination as being enlarged — may we see the x-ray films?

DR STANLEY M. WYMAN: This film was taken with the patient supine and with the x-ray tube quite close to her, therefore, the apparent enlargement of the heart is not valid because of magnification and because of the relatively high position of the diaphragm. Also, the chest is rotated on the film, so that I think it is not safe to make any conclusion at all about the heart size from this examination. There is probably some calcification in the aortic arch seen at that point. The mention

of density at the right apex I am not able to confirm, and I am not impressed by the prominence of the hilar pulmonary vascular shadows in this type of film.

DR SCHIER: You do not see any calcification in the region of the aortic and mitral valves?

DR WYMAN: I do not believe that calcification in that area would show in this type of film, and she was not fluoroscoped. We do have films of the skull that are very fragmentary because of her condition, I assume, but there is a suggestion on two of these films of a calcified vessel seen through the right orbit and lying in the expected location of the internal carotid artery. This may represent a calcified vessel, but I am unable to be certain of the observation from these poor films.

DR SCHIER: That knocks the props from explaining the murmur by left ventricular dilatation. I suppose arteriosclerosis in the valves would explain the murmur.

The lesion at the right apex might well have been tuberculous — in the welter of symptoms and signs a sputum examination may have been overlooked, and we know that tuberculosis is four or five times more common in diabetic patients than in the population at large.

The patient received massive doses of penicillin, which brought her temperature down only temporarily. I assume that the spinal tap was done to rule out possible meningitis. Was the globulin or the gold-sol curve elevated? What did the culture show?

DR TRACY B. MALLORY: No globulin is reported.

DR JAMES WYNGAARDEN: The culture was negative.

DR SCHIER: No further mention is made of blood cultures. On the seventh day there was a change in the quality of the heart sounds. First the development of an aortic systolic murmur, a faint second sound and an aortic diastolic murmur. These events and the evidence of septicemia lead me to conclude that this patient developed an acute endocarditis of the aortic valves. The mid-diastolic murmur at the apex became definite four days later and may have been the result of involvement of the mitral valves by the same process or an Austin-Flint murmur associated with the aortic-valve incompetence — resulting from vegetations or perhaps actual perforation of the valves by the destructive process. Why was the heart involved

THE HEALTH PROTECTION CLINIC

DIFFERENT projects have been underway for varying lengths of time whereby the person interested in his health problems may undergo a "screening" technic to eliminate, so far as possible, the presence of certain diseases. It seems logical that proposals should be made to amalgamate these screening processes—for cancer, for heart disease, for diabetes, for tuberculosis and for other diseases—under one roof and at one time, for what they are worth.

It is difficult to evaluate this worth on a statistical basis. The most objective mathematician would hardly dare to set an exact price on the saving of a life, and screening technics are capable not only of discovering an uncertain proportion of per-

sons with incipient disease out of the total number examined, but of assuring many of the others of their general good health at the time of examination.

The screening technic itself must naturally not be overrated nor the object of too much enthusiasm. The course of disease may be inexorably progressive or it may first become discoverable after the technic of discovery has declared the patient to be apparently physically fit. Nevertheless, much more can be done to eradicate incipient disease or to mitigate its course than was possible a decade ago.

An objective to be achieved if the health protection clinic is to serve its purpose is that of streamlining its technic. If the processes of discovering the presence or absence of disease are to be made possible on a large scale, they must be so simple that the whole plan does not fall from the sheer weight of man hours involved.

If health protection services, moreover, are to be offered freely or in any other manner to the public, social and economic problems must be settled. Whether the means test, as either an indignity or a dignity, is to be employed must be decided. The method of reference of patients to the clinics and the disposition of them after screening must be determined, as well as the financing of the whole enterprise. The interests of the private practitioner must be protected at all costs, for he is still and will remain the most effective and the most highly considered dispenser of health services.

In this respect it may be pertinent to observe that improvements in health services, as they have generally been offered, have seemed usually to rebound to the advantage of the practitioner. Obviously the health protection clinic as a public service is social medicine. Whether it represents also socialized medicine is a matter of definition, but if it does, the country has enjoyed or suffered under socialized medicine to some degree and in various forms for a number of years.

The important point is that if the practice of medicine continues to change its form, as it has been doing since the Babylonian physicians first added liver divination to their prognostic armamentarium, its course will be truer and its benefits greater if the medical profession goes with it and guides it, and

DR MALLORY Only that single culture is reported

CLINICAL DIAGNOSES

Acute bacterial endocarditis
Cholemia
Diabetes mellitus

DR SCHIER'S DIAGNOSES

Diabetes mellitus
Acute endocarditis, mitral
Septicemia
Atheromatous arteriosclerosis
Hemorrhagic glaucoma of right eye
Terminal hepatitis

ANATOMICAL DIAGNOSES

Endocarditis, acute bacterial, of mitral valve
Abscesses, multiple, of heart, spleen and kidneys
Portal cirrhosis of liver, post-necrotic type
Pulmonary tuberculosis, active, right apex
Patent ductus arteriosus
(Diabetes mellitus)
Arteriosclerosis, generalized, moderate

PATHOLOGICAL DISCUSSION

DR MALLORY Autopsy confirmed the diagnosis of bacterial endocarditis. When the pericardium was first opened we found a small amount of fresh blood but no inflammatory changes to indicate an infectious pericarditis. On inspecting the surfaces of the heart, we noted several small superficial abscesses, one of which immediately adjoined a coronary vessel, the surrounding tissues were ecchymotic, and we thought there had been a little leakage of blood from the coronary artery to account for the blood in the pericardium. The mitral valve showed a very large shaggy vegetation extending almost two thirds around the orifice. The chordae tendineae were nearly normal—possibly slightly thickened. The annulus of the mitral valve

showed calcification, and there probably was a slight underlying old rheumatic heart disease. The ductus arteriosus was found to be still patent. At the pulmonary end it measured nearly 1 cm in diameter but as it approached the aortic orifice it narrowed markedly and the opening into the aorta measured only 1 mm in diameter. I do not believe a significant amount of blood was passing through and doubt that any of the murmurs were explained on that basis, they probably all arose from extensive mitral involvement. Both infarcts and pyemic abscesses were found in various organs. In the spleen there was one bland infarct and one septic one. There were multiple abscesses in the kidney but no characteristic infarcts. The liver showed a severe degree of cirrhosis of the coarsely nodular, post-necrotic type, and there were demonstrable varices in the lower portion of the esophagus. We found no gross abscesses in the liver, but, on microscopical examination, numerous foci of sepsis were found and I think the combination of old liver disease and scattered fresh necrosis constituted adequate explanation of the terminal liver insufficiency. One large, well encapsulated tuberculous focus was present at the apex of the right lung.

We did not have permission to examine the head.

DR KRANES Did the post-mortem cultures grow the same organisms that were found during life?

DR MALLORY We grew a pure culture of beta-hemolytic streptococci from one of the heart abscesses. Cultures from the kidney grew mixed organisms, both beta-hemolytic and alpha-hemolytic streptococci and colon bacilli.

DR MEANS Could penicillin have been responsible for the colon bacilli? Do they not come in when penicillin is administered?

DR MALLORY They do in open lesions such as bronchiectatic cavities but I do not believe they do within the tissues of the body.

mycin has produced all the toxic effects observed with streptomycin.⁶ In animals it has been found that the acute toxicity—that is, the amount that is fatal for an animal in a single dose—is essentially the same for both compounds.^{4, 5} The histamine-like effect obtained from one lot of dihydrostreptomycin was only about a sixth of that produced by the lot of streptomycin from which it was derived.⁴ In chronic toxicity experiments dihydrostreptomycin proved to be less toxic, in that larger doses given over a longer period were required to produce neurotoxic effects equivalent to those obtained from streptomycin.⁶ There was also some indication that the local ulceration and induration resulting from dihydrostreptomycin in animals were less marked than those produced by streptomycin.

The effects of the use of dihydrostreptomycin in the treatment of human beings have thus far been reported in only a small number of patients, some of whom were treated with impure materials.¹⁰⁻¹³ The results in these cases indicate that dihydrostreptomycin produces all the toxic effects that have been observed from streptomycin. Dihydrostreptomycin, however, may have somewhat less neurotoxicity. The impression gained from the few cases thus far studied after the use of large doses of dihydrostreptomycin is that the vestibular damage occurs later and less uniformly and may be less disabling than that after streptomycin.

The most striking observations, however, have been made in patients who have been unable to tolerate streptomycin because of fever, rashes or other evidences of sensitization. In such patients dihydrostreptomycin has been well tolerated, and it has been possible to continue the treatment of such patients without ill effects.^{5, 13} Some of the experiences with early lots suggested that dihydrostreptomycin was more irritating locally, particularly when given intrathecally.¹² By the latter route streptomycin was said to be preferable,¹³ although the irritation observed from the intrathecal injections of dihydrostreptomycin may have been the result of the use of impure preparations. Dihydrostreptomycin has shown the same tendency as streptomycin to produce resistant organisms and neither compound is effective in the treatment of infections with streptomycin-resistant organisms.⁹

It therefore appears that dihydrostreptomycin may prove useful in the treatment of patients who show allergic sensitivity reactions to streptomycin. It may also prove to be more desirable than streptomycin in patients who require large doses or prolonged treatment as in the therapy of tuberculosis. Further experience is necessary before even these conclusions can be justified.

INDIAN GIVER

THE Great White Father, despite bumper budgets of recent years, has turned out to be, in the case of his copper-colored children, an Indian giver. The original possessor of the country's fields and forests, now one of the world's most forgotten displaced persons, surrendered these possessions (after a struggle) for the opportunity of living in squalor as a permanent Guest of the Nation.

In both 1947 and 1948, according to *Washington Report on the Medical Sciences*, teams selected by the American Medical Association and sponsored by the Department of the Interior inspected Indian reservations in the West and found appalling conditions of health and living. The Bureau of Indian Affairs of the Department of the Interior then asked for a "minimum needs" budget of \$9,163,814, from which the Budget Bureau promptly slashed \$1,500,000.

Medical Director Fred Foard, protesting both the budget cut and conditions that make it impossible

does not try simply to interpose inadequate obstacles in its path

It seems reasonable that pilot studies at least should be made in the establishment of health protection clinics. From the lessons that they teach new bearings can be taken to guide progressive medicine on its course

GROUP HEALTH ASSOCIATION

TEN years ago in Washington, D. C., bitter controversy arose regarding the so-called Group Health Association, and much opposition to its activities was encountered. Time has passed and views have changed, and elsewhere in this issue of the *Journal* a report appears of the first ten years of that organization, about whose activities there was such a wide difference of opinion at that time regarding its ethical and legal status.

Statistics may be a notoriously unsound basis for the drawing of conclusions, and it is important to note that the author himself states that at least one reason for the fact that the mortality rates compared very favorably with those from the community at large may be that the group so covered was in a higher financial bracket than some other groups. However, the average family income of the group studied would hardly, in these days, be considered much above the lines drawn by various insurance companies to separate those in low income brackets from those in the medically indigent class.

One of the criticisms often made of the attitude of the medical profession is that it has been slow to do anything in the way of constructive planning to meet the needs of present conditions. It is with this criticism in mind that the *Journal* is publishing the article in question, which deals with the experience of a small group in a specific area in the country. It is important to appreciate that it is the *local* physicians who should be in control of the *local* needs of any community, whatever the means or agency may be that attempts to provide good medicine at a cost within the range that the individual can pay. If state and federal aid is needed — and it seems likely that it will be — such aid must not predicate jurisdiction over the *local* needs and problems.

How to co-ordinate local, with general over-all supervision is the question that is fundamental to success.

DIHYDROSTREPTOMYCIN

DIHYDROSTREPTOMYCIN, a new derivative of streptomycin, has recently become available. It is made from salts of streptomycin by a process of catalytic hydrogenation that adds about one molecule of hydrogen to each molecule of streptomycin.^{1,2} The resulting dihydrostreptomycin salts appear to be more stable than the parent compounds in that, unlike the latter, they are not inactivated by cysteine, hydroxylamine or semicarbazide and are not degraded by heating with alkali. Comparative tests of the activity of dihydrostreptomycin and its parent streptomycin have shown that both have essentially the same activity in vitro against most bacteria.^{2,3,4-7} Against some species or strains of organisms, including occasional strains of tubercle bacilli and of salmonella, the dihydrostreptomycin, weight for weight, may be only two thirds or even as little as a fourth as active as streptomycin.^{4,5} In no case has a dihydrostreptomycin compound been found to be more active than its parent streptomycin.⁵ The antibacterial actions of dihydrostreptomycin and streptomycin are similarly affected by changes in pH⁴ and in certain components of the medium.^{4,8} Organisms resistant to streptomycin are equally resistant to dihydrostreptomycin.^{4,6,7} Some workers have suggested that the antibacterial activity of dihydrostreptomycin results from its being oxidized to streptomycin by bacteria.⁹

In animal experiments^{4,5,10} and in man^{10,11} both compounds appear to be absorbed and excreted in essentially the same manner. They appear to be about equally active, weight for weight, against infections in animals with strains of tubercle bacilli^{5,6,7,12} and with most of the pathogenic organisms that have been tested.^{1,4,5} The parent streptomycin, however, appears to be more active on a weight basis against some of these infections.⁵ Dihydrostreptomycin has no therapeutic effect on infections of animals with organisms that are resistant to streptomycin.^{6,7}

The only therapeutic advantage of dihydrostreptomycin has been in toxicity, although dihydrostrepto-

found that the admixture of semen with urine, blood, urethral secretion, sputum, sweat, lachrymal fluid, milk, tea, coffee and cocoa had no deleterious effect upon the phosphatase activity. Likewise, penicillin or sulfathiazole did not affect the phosphatase activity. Dried stains retained activity for several months.

Evidence of the presence of semen on a garment in a case of rape, obtained by the use of the acid phosphatase test, has so far been introduced in the Superior Court in Massachusetts on only one occasion. There is, however, little reason to doubt that the test will be used frequently, and no difficulty is anticipated in having such evidence accepted by the Court, provided it is introduced by a qualified expert.

MISCELLANY

RICHARDSON LECTURES

The Massachusetts General Hospital on April 8 inaugurated the Edward Peirson Richardson Lectures in Medical Science. A portrait of Dr Richardson, former chief of the surgical services, was unveiled, and the first lecture in the series was delivered by R S Pilcher, MSc FRCS, professor of surgery at University College Hospital London on Bronchiectasis.

CORRESPONDENCE

LOCAL REGISTRATION OF PHYSICIANS

To the Editor: The Franklin District Medical Society has recently discovered that approximately 40 per cent of the physicians living and practicing in Greenfield have not been registered with the town clerk as required under the provisions of Chapter 55, Section 3, of the Acts of 1917. This deficiency has been corrected, but it brings up the question whether other fellows of the Massachusetts Medical Society have failed to register with their town or city clerks.

It is important that correct registration be completed, because the physician is liable to a fine up to \$100.00 for not so registering, the town or city clerk is liable to a fine up to \$15.00 for each physician not registered by him, and, I am informed, should a physician in this status be involved in court proceedings, should be adequate in all other respects, and should even successfully defend himself in a malpractice suit he would not be entitled to the protection of the law because he was practicing medicine illegally.

LAWRENCE R DAME, M D

Greenfield, Massachusetts

"SCIENCE AND IMMORTALITY"

To the Editor: It was with great pleasure that I read the editorial "The Second Mile," which, to me, embodies the philosophy of the patient-doctor relationship.

Medical school seems to be a place where many do not "have the supporting strength of a belief in the hereafter" and a place where editorials such as yours should do an immeasurable amount of good.

Being a New Hampshire "Yankee" myself, I feel doubly proud to know that a New England group has sponsored the publication of thoughts such as these, which are so greatly needed.

EDWARD H ROBINSON, 1949

Jefferson Medical College

BOOK REVIEWS

Medullary Nailing of Küntscher. By Lorenz Böhler, M D. First English edition, revised by the author. Translated from the eleventh German edition by Hans Tretter, M D. 4th, cloth 386 pp., with 1261 illustrations. Baltimore: Williams and Wilkins Company, 1948. \$7.00.

This is the most authoritative study on the medullary nailing of Küntscher. Professor Böhler has had a most extensive experience in the treatment of fractures by the older conventional means. This should make his judgment of the new technic particularly valuable. The discussion of indications, complications and end results is based upon a review of 600 patients with fractures treated by medullary nailing. The author considers closed medullary nailing superior to all previously known methods in fresh fractures of the femoral shaft. But not all fractures are suitable for this method. The general condition of the patient must be good, with healthy condition of the skin. It is easiest to use in fractures of the middle third. In fractures of the tibia and humerus equally good results and no greater difficulty are encountered with the older methods. The indications for intramedullary nailing are not so wide as universally supposed. This method should not be used for the clavicle or for fractures near a joint. It should be employed only by physicians of wide experience in handling fractures. In compound fractures the danger of infection is great. There is no advantage in nailing in the presence of pseudarthrosis. The complications are not often seen, but death (from shock), infection, wrong placement of the nail, splitting of the bone and breaking of the nail occur. There is an excellent chapter on the problem of callus. Callus is inhibited by the presence of the nail. Without proper impaction there may be distraction of the fragments preventing union. This book can be recommended as the best and most authoritative discussion on the intramedullary nailing of Küntscher that has so far been published.

Sterility and Impaired Fertility. Pathogenesis, investigation and treatment. By Cedric Lane-Roberts, CVO, MSc, FRCS, FRCOG, Albert Sharman, M D, Pb D, MRCOG, Kenneth Walker, M A, M B, B C (Cantab), FRCS, FICS, B P Wiesner, D Sc., Pb D, FRSE, and Mary Barton, M B, BS 8th, cloth 400 pp., with 96 illustrations and 18 tables. New York: Paul B Hoeber, Incorporated, 1948. \$6.50.

This book is a second edition, although not so stated on the title page, of a work first published in 1939. This edition has been revised in the light of recent developments, especially in diagnosis and therapy. In diagnosis the precise use and interpretation of postcoital tests and the use of invasion tests are discussed. The technics of semen analysis and of determination of pregnanediol in urine have been simplified. The importance of extended use of cyclical temperature records for the study of ovarian function, anovulatory cycles, inadequate luteinization and the diagnosis of impending abortion is considered. Also, the value of the important tubal insufflation diagnostic test and its validity, and urinary hormone analysis are discussed. In the field of therapy the use of endocrine preparations, the sulfonamides and penicillin, and of x-ray stimulation, especially of the pituitary body, in cases of anovulation, are singled out for special mention. The controversial method of artificial insemination is fully discussed in its clinical, legal, moral and social aspects. The question of terminology is clarified. The text is divided into two parts, the first being devoted to male and the second to female fertility and sterility.

The authors are British, and the printing was done in Great Britain and the book bound in the United States. The publication is excellent in every way. A good legible type is well printed on a coated paper. A number of appendices, a long bibliography and a good index conclude the volume. The book is recommended for all medical libraries as a standard reference work and to all persons interested in the subject.

to provide the country's quarter of a million reservation Indians with good medical and public-health care, plans to fight for "reforms of a system in which field medical officers are wholly subordinate to lay commissioners, salaries of doctors and nurses are inadequate and central direction is impossible"

These wards of the state are obviously permanently displaced, perhaps a little more of the nation's charity might begin at home

MASSACHUSETTS MEDICAL SOCIETY

DEATH

HANNIGEN — Robert C. Hannigen, M.D., of Amesbury, died on December 16. He was in his seventy-second year.

Dr. Hannigen received his degree from Medical School of Maine, Portland, in 1901.

His widow, three sons and a daughter survive.

NOTES FROM THE MEDICAL EXAMINER

ACID PHOSPHATASE TESTS AS EVIDENCE OF RAPE

The family physician is usually the first person called when aid or advice is sought by the victim of a sexual assault. His duties in such cases include both the care of the patient and the accumulation of evidence likely to be of value in establishing identity or guilt of the assailant. The evidence is two-fold: that of physical violence suffered by the victim, as shown by bruises, scratches, or other injuries of her body, and evidence of ejaculate on or about her body. Since rape of a child or woman not under the influence of drugs or submitting from fright is practically impossible without leaving marks of violence on the extremities or genitalia, the absence of such injuries casts serious doubts on the fact of the alleged rape even though semen may be demonstrated.

The identification of spermatozoa in stained smears from the victim's perineum or vagina is obviously the best proof of the presence of semen. Identification is usually made on material from four sources: vaginal content, water suspensions of material clinging to the perineum or thighs, soiled pubic hair and stained clothing. In the first two instances smears should be made and dried promptly. The specimens should be submitted in dust-protective wrapping to a laboratory for staining and study by an expert.

Direct demonstration of spermatozoa is frequently impossible, owing either to destruction of the cells in the vagina or their absence in the ejaculate (aspermia or vasectomy). The survival of spermatozoa in the vagina after coitus varies from thirty minutes to twenty-four hours.¹ The phosphatase

test, because it does not depend on intact sperm cells, is a useful adjunct in the study of material suspected of representing ejaculate. The specimens to be collected are clothing bearing stains possibly due to semen, and if feasible, aspirated fluid vaginal content. Stains should be dried, fluid should be refrigerated in a sterile container until testing is done.

Determination of acid phosphatase as a test for seminal stains on clothing was first described by Lundquist and Rasmussen in 1945, and extensive studies by Rüsfieldt² and Hansen appeared in 1946. The procedure is based on the fact that ejaculate contains a large proportion of prostatic fluid and therefore a high concentration of acid phosphatase derived from prostatic glandular secretion. The demonstration of this enzyme consists of several steps.

Preparation of a saline extract of the dried stain or dilutions of the vaginal content. In stained cloth, the areas to be tested may be selected under ultraviolet illumination, which causes semen as well as many other biologic fluids to fluoresce.

Determination of the acid phosphatase activity of the saline extract by measurement of the phenol released by an aliquot of the extract from a phenylphosphate substrate in one hour under controlled conditions.³

Calculation of the acid phosphatase activity of the original specimen in units per cubic centimeter. This is accomplished directly with liquid specimens and in the case of dried stains by application of a factor that relates area of dried stain to cubic centimeter of original fluid causing that stain. The latter procedure is derived from experiments in similar samples of cloth using milk as the fluid, since the spreading power of milk is similar to that of semen.⁴ One unit of acid phosphatase activity is that of 1 cc of original fluid that will hydrolyze 1 mg of phenol in one hour at pH 4.9 and 37° F.

The acid phosphatase content of all body fluids other than prostatic secretion is less than 20 units, whereas that of ejaculate varies from 400 to 8000 units per cubic centimeter and is high even in the presence of azoospermia or aspermia.² Dried stains or fluid found to contain more than 100 units per cubic centimeter of original fluid are interpreted as indicative of the presence of semen in the specimen.

The technic has gained favor in medicolegal investigation, since it allows the recognition of semen long after the ejaculation or assault has occurred. Rüsfieldt demonstrated increased phosphatase activity corresponding to the content of semen in vaginal fluid six and twelve hours after coitus but not after twenty-four hours. He

found that the admixture of semen with urine, blood, urethral secretion, sputum, sweat, lachrymal fluid, milk, tea, coffee and cocoa had no deleterious effect upon the phosphatase activity. Likewise, penicillin or sulfathiazole did not affect the phosphatase activity. Dried stains retained activity for several months.

Evidence of the presence of semen on a garment in a case of rape, obtained by the use of the acid phosphatase test, has so far been introduced in the Superior Court in Massachusetts on only one occasion. There is, however, little reason to doubt that the test will be used frequently, and no difficulty is anticipated in having such evidence accepted by the Court, provided it is introduced by a qualified expert.

MISCELLANY

RICHARDSON LECTURES

The Massachusetts General Hospital on April 3 inaugurated the Edward Pearson Richardson Lectures in Medical Science. A portrait of Dr. Richardson, former chief of the surgical services, was unveiled, and the first lecture in the series was delivered by R. S. Fisher, M.S. F.R.C.S., professor of surgery at University College Hospital, London and a Bronchiectasis.

CORRESPONDENCE

LOCAL REGISTRATION OF PHYSICIANS

To the Editor: The Franklin District Medical Society has recently discovered that approximately 40 per cent of the physicians living and practicing in Greenfield have not been registered with the town clerk as required under the provisions of Chapter 55, Section 3, of the Acts of 1917. This delinquency has been corrected, but it brings up the question whether other fellows of the Massachusetts Medical Society have failed to register with their town or city clerks.

It is important that correct registration be completed, because the physician is liable to a fine up to \$100.00 for not so registering, the town or city clerk is liable to a fine up to \$1.00 for each physician not registered by him, and, I am informed, should a physician in this status be involved in court procedures, should be adequate in all other respects, and should even successfully defend himself in a malpractice suit he would not be entitled to the protection of the law because he was practicing medicine illegally.

LAWRENCE R. DAME, M.D.

Greenfield, Massachusetts

"SCIENCE AND IMMORTALITY"

To the Editor: It was with great pleasure that I read the editorial "The Second Mile," which, to me, embodies the philosophy of the patient-doctor relationship.

Medical school seems to be a place where many do not have the supporting strength of a belief in the hereafter and a place where editorials such as yours should do an immeasurable amount of good.

Being a New Hampshire "Yankee" myself, I feel doubly proud to know that a New England group has sponsored the publication of thoughts such as these, which are so greatly needed.

EDWARD H. ROBINSON, 1949

Jefferson Medical College

BOOK REVIEWS

Manual of Nailing of Küntscher. By Lorenz Böhler, M.D. First English edition, revised by the author. Translated from the eleventh German edition by Hans Tretter, M.D. 4th, cloth, 266 pp., with 1261 illustrations. Baltimore: Williams and Wilkins Company, 1948. \$7.00.

This is the most authoritative study on the medullary nailing of Küntscher. Professor Böhler has had a most extensive experience in the treatment of fractures by the older conventional means. This should make his judgment of the new technic particularly valuable. The discussion of indications, complications and end results is based upon a review of 600 patients with fractures treated by medullary nailing. The author considers closed medullary nailing superior to all previously known methods in fresh fractures of the femoral shaft. But not all fractures are suitable for this method. The general condition of the patient must be good, with healthy condition of the skin. It is easiest to use in fractures of the middle third. In fractures of the tibia and humerus equally good results and no greater difficulty are encountered with the older methods. The indications for intramedullary nailing are not so wide as universally supposed. This method should not be used for the clavicle or for fractures near a joint. It should be employed only by physicians of wide experience in handling fractures. In compound fractures the danger of infection is great. There is no advantage in nailing in the presence of pseudarthrosis. The complications are not often seen, but death (from shock), infection, wrong placement of the nail, splitting of the bone and breaking of the nail occur. There is an excellent chapter on the problem of callus. Callus is inhibited by the presence of the nail. Without proper impaction there may be distraction of the fragments preventing union. This book can be recommended as the best and most authoritative discussion on the intramedullary nailing of Küntscher that has so far been published.

Sterility and Impaired Fertility. Pathogenesis, investigation and treatment. By Cedric Lane-Roberts, C.V.O., M.S., F.R.C.S., F.R.C.O.G., Albert Sharman, M.D., Ph.D., M.R.C.O.G., Kenneth Walker, M.A., M.B., B.C. (Cantab.), F.R.C.S., F.I.C.S., B.P. Wiesner, D.Sc., Ph.D., F.R.S.E., and Mary Barton, M.B., B.S. 8th, cloth, 400 pp., with 96 illustrations and 18 tables. New York: Paul B. Hoeber, Incorporated, 1948. \$6.50.

This book is a second edition, although not so stated on the title page, of a work first published in 1939. This edition has been revised in the light of recent developments, especially in diagnosis and therapy. In diagnosis the precise use and interpretation of postcoital tests and the use of invasion tests are discussed. The technics of semen analysis and of determination of pregnanediol in urine have been simplified. The importance of extended use of cyclical temperature records for the study of ovarian function, anovulatory cycles, inadequate luteinization and the diagnosis of impending abortion is considered. Also, the value of the important tubal insufflation diagnostic test and its validity, and urinary hormone analysis are discussed. In the field of therapy the use of endocrine preparations, the sulfonamides and penicillin, and of x-ray stimulation, especially of the pituitary body, in cases of anovulation, are singled out for special mention. The controversial method of artificial insemination is fully discussed in its clinical, legal, moral and social aspects. The question of terminology is clarified. The text is divided into two parts, the first being devoted to male and the second to female fertility and sterility.

The authors are British, and the printing was done in Great Britain and the book bound in the United States. The publication is excellent in every way. A good legible type is well printed on a coated paper. A number of appendices, a long bibliography and a good index conclude the volume. The book is recommended for all medical libraries as a standard reference work and to all persons interested in the subject.

OFFICERS OF THE MASSACHUSETTS MEDICAL SOCIETY, 1948-1949

DR. ARTHUR W. ALLEN, *President-Elect**White Star*

PROGRAM OF THE ONE HUNDRED AND SIXTY-EIGHTH ANNIVERSARY OF THE MASSACHUSETTS MEDICAL SOCIETY

Monday, Tuesday, Wednesday and Thursday, May 23, 24, 25 and 26, Worcester Memorial Auditorium and Hotel Sheraton, Worcester

The Registration Desk will be located on the Stage of the Auditorium, and all who attend the meeting are requested to register

MONDAY AFTERNOON, MAY 23

- 4:30 Supervising Censors' Meeting (Room E, Hotel Sheraton)
6:00 Cotting Supper for Councilors (Ballroom Hotel Sheraton)

8:55 *A Motion Picture Entitled "Dermatoses of Industrial Workers"*

9:30 *A Public-Health Heart Program—First Report* Dr. EGON E. KATTWINKEL, Newton Chief of cardiology, Newton-Wellesley Hospital Drs VLADO A. GETTING, ERNEST M. MORRIS, H. M. LOMBARD and LEWIS C. ROBBINS

9:55 *The National Health Service—Recommendations of the Hoover Commission* Dr. HUGH R. LEAVELL, Boston Professor of public-health practice, Harvard School of Public Health

Bachrach

DR. DANIEL B. REARDON, President

Fasch

DR. DONALD MUNRO, Vice-President

MONDAY EVENING, MAY 23

- 7:00 Annual Meeting of the Council (Ballroom, Hotel Sheraton)

TUESDAY MORNING, MAY 24

First General Session

LITTLE THEATER, WORCESTER MEMORIAL AUDITORIUM
DR. JOHN J. DUMPHY, Chairman
DR. BAYCROFT C. WHEELER, Co-chairman

10:20 *Compulsory Health Insurance—Is this the Best Way to Improve Medical Care?* Dr. FRANK H. LAHEY, Boston Director, Lahey Clinic.

11:00 Annual Meeting of the Massachusetts Medical Society (Little Theater, Worcester Memorial Auditorium)

Annual Oration (following annual meeting) Some Responsibilities of Medical Education Dr. C. SIDNEY BURWELL, Brookline Dean, Harvard Medical School

Annual Luncheon (following annual oration) tickets must be procured in advance of the meeting

TUESDAY AFTERNOON, MAY 24

Second General Session

LITTLE THEATER, WORCESTER MEMORIAL AUDITORIUM
DR EDWARD P BAGG, *Chairman*
DR DONALD MUNRO, *Co-chairman*

- 2 00 *Pitfalls in the Diagnosis of Diarrhea* DR HUGH TATLOCK, Northampton Staff physician, Cooley-Dickinson Hospital, consultant in medicine, Veterans Administration Hospital
- 2 15 *Pitfalls in the Diagnosis of Continued Fever* DR FRANKLIN K PADDOCK, Pittsfield Attending physician, Pittsfield General Hospital
- 2 30 *Pitfalls in the Diagnosis of Persistent Cough* DR PAUL R DUFAULT, Rutland Superintendent, Rutland State Sanatorium
- 2 50 *Evaluation of the Papanicolaou Technique in the Diagnosis of Malignant Disease* DR HOWARD ULFELDER, Winchester Clinical associate in surgery, Harvard Medical School, assistant surgeon, Massachusetts General Hospital, senior surgeon, Pondville Hospital
- 3 15 *The Present Status of the Management of Thyroid Disease* DR GEORGE CRILE, JR., Cleveland, Ohio Department of Surgery, Cleveland Clinic
- 3 40 *Hospital Administration as a Medical Specialty* DR T STEWART HAMILTON, Newton Director, Newton-Wellesley Hospital
- 4 05 *Observations on Reduced Incidence of Embolism Postoperative ambulation dicumarol routine* DR JAMES C McCANN, Worcester Senior surgeon, St Vincent Hospital
- 4 30 *A Motion Picture Entitled "Anomalies of the Bile Duct and Blood Vessels"*

TUESDAY EVENING, MAY 24

BALLROOM, HOTEL SHERATON

- 8 15 *Worcester Hofbrau Night* (Free beer, free entertainment and music at the invitation of the Worcester District Medical Society)

WEDNESDAY MORNING, MAY 25

Third General Session

LITTLE THEATER, WORCESTER MEMORIAL AUDITORIUM
DR GEORGE R DUNLOP, *Chairman*
DR FRED H ALLEN, *Co-chairman*

- 8 50 *A Motion Picture Entitled "Management of the Failing Heart"*

Symposium on Gastric and Duodenal Ulcer

- 9 25 *Medical Aspects* DR SARA M JORDAN, Boston Director, Department of Gastroenterology, Lahey Clinic, physician, New England Baptist Hospital and New England Deaconess Hospital
- 9 50 *The Roentgenologist's Contribution* DR JOHN D CAMP, Rochester, Minnesota Professor of radiology, Mayo Foundation, consultant in roentgenology, Mayo Clinic
- 10 15 *The Management of Hemorrhage* DR BURRILL R CROHN, New York City Consultant in gastroenterology, Mt. Sinai Hospital, consultant, Veterans Administration, Halloran Hospital, Staten Island, New York

- 10 40 *The Surgeon's Point of View* DR JOHN D STEWART, Buffalo, New York. Professor of surgery and chairman of the Department of Surgery, University of Buffalo School of Medicine.

WEDNESDAY MORNING, MAY 25

LITTLE THEATER, WORCESTER MEMORIAL AUDITORIUM

- 11 05 *The Shattuck Lecture* La médecine du cœur

DR PAUL D WHITE, Boston Clinical professor of medicine, Harvard Medical School, consultant in medicine, Massachusetts General Hospital, executive director, National Advisory Heart Council

WEDNESDAY NOON, MAY 25

Section Meetings and Luncheons

12 00 m — 2 00 p m

Section of Medicine

STAGE, WORCESTER MEMORIAL AUDITORIUM

DR LAURENCE B ELLIS, Cambridge, *Chairman*
DR ALLEN S JOHNSON, Longmeadow, *Vice-chairman*
DR JAMES A HALSTED, Dedham, *Secretary*

Therapeutic Advances in the Treatment of Diarrheal Disturbances of Inflammatory Origin DR BURRILL R CROHN, New York City Consultant in gastroenterology, Mt Sinai Hospital, consultant, Veterans Administration, Halloran Hospital, Staten Island, New York

Section of Pediatrics

ASSEMBLY ROOM, WORCESTER MEMORIAL AUDITORIUM

DR W BRADFORD ADAMS, Springfield, *Chairman*
DR GERALD N HOFFEL, Boston, *Secretary*

Problems of Pediatric Radiology DR EDWARD B NEUBAUER, Cambridge Radiologist, The Children's Hospital, Boston

Section of Radiology

MALE CHORUS ROOM, WORCESTER MEMORIAL AUDITORIUM

DR ALBERT M MOLONEY, Boston, *Chairman*
DR LAURENCE L ROBBINS, Boston, *Secretary*

Significant Roentgenologic Findings in Intracranial Disturbances DR JOHN D CAMP, Rochester, Minnesota Professor of radiology, Mayo Foundation, consultant in radiology, Mayo Clinic.

Section of Physical Medicine

MUSICIANS' ROOM, WORCESTER MEMORIAL AUDITORIUM

DR DAVID C DITMORE, Boston, *Chairman*
DR ARTHUR L WATKINS, Boston, *Secretary*

Rehabilitation of the Patient with Hemiplegia DR WILLIAM B SNOW, New York City Assistant professor of medicine, Columbia University, College of Physicians and Surgeons, director, Department of Physical and Occupational Therapy, Columbia Presbyterian Medical Center

WEDNESDAY AFTERNOON, MAY 25

Fourth General Session

LITTLE THEATER, WORCESTER MEMORIAL AUDITORIUM

DR DONALD B CHEETHAM, *Chairman*
DR LAWRENCE R DAME, *Co-chairman*

- 2 00 *Pitfalls in the Diagnosis of Backache* DR CHARLES E AYERS, Worcester Orthopedic surgeon, The Memorial Hospital
- 2 15 *Pitfalls in the Diagnosis of Rectal Bleeding* DR E PARKER HAYDEN, Boston Associate visiting surgeon, Massachusetts General Hospital

- 2 30 *Pitfalls of Chemotherapy and Antibiotics in Surgery* DR. ALLEN G RICE, Springfield Consulting surgeon, Springfield Hospital
- 2 50 *Intellectual and Emotional Evaluation of the Sick Child* DR. JAMES MARVIN BATY, Belmont Professor of pediatrics, Tufts College Medical School, physician-in-chief, Boston Floating Hospital
DR ROWLAND G FREEMAN, Milis Assistant professor of psychiatry Tufts College Medical School and psychiatrist, Boston Floating Hospital
- 3 15 *Diabetes — Some Fundamental Considerations* DR W RICHARD OHLER, Boston Chief, Diabetic Clinic, Boston City Hospital, president, New England Diabetic Association
- 3 40 *The Problem of Diagnosis and Management of Chronic Recurrent Headache* DR H HOUSTON MERRITT, professor of neurology, New York City Columbia University, College of Physicians and Surgeons; director of service of neurology, Neurological Institute, Presbyterian Hospital
- 4 05 *Mechanical and Clinical Considerations in the Medical Care of Patients with Low Back Pain* DR WILLIAM B SNOW, New York City Assistant professor of medicine, Columbia University, College of Physicians and Surgeons, director, Department of Physical and Occupational Therapy, Columbia Presbyterian Medical Center
- 4 30 *A Motion Picture Entitled "Fractures An introduction"*

WEDNESDAY EVENING, MAY 25

- 6 00 Cocktail Party (CRYSTAL ROOM, HOTEL SHERATON)
Tickets must be procured in advance
- 7 00 Annual Dinner of the Massachusetts Medical Society (BALLROOM HOTEL SHERATON)

Presiding

DR. DANIEL B REARDON, president, Massachusetts Medical Society

Guest Speaker

ROSCOE POUND, LL D, University Professor, Emeritus, Harvard University, formerly dean, Harvard Law School The Professions in the Society of Today

Ladies may be invited to attend the dinner

Tickets for the dinner must be procured in advance of the meeting

THURSDAY MORNING, MAY 26

Fifth General Session

LITTLE THEATER, WORCESTER MEMORIAL AUDITORIUM

DR JAMES T BROSNAW, *Chairman*

DR NORMAN B McWILLIAMS *Co-chairman*

- 9 00 *A Motion Picture Entitled "Physiology of Normal Menstruation"*
- 9 25 *Some Problems in Interpretation and Management of Chondromatous Tumors in Bone* DR GRANVILLE A BENNETT, Chicago Professor and head of the Department of Pathology University of Illinois College of Medicine
- 9 50 *Diagnostic Procedures in Virus Diseases* DR F SURGENT CHIEVER, Wellesley Assistant professor of bacteriology and immunology, Harvard Medical School

- 10 15 *Management of Abnormal Uterine Bleeding* DR. GEORGE VAN S SMITH, Brookline William H Baker Professor of Gynecology, Harvard Medical School, surgeon-in-chief, Free Hospital for Women, Brookline
- 10 40 *Fetal Loss as Influenced by the Administration of Diethylstilbestrol* DR. OLIVE WATKINS SMITH, Brookline Director, Fearing Research Laboratory, Free Hospital for Women, Brookline
- 11 05 *Skin Manifestations of Avitaminoses* DR CHESTER N FRAZIER, Boston Edward Wigglesworth Professor of Dermatology, Harvard Medical School, chief, Dermatological Service, Massachusetts General Hospital
- 11 30 *Present Concepts of Nutrition* DR FREDRICK J STARE, Newton Professor of nutrition, Harvard School of Public Health, associate in medicine, Peter Bent Brigham Hospital

THURSDAY NOON, MAY 26

Section Meetings and Luncheons

12 00 m — 2 00 p m

Section of Surgery

STAGE, WORCESTER MEMORIAL AUDITORIUM

DR. ROBERT E GROSS, Boston, *Chairman*

DR FRANKLIN G BALCH, JR., Boston, *Secretary*

Some Studies in Gastric Secretion of Surgical Interest DR. FRANCIS D MOORE, Boston Moseley Professor of Surgery, Harvard Medical School, surgeon-in-chief, Peter Bent Brigham Hospital

Lecture Hall 9-10 a m

MEDICAL CONFERENCE PROGRAM

Friday, May 6 — The Importance of Hypothalamus to Adrenal Cortical Function Dr David M Hume

Wednesday, May 11 — Pediatric Clinicopathological Conference Drs James M Baty and H E MacMahon

Friday, May 13 — Experiences with Grafting Procedures in Vascular Surgery Dr Charles A Hufnagel

Tuesday, May 17 — Rheumatoid Spondylitis Dr Edward H Fischer

Friday, May 20 — Clinical Uses of Aureomycin Dr Harvey S Collins

Tuesday, May 24 — Recent Investigations in Virus Diseases Dr Lewis W Kane

Friday, May 27 — The Effect of Trimethadione (Tridione) and Other Drugs on the Major Convulsive Seizures Produced by Di-Isopropyl-Fluorophosphate (DFP) Dr Harold E Himwich

Tuesday, May 31 — Biological Antagonists Dr John J Finn

From 9 to 10 a m on Wednesday (except the second Wednesday), Thursday and Saturday mornings, clinics will be given by members of the hospital staff. Medical Rounds are conducted each weekday except Saturday by members of the hospital staff from 12 to 1 p m. On the second and fourth Fridays of the month, May 13 and 27, Therapeutic Conferences will be held with round-table discussion from 2 to 4 p m. Dr Robert P McCombs as moderator. On the second and fourth Fridays, May 13 and 27, Dr Merrill Sosman will conduct X-Ray Conferences from 4 to 6 p m.

On Saturday mornings from 9 to 10 a m Surgical Clinics are conducted by Dr C Stuart Welch.

All exercises are open to the medical profession

BOSTON CITY HOSPITAL HOUSE OFFICERS' ASSOCIATION

The following program of the Boston City Hospital House Officers' Association will be presented in the Evening Lecture Series

May 10 Precancerous Skin Lesions Stephen Rothman, M D, professor of dermatology, University of Chicago, the School of Medicine.

This program will be held at 7 00 p m in the New Cheever Amphitheater of the Dowling Building, Boston City Hospital. All interested persons are invited to attend.

A VARIANT OF THE HOFSTATTER-CULLEN SIGN IN INTRA-ABDOMINAL HEMORRHAGE FROM ECTOPIC PREGNANCY*

With a Note on the Mechanism of Its Production

JOHN FALLON, M D, † AND JOHN J. MANNING, M D ‡

WORCESTER, MASSACHUSETTS

ORDINARILY one thinks of Cullen's sign — when it is thought of at all — as the blue navel of ectopic pregnancy. Actually, other diseases can produce the phenomenon, it often appears away from the umbilicus, other colors are as frequent as blue, and it was first described by Hofstätter.¹ Cullen's² classic description and Brödel's⁴ painting of his case, however, taught the world to look for the sign and English-speaking nations to call it Cullen's.

The sign can be caused by intra-abdominal hemorrhage from any source and is counterfeited by other nonbloody fluids. After ectopic pregnancy, the next most frequently reported cause is acute pancreatic necrosis, but upon meeting the phenomenon one should consider everything capable of producing colored intra-abdominal fluid, whether in the peritoneal cavity, retroperitoneally or in the abdominal wall.

The mark may be red, purple, blue, green, tan, yellow or many colors. In the 70 occurrences (in ectopic pregnancy) that we have been able to trace, the location was most often at the umbilicus, but hernial sacs and old surgical scars are frequent sites. In 2 of the collected cases and in the case described below, the discolorations appeared in still other areas. These 3 cases suggest a hypothesis for the mechanism of production of the sign.

Stabler's⁵ patient, at an undeterminable time after the hemorrhage, had a sharply defined, comma-shaped, dark-purple mark, about 20 by 7 mm in diameter, located 2 or 3 cm downward and to the left of the umbilicus, a second, circular blue mark 2 or 3 cm in diameter, in the midline a third of the distance from the umbilicus to the symphysis, and a third mark the color of a fresh bruise, 2 or 3 cm in diameter, and "shaped roughly like the ace of clubs,"

in the skin over the left external inguinal ring. Inspection of the underlying peritoneum showed no gross abnormality; incisions into the marks themselves demonstrated ecchymoses. Stabler found no blood in the peritoneal tissues at the (unspecified) site of his incision. The amount of intraperitoneal hemorrhage was small, 90 to 120 cc.

Neumann's⁶ patient, with a large but unmeasured amount of partly clotted blood in the peritoneal cavity, on the tenth day after her first symptom showed two nonumbilical ecchymoses. One was at the level, but a little to the left, of the umbilicus, and the other was 2 or 3 cm beneath it in the midline, both were irregularly outlined, each approximated 2 cm in diameter, one was green, and the other yellow-green.

In the third of the 3 erratic cases, the patient (F C 24617) had three separate ecchymoses: a small, irregular stain in the umbilicus and in one quadrant of the umbilical ring and two larger circular stains, 7 cm in diameter, symmetrically located on either side of the umbilicus with their medial borders 6 cm from the midline. The color approximated that of venous blood, and its hue was constant although the intensity varied. Lines of varying intensity formed arcs of concentric circles the common center of which was the umbilicus, a phenomenon that we cannot explain. The two larger spots were slightly raised, none of the three was tender.

A photograph (Fig 1) was taken eight hours after the first symptom, which, conveniently for fixing the time of hemorrhage from the ruptured tube, was an unheralded syncope. The time of appearance of the sign is fixed as between four hours (examination by the referring physician, a competent observer) and six hours after syncope (discovery at examination on admission). The amount of blood, widely distributed throughout the peritoneal cavity and partly clotted, was 400 cc (300 cc measured, and 100 cc estimated).

*Presented at the annual meeting of the New England Surgical Society, New Haven, Connecticut, October 2, 1948.

†From the surgical services of the Fallon Clinic and St. Vincent Hospital.

†Surgeon, Fallon Clinic and St. Vincent Hospital.

‡Surgeon, Fallon Clinic; assistant surgeon, St. Vincent Hospital.

The patient was thirty-seven years old, of moderate height, weighed 138 lb and had a muscular abdominal wall with average panniculus. No hot-water bottle, electric pad, cupping or other mechanical, thermal or chemical agent that might conceivably have given rise to the ecchymoses had been used. Search of the abdominal wall from without and from within, showed no anomalies, hernias, unusual umbilical depression, apertures or thin spots. There were no adhesions. Because of the degree of shock, which was out of proportion to the moderate hemorrhage, the discolored areas were not explored.

Many theories have been suggested to explain the mechanism of the Hofstatter-Cullen sign. In a thin, translucent hernial sac, dark-colored intraperitoneal fluid can be seen through the wall; this has been demonstrated artificially by us, and clinically proved by Esau's⁷ case, in which, after removal of the abdominal blood, the color in an umbilical hernia disappeared whereas that of a surrounding ecchymosis persisted. Transvisibility, however, would explain only a few of the reported cases.

Other theories advanced do not coincide with appearances that the eye records — for example, dilatation of umbilical veins or engorgement of omental vessels showing through the skin. Ordinarily, it is assumed that the color is from pigmented material that has penetrated the abdominal wall after crossing the peritoneal barrier by following adhesions or lymphatics or by finding subvisible peritoneal apertures. After crossing the peritoneum, the pigment is transported to the subcutaneous tissues by lymphatics, so, at least, goes the assumption.

There is a basis for such an assumption: networks of subcutaneous and deeper lymphatics in the abdominal wall communicate at the umbilicus with a similar network just external to the peritoneum.^{8,9} The relation between the umbilical pathway and metastasis from breast cancer has long been accentuated. Intra-abdominal cancer may metastasize to the umbilicus, as pointed out by Warner¹⁰ and others.

But it is not ordinarily the function of lymphatics to pick up material, carry it a little way and then discharge it into surrounding tissues. Lymphatics carry their burden, through glands and ultimately the vascular tree, away and out of sight. Lymphatics should prevent the appearance of Cullen's sign.

Furthermore, the pigment of the sign does not follow the course of a lymphatic or group of lymphatics, as does the inflammation in lymphangitis. Contrarily, the color has the appearance of being deposited in a spot from which it spreads by direct extension. Thus in the case described above, the regular circles were at least 1 cm. in diameter smaller when seen at admission than two hours later, when the photograph was taken. Incidentally, on admission the color was a brighter, more nearly arterial

red, and the small ecchymosis in the umbilicus was absent or so faint as to escape notice.

The locations of the signs in reported cases — the umbilicus, spreading outward from the umbilicus, in hernias and scars and especially the pattern of the case described, with symmetrical circles over points where vessels commonly perforate the anterior rectus sheath — suggest that, once the causative fluid has passed the peritoneum in such amounts that lymphatics do not carry it away, its distribution may be guided by fascial planes and fascial apertures, as in hypodermoclysis or extravasation of urine. There are major fascial gaps (thinning might be a better word) at the umbilicus, midline and inguinal rings and in hernias and scars, there are minor ones where vessels perforate the rectus sheath. In Stabler's case a discoloration appeared over the external inguinal ring, and both Stabler's and Neumann's patients showed marks in the midline and over possible sites of perforating vessels.

How does material cross the peritoneal barrier? Lymphatics external to the peritoneum, whether in intra-abdominal adhesions or the normal peritoneal space, would not transport material across the peritoneum but would only pick it up after crossing, and it is our impression that lymphatics do not habitually perforate the peritoneum. Scraping of holes in the peritoneum by hard lumps of feces in the colon seems far-fetched, anomalous, subvisible peritoneal apertures are reminiscent of Galen's inter-ventricular pores. No new or special hypothesis is needed. Peritoneum is not the formaldehyde-hardened, watertight bulkhead of dissecting-room memories but a living, permeable membrane passing both fluid and particulate matter. The bulkhead concept, however, persists in the subconscious, as witnessed by the wide acceptance of endometriomas in the umbilicus or abdominal wall as an argument against the direct-implant theory of endometriosis. Yet the fluids and cells of all peritoneal exudates, to get into the peritoneal cavity from the extraperitoneal vessels whence they originate, somehow must transpass the peritoneum. Evidence of peritoneal crossing in the other direction is provided by the choking of omental lymphatics, which are extraperitoneal, by the contents of a perforated hemorrhagic cyst. Large amounts of intraperitoneal blood disappear in twenty-four hours or, if clotted, in a few days.¹¹ Graphite passes through the peritoneum¹², so can a fertilized ovum — to develop in the subcutaneous tissues of the abdominal wall.¹³

Why do not colored peritoneal fluids always discolor the abdominal wall? A possible explanation is the intraperitoneal distribution of the fluid and the relative surface areas of various parts of the peritoneum. Of the total peritoneal surface available for the transpassing of material, parietal peritoneum is only a small fraction, and the peritoneum of the anterior abdominal wall is but part of the fraction. Intestine, mesentery and omentum may hold some,

much or all of a given intraperitoneal fluid away from contact with this fraction of a fraction

SUMMARY

The Hofstätter-Cullen sign need not be blue, can appear elsewhere than at the umbilicus and is far from pathognomonic of extrauterine pregnancy. Probably, it can be caused by any condition producing colored intra-abdominal fluid.

A variant of the sign is reported consisting of symmetrical, red, circular stains at either side of the umbilicus, over points where vessels often perforate the rectus sheath.

The location of the stains in this and in 2 somewhat similar cases, as well as the more ordinary localizations over hernias, in scars and at the umbilicus, suggests that the pigments that usually produce the phenomenon may reach their destination by following ordinary fascial planes and openings rather than by depending upon exceptional lymphatic function or subvisible peritoneal apertures.

THE EFFECT OF ORAL THERAPY WITH COBALTOUS CHLORIDE ON THE BLOOD OF PATIENTS SUFFERING WITH CHRONIC SUPPURATIVE INFECTION*

JOSEPH C ROBINSON, M D,† G WATSON JAMES, III, M D,‡ AND ROBERT M KARK, M R C P (Lond)§

CHICAGO, ILLINOIS

DURING a study of prolonged suppurative infection in 91 young men, we observed reticulocytosis, which was followed by increases in hematocrit and hemoglobin values, in the blood of patients being given cobaltous chloride by mouth.¹ These findings were not completely unexpected since it has long been known that cobalt is a hematopoietic agent effective in deficient² and healthy animals.³ Therapy with cobalt apparently stimulates red-cell production in children,⁴ as well as in adults,⁵ and also protects animals from developing anemia when sterile suppuration is induced experimentally.⁶

As far as we are aware cobalt has not been employed in this country in the treatment of patients ill with chronic sepsis. This report therefore presents observations on the blood of 9 patients suffering with prolonged suppurative infections who were

treated for two to eleven weeks by the daily oral administration of 20 to 60 mg of cobaltous chloride.

MATERIAL AND METHODS

Methods

Hemoglobin determinations were made by a photoelectric method⁷, hematocrit values, red-cell counts, white-cell counts, reticulocyte counts and differential white-cell counts were done according to methods described by Wintrobe.⁸ Plasma volume was determined by Gregersen's⁹ modification of the technic of Gibson and Evans,¹⁰ using the dye T-1824, plasma iron, after that of Kitzes et al,¹¹ and plasma copper by a modification of the method of Cartwright and his associates.¹²

Patients

Nine male patients were selected for study. Their average age was twenty-five years (the oldest was thirty-six and the youngest eighteen years of age). Three patients had been injured by automobiles, and 6 had been wounded by bullets or fragments from land mines. When first selected for this study patients had already spent an average of twenty-eight months in hospitals because of chronic osteo-

sites of sepsis¹ The organisms were identified and were usually found to be resistant to penicillin or streptomycin In these patients plasma iron levels were low, and plasma copper levels were increased Control measurements of blood volumes, hemoglobin levels, hematocrit values and cell counts were made on at least two occasions before therapy was instituted

After the patients had been observed during the control period they were treated with 20 to 60 mg

RESULTS

Hematologic data on individual patients are given in Table 1 and Figure 1 Average data for the 9 patients during the control period and at the end of therapy with cobaltous chloride are recorded in Table 2 and are contrasted with average data obtained from 10 patients bed ridden with fractures or orthopedic abnormalities, who were free from infection during their illness¹

Before treatment, red-cell counts, reticulocyte counts, hemoglobin concentrations, hematocrit levels and total circulating hemoglobin were constant and reduced below the levels found in the bedridden control subjects. The significant deviations

occurred during the first eight weeks of treatment with cobalt. An extensive sequestrectomy of the femur was performed during the ninth week of therapy, and, during the next two weeks while he was still taking cobalt, the total circulating

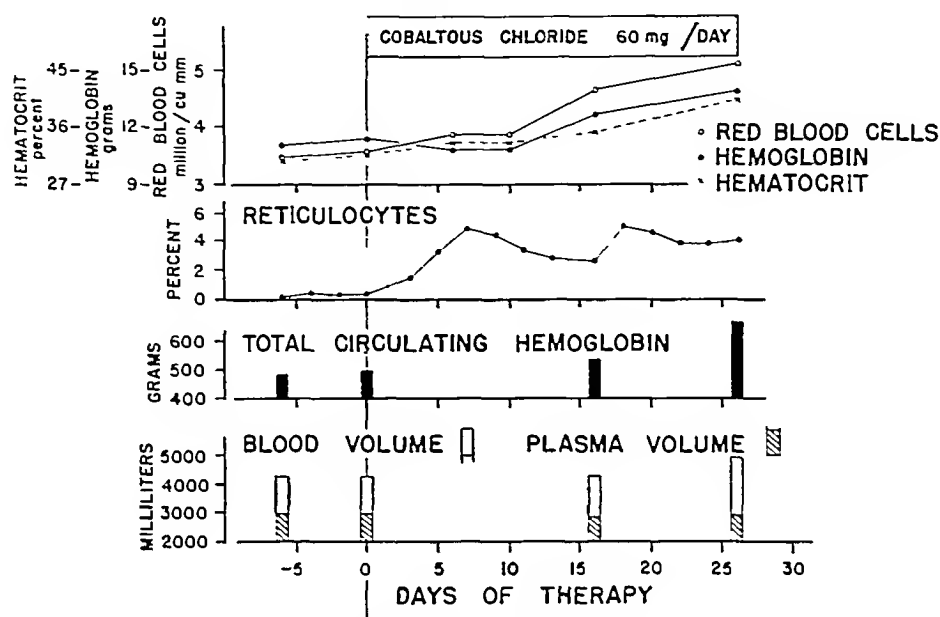

FIGURE 1 Effect of Therapy with Cobaltous Chloride on the Blood of a Nineteen-Year-Old Male Patient with Chronic Cystitis and Osteomyelitis Following a Bullet Wound

from the normal were in measurements of total circulating hemoglobin, which was reduced on the average 26 per cent below levels found in the controls.

After treatment with cobaltous chloride reticulocyte responses were observed in each of the 9 pa-

tients. hemoglobin, red-cell count and hematocrit levels returned to pretherapy levels.

From Table 2 it can be seen that on the average the blood values of the 9 patients had reached normal levels after cobalt therapy. There was a significant change in the blood volume, owing in the

tients. These occurred as early as the fourth day and continued throughout therapy. The maximal reticulocyte percentages were usually observed between the sixth and tenth days, and did not exceed 5 per cent in any case. A typical reticulocyte response is shown in Figure 1. In this patient, as in the other 8 (Table 1), a steady increase in red-cell counts, hematocrit levels and total circulating hemoglobin followed the reticulocyte response. In Case 3 considerable increases in blood values oc-

curred during the first eight weeks of treatment with cobalt. The total circulating hemoglobin increased, on the average, 29 per cent above the levels before therapy. White-cell counts and differential cell counts showed few changes and mean corpuscular volume altered but slightly. In 4 patients, in whom measurements were made before and after treatment with cobalt, plasma iron and copper levels were not affected by cobalt therapy.

fer from the blood to the bone marrow. There is good evidence in the literature that cobalt inhibits the respiration of micro-organisms as well as animal tissues and tumors¹⁵ and that it does so by inhibiting -SH groups of enzyme systems¹⁶. Oral therapy with sulfur-containing amino acids, such as cysteine and also to a lesser extent with histidine, inhibits the effects of cobalt in producing polycythemia in rats, and parenteral cobalt-cysteine complexes are also unable to produce polycythemia¹⁷. Ascorbic acid, a reducing substance, also inhibits the effects of cobalt in producing polycythemia in rabbits¹⁸ and dogs¹⁹.

As our patients developed a blue discoloration of the skin we speculated that the "cyanosis" and bone-marrow anoxia were due to methemoglobin, produced by cobalt interference with the normal reconversion in the red blood cell of methemoglobin to hemoglobin — a reducing mechanism that is continuously taking place in the blood²⁰. We therefore examined the blood of 4 patients spectroscopically but were not able to detect methemoglobin after therapy with cobalt. The mechanism of cobalt activity in patients with chronic infection therefore remains unexplained and requires further study.

SUMMARY

Nine patients suffering with chronic suppurative infections were treated with 20 to 60 mg a day of cobaltous chloride given by mouth for a period of two to eleven weeks. In all patients a reticulocytosis was observed within six days. This was followed by increases in red-cell counts, in hemoglobin values, in hematocrit levels, in blood volume and in total circulating hemoglobin.

We are indebted to Brigadier General Harry A. Offutt, M.C., U.S.A., commanding officer and Colonel Ralph M. Thompson, M.C., U.S.A., chief of the laboratory service, Percy Jones General Hospital for their help in making this investigation possible. We also appreciate the assistance given by officer and enlisted personnel from Percy Jones General Hospital.

Dr L. G. McLean and Mr T. Wallace of Smith, Kline and French Laboratories, arranged for the preparation of the cobaltous chloride tablets, and we wish to thank them for this service.

We are especially grateful to Mrs Vera P. Robinson for technical assistance.

Toxicity

During therapy with cobalt slight loss of appetite was observed in 2 patients. All patients developed a dusky discoloration of the skin, especially marked below the eyelids. This change in the color of the skin was probably due to the dye T-1824 used for measuring blood volumes, but it may have been an effect of cobalt therapy. No other abnormal signs or symptoms of cobalt toxicity were observed.

DISCUSSION

The anemia associated with chronic infection is usually not severe. With present-day attention to the protein and other nutritional requirements of the chronically ill and with present-day emphasis on the liberal use of blood and blood substitutes, gross anemia is rarely found in patients with prolonged sepsis. For example, only 6 out of 91 men suffering with chronic suppuration of the bones and soft tissues had hemoglobin concentrations below 12 gm per 100 cc. On the other hand, when blood-volume studies were done it was found that the total circulating hemoglobin was considerably reduced when compared with the total circulating hemoglobin of bed-ridden control subjects or when compared with the total circulating hemoglobin of healthy persons who were up and about.¹

The 9 patients reported in this paper were ill with chronic sepsis. In them plasma copper was elevated and plasma iron was reduced. Although hemoglobin concentrations and red-cell counts were reduced only slightly below levels found in the control subjects, the total circulating hemoglobin was reduced on the average by 26 per cent and may therefore have indicated lowered total blood volume.

Hematopoietic responses to therapy with cobaltous chloride, which were observed in each patient, indicate that cobaltous chloride produced an active stimulus to erythropoiesis, since a distinct reticulocytosis preceded the rise in erythrocyte count. Reticulocytes are not increased and do not increase spontaneously in patients at times when they are ill with chronic sepsis. The reticulocytes in the 91 patients mentioned above averaged 0.7 per hundred red blood cells and in only 1 case did they reach 2.0 per cent. Spontaneous increases in blood values were never observed when suppuration persisted. This, of course, is common knowledge.^{8, 12}

Preliminary observations on the effect of cobalt on the blood of normal and anemic persons have been reported in the German literature by Weissbecker and Maurer.⁶ They state that after daily oral therapy with 500 mg of cobalt chloride a reticulocyte peak occurred on the third day, and thereafter increases in erythrocyte, hemoglobin and hematocrit values occurred. Mean corpuscular volume and red-cell diameter decreased. The Price-Jones curve shifted to the left, and its base broadened. Osmotic resistance, serum bilirubin, white-

cell count and differential cell count remained unchanged. Blood volume increased, but plasma volume remained steady. In normal adults a "true" polycythemia developed, and blood levels returned to normal in patients anemic from blood loss.

In the anemia of chronic infection adequate responses occurred in some patients. However, in those who had severe chronic infection the effects of cobalt therapy were small and consisted of reticulocyte responses and bone-marrow maturation. The authors state that in patients with chronic infection the available serum iron was an index of ability to regenerate blood. In the 9 patients reported above, plasma iron was reduced but not to very low levels. These patients were well fed. Their nutritional status regarding protein and vitamins was good even after two years in the hospital. The German authors make no comment on the nutritional status of their patients ill with chronic sepsis, but it is reasonable to suspect that they were not so well fed as our patients. It is possible that nutritional disturbances in some patients account for failure to respond maximally to cobalt.

Weissbecker and Maurer used large doses of cobalt. They gave 500 mg by mouth each day and observed toxic symptoms in themselves and in their patients. These consisted of nausea, vomiting, diarrhea and reddening of the face and extremities, which was accompanied by hot flushes. With 60 mg a day by mouth after meals neither ourselves nor our patients experienced untoward symptoms. However, 2 of the patients suffered somewhat from anorexia.

The mode of action of cobalt on the blood remains a mystery. Specific effects of cobalt therapy on anemia are seen in cattle and sheep that graze on grass deficient in this trace element,² and good hematopoietic responses occur after therapy with very small amounts (0.1 mg) of cobalt. Castle,¹⁴ in a recent talk, suggested that cobalt-deficient animals are really suffering from vitamin B₁₂ deficiency. He speculated that normally bacteria in the rumen of cattle synthesize vitamin B₁₂—a cobalt-containing organic substance—and that the vitamin exerts a specific effect on hematopoiesis after it is absorbed. He also suggested that when the animals live on cobalt-deficient feed the intestinal flora are not able to form the vitamin. Consequently, the animals develop vitamin B₁₂ deficiency and become anemic.

It does not seem possible that cobalt exerts a specific effect on the blood in patients with chronic infections. Their anemia is refractory to therapy with liver, which contains vitamin B₁₂, and they require relatively large quantities of cobalt for erythropoiesis to take place. It is more likely that the hematopoiesis that follows massive cobalt therapy is due to a nonspecific stimulus to the bone marrow. This may be a consequence of generalized tissue anoxia or may follow impaired oxygen trans-

fer from the blood to the bone marrow. There is good evidence in the literature that cobalt inhibits the respiration of micro-organisms as well as animal tissues and tumors¹⁵ and that it does so by inhibiting -SH groups of enzyme systems¹⁶. Oral therapy with sulfur-containing amino acids, such as cysteine and also to a lesser extent with histidine, inhibits the effects of cobalt in producing polycythemia in rats, and parenteral cobalt-cysteine complexes are also unable to produce polycythemia¹⁷. Ascorbic acid, a reducing substance, also inhibits the effects of cobalt in producing polycythemia in rabbits¹⁸ and dogs¹⁹.

As our patients developed a blue discoloration of the skin we speculated that the "cyanosis" and bone-marrow anoxia were due to methemoglobin, produced by cobalt interference with the normal reconversion in the red blood cell of methemoglobin to hemoglobin — a reducing mechanism that is continuously taking place in the blood²⁰. We therefore examined the blood of 4 patients spectroscopically but were not able to detect methemoglobin after therapy with cobalt. The mechanism of cobalt activity in patients with chronic infection therefore remains unexplained and requires further study.

SUMMARY

Nine patients suffering with chronic suppurative infections were treated with 20 to 60 mg a day of cobaltous chloride given by mouth for a period of two to eleven weeks. In all patients a reticulocytosis was observed within six days. This was followed by increases in red-cell counts, in hemoglobin values, in hematocrit levels, in blood volume and in total circulating hemoglobin.

ERYTHROPOIETIC EFFECT OF COBALT IN PATIENTS WITH OR WITHOUT ANEMIA*

LIONEL BERK, M D,† JOSEPH H BURCHENAL, M D,‡ AND WILLIAM B CASTLE, M D§

BOSTON AND NEW YORK CITY

COBALT in the form of one of its salts, usually cobaltous chloride or cobaltous nitrate, has been shown to produce polycythemia in amphibia, birds and mammals¹⁻³. In mammals the increased concentration of red blood cells in the circulation is due, as in other types of polycythemia, largely to an increase in the circulating red-cell mass⁴⁻⁶. That the polycythemia is produced by increased red-cell production is indicated by an initial or by a maintained reticulocytosis,⁶⁻⁷ and an increase in erythroid cells in the bone marrow⁸⁻⁹ and in extramedullary locations.⁹ In some species the slight bilirubinemia⁷ presumably results from a partially compensatory increase in erythrocyte destruction. There is no evidence that cobalt administration causes the development of red blood cells containing an abnormal form of hemoglobin¹⁰ or one with a lessened capacity for the transport of oxygen.⁹ However, the resemblances of cobalt polycythemia to experimental polycythemia induced in various ways by anoxia of the bone-marrow cells may find an explanation in recent observations¹¹⁻¹² indicating that cobalt inhibits the respiration of certain bacteria, perhaps owing to the formation of partially reversible complexes between cysteine or histidine, cobalt and oxygen. Results in animal experiments suggest that such complexes are not readily dissociated in the body¹⁰ and so point to the possibility that their formation creates in effect anoxia of the erythroid cells of the bone marrow, with its characteristic increase in erythropoiesis.

Since the pioneer observations of the Waltners¹ in 1929, metallic cobalt or its salts have been administered in animals and in man in efforts to combat the anemia produced by disease. For example, Kleinberg, Gordon and Charipper⁸ reported that cobaltous nitrate was able to counteract the inhibitory effect on erythropoiesis of benzol administration in rabbits. Recently Wintrobe and his associates¹³ showed that cobalt administration abolished the anemia or even produced polycythemia in rats in which sterile inflammation had been created by the intramuscular injection of turpentine. Only a few results, for the most part all too

briefly documented, have been reported from the use of cobalt salts as a stimulus to erythropoiesis in human disease.¹⁴⁻¹⁸ However, almost at the time of the beginning of the present investigation, Weissbecker and Maurer¹⁹ briefly indicated in the German literature that the oral administration of 500 mg of cobaltous chloride daily produced with regularity in normal subjects reticulocyte responses and thereafter increases in red-cell, hemoglobin and hematocrit values. They confirmed the animal observations showing a decrease in mean corpuscular volume and diameter of the red blood cells and noted, likewise, an increase in circulating red-cell mass but not in plasma volume. No changes in serum bilirubin or in total or differential white-cell counts were observed. In some patients with the anemia of chronic infection, similar or less pronounced erythropoietic responses occurred. The toxic effects observed consisted of anorexia, nausea, vomiting, diarrhea and flushing of the face and extremities.

In the present work, an attempt was made to study the erythropoietic effect of cobalt first in hematologically normal patients. Then, especially because of the apparently successful results of Kleinberg and his associates⁸ in rabbits poisoned with benzol, it was proposed to extend the observations to patients with anemias refractory to recognized forms of treatment. If effective in causing increased erythropoiesis, cobalt therapy might be useful as a substitute, at least in part, for the repeated transfusions required in the treatment of such patients.

METHODS

Cobaltous chloride ($\text{CoCl}_2 \cdot 6 \text{H}_2\text{O}$) in the form of a 2.5 per cent aqueous solution was administered to 61 patients. Unless otherwise indicated, the dose of the solution employed was 4 cc containing 100 mg of cobaltous chloride given orally, thrice daily after meals, well diluted with water.

During a control period of not less than five days, two or more complete blood counts and daily reticulocyte counts were made. Then, with the institution of cobalt therapy, daily reticulocyte counts were continued for at least ten days in most patients, and complete blood counts were made at least once weekly for two to fourteen weeks. The red-cell and white-cell counts were made from venous blood samples in the usual manner with the use of United States Bureau of Standards certified pipettes. Hemoglobin estimations were done with an Evelyn photoelectric colorimeter with a factor of 2.58. It was considered that 15.6 gm of hemo-

globin was equivalent to 100 per cent. Hematocrit determinations were performed by the method of Wintrobe, and the mean corpuscular volume and mean corpuscular hemoglobin concentration were calculated. Reticulocytes were counted by means of coverslips previously coated with a film of brilliant cresyl blue dissolved in absolute alcohol. After the film was dry, a fresh drop of blood was spread upon the coverslip in the usual manner and was thereafter fixed and counterstained with Wright's

into three groups chiefly on the basis of the amount of cobaltous chloride administered.

Subgroup A Eight patients with various psychoses were given 100 mg of the medication in a single daily dose for six days. During this period, as shown in Table 2, small reticulocyte responses were observed in 6 patients. The dose of cobalt was then increased to 200 mg, once daily. The 2 remaining patients then showed within seven days reticulocyte responses for the first time, and the

stain. The percentage of reticulocytes was then estimated by a count of at least 1000 red blood cells under the oil immersion lens.

RESULTS

The types of patients to whom cobaltous chloride was administered are indicated in Table 1. In the 31 patients who were treated for less than four weeks, cobalt administration was discontinued in 24, chiefly because of the irritant effects on the alimentary tract noted in Table 1, and in 7 convalescent subjects because early discharge from the hospital rendered further observations impossible. The erythropoietic effects observed in the patients without anemia are summarized in Table 2, and illustrations of those noted in 1 normal and in 3 anemic patients are presented in Figures 1 to 4.

Patients without Anemia

These 17 patients were without significant hematologic abnormality and can be subdivided

other 6 patients showed a second and slightly greater peak of reticulocytes. Thereafter, therapy with cobaltous chloride was continued with occasional unavoidable omissions, especially after the ninth week, for twelve weeks in all. During this time, moderate increases in red blood cells, in hemoglobin and in hematocrit of venous blood samples occurred in all but 1 case (Case 7, red blood cells), as shown in Table 2. No toxic effects were noted in any of the patients of this group, nor did any significant improvement in mental status develop.

Subgroup B Seven patients — in 4 cases convalescent from cerebral vascular accidents and in 1 each with prostatism, mental deficiency and senility — were given cobaltous chloride in a dose of 100 mg three times a day. In 6 patients the drug was administered for only one or two weeks prior to discharge from the hospital. However, daily counts showed within ten days reticulocyte peaks in most cases significantly greater than those in the cases included in Subgroup A. In the remaining patient

(Case 9), a sixty-seven-year-old man with marked generalized osteoporosis and osteoarthritis, the drug was administered for eleven weeks. The striking results upon red-cell and hemoglobin levels are

of a pre-existing and otherwise silent duodenal ulcer, no unfavorable effects attributable to the medication were noted in the patients comprising this subgroup

summarized in Table 2 and are shown graphically in Figure 1. Although blood loss during the first week of treatment may have been responsible for the first reticulocyte peak, thereafter somewhat elevated reticulocyte counts appeared in successive waves of several days each. After ten weeks of treatment, the patient began to complain of poor appetite and sensations of fullness in the head. Consequently, cobalt administration was stopped a week later, and five days thereafter, at the height of the polycythemia, 500 cc of blood was removed

Subgroup C Two patients (Cases 16 and 17), who were convalescent from cerebral vascular accidents, received cobaltous chloride as follows on the first day 100, on the second day 200, on the third day 300, and thereafter 400 mg three times daily. Both patients showed reticulocyte responses

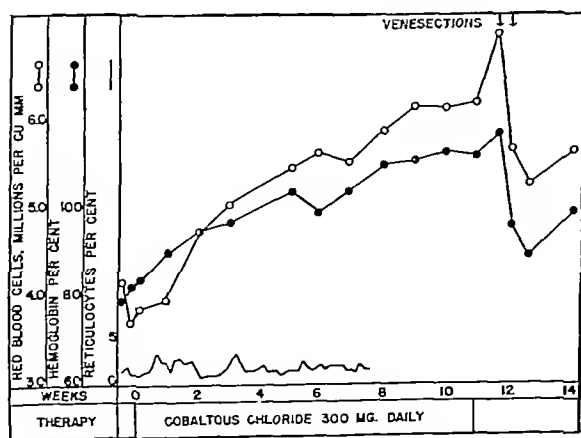

FIGURE 1 *Results of Cobalt Administration in Case 9*

This was a sixty-seven-year-old man with generalized osteoporosis and osteoarthritis. Because of manifest polycythemia after eleven weeks of cobalt therapy, two venesections of 500 cc each were performed. The red blood cells so obtained contained no abnormal forms of hemoglobin and survived normally in a suitable recipient.

on two successive days. Except for the hematemesis in this patient, which presumably, in the light of a subsequent x-ray examination, was due to irritation

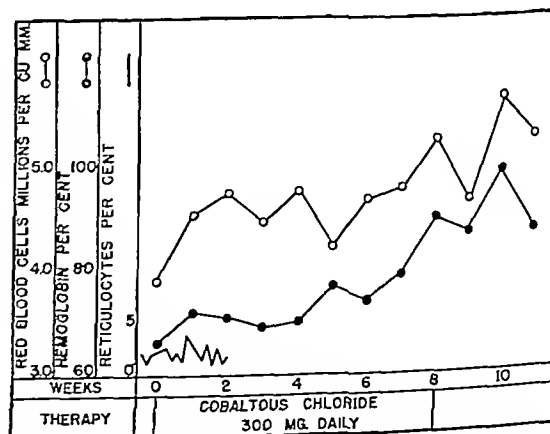

FIGURE 2 *Results of Cobalt Therapy in a Fifty-Three-Year-Old Man (Case 18) with Mild Hypochromic Anemia due to Chronic, Moderately Active Rheumatoid Arthritis*

of slight degree. After two weeks of this regime, 1 patient (Case 17) demonstrated severe nausea and vomiting with hemoconcentration that disappeared when the drug was stopped. The other patient (Case 16) was successfully treated for six weeks. Daily reticulocyte counts were performed throughout this period and showed a wave-like rise and fall over periods of several days. During this time, the red blood cells, hemoglobin and hematocrit exhibited the moderate increase shown in Table 2.

The patient complained only of anorexia and had no nausea or vomiting.

An attempt was made to administer 100 mg of cobaltous chloride, three times a day, simultaneously to two groups of 6 patients with pernicious anemia maintained in complete remission in an outpatient clinic by means of monthly injections of concentrated liver extract. However, without exception each patient reported a week later that with the first dose of the medication symptoms appeared. Indeed, after either the first dose or the first few doses, nausea and vomiting, sometimes of considerable severity, compelled the discontinuation of the medication by the patient himself. Subsequent inquiry revealed that 2 patients had also noticed palpitation and 2 had experienced constipation (Table 1). In individual patients nosebleed, swelling of the hands and feet, abdominal pain, dizziness and diarrhea appeared clearly to result from the medication. All symptoms disappeared a few hours after the drug was stopped.

Patients with Anemia

Cobaltous chloride was administered at the rate of 100 mg, three times a day, to 32 patients with various types of anemia refractory to treatment. Of these, 20 took the medication for over four weeks. The number of each type of patient treated, as well as the untoward symptoms that occurred, is shown in Table 1. Of the 5 patients with moderate anemia associated with chronic infections (pulmonary tuberculosis in 3 and rheumatoid arthritis in 2), 4 re-

during the period of cobalt administration he ran a low-grade fever, and occasional sputums were positive for tubercle bacilli without evidence of change in x-ray films of the chest. Cobalt administration appeared to aggravate mildly this patient's occasional episodes of nausea and vomiting. The hematologic data for these patients are presented in Figures 2 and 3. Five patients with "refractory" anemia and hypercellular bone marrow, presumably of the type described by Bomford and Rhoads,²⁰ of

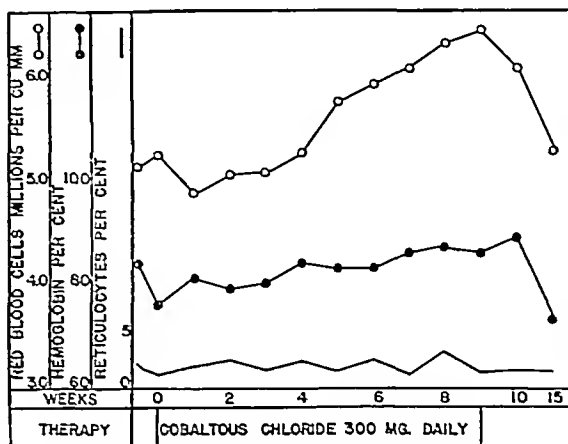

FIGURE 4 Results of Cobalt Therapy in a Thirty-Six-Year-Old Italian Woman (Case 22) with Familial Microcytic (Cooley's Trait) Anemia

Note the relatively greater increase in the red blood cells than in the hemoglobin in response to cobalt administration.

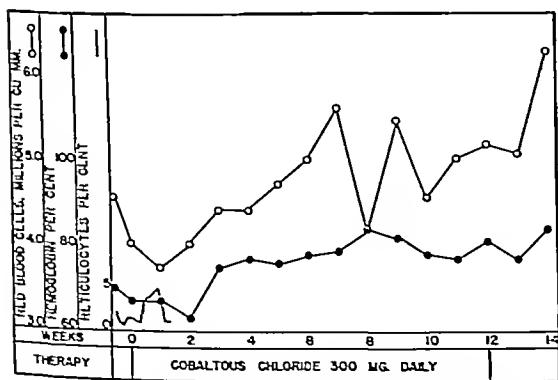

FIGURE 5 Results of Cobalt Therapy in a Forty-Eight-Year-Old Man (Case 19) with Mild Hypochromic Anemia due to Chronic, Advanced Pulmonary Tuberculosis

ceived treatment for over four weeks, of these, 2 patients (Cases 18 and 19) showed reticulocyte responses and subsequent rises in blood values. Case 18 was a fifty-three-year-old mason with chronic rheumatoid arthritis, who ran a temperature above 100°F and an elevated sedimentation rate during the period of cobalt administration. Case 19 was a forty-eight-year-old pipe fitter who showed multilobar cavitation of the upper right lung and nodular lesions in the centers of both lungs. On bed rest

whom 4 were treated for over four weeks with cobaltous chloride, yielded no definite reticulocyte responses or rises in blood values.

Sixteen patients with anemia accompanying various forms of leukemia or lymphoma were treated with cobaltous chloride. Of these, 10 received the material for over four weeks. In 2, daily reticulocyte counts were made during the first ten days of therapy and showed no evidence of significant increase. In 2 other patients, both with anemia associated with reticulum-cell sarcoma, there was perhaps suggestive evidence of an effect upon circulating red-cell values that became apparent more than a month after cobalt treatment had been begun. Thus, in 1 patient (Case 20) during a period of four months, nitrogen mustard therapy on three occasions and multiple transfusions within a few days of 2500 or more cc of whole blood on four occasions failed to elevate the hemoglobin more than temporarily above 54 per cent. However, after cobalt therapy for two months, a fifth series of transfusions comprising 2500 cc of whole blood raised the hemoglobin promptly from 32 to 83 per cent. Cobalt therapy was then continued for two more months, during which the hemoglobin values remained above 85 per cent. Two months after the cessation of cobalt therapy, the hemoglobin was 72 per cent. At this time, because of enlargement

of lymph nodes, a course of nitrogen mustard therapy was given. A month later the patient's hemoglobin was 57 per cent, and he was again started on therapy with cobaltous chloride. Two weeks thereafter, when his hemoglobin was 39 per cent, he was given multiple transfusions comprising 3500 cc of whole blood, which brought his hemoglobin up to 73 per cent. During the next six weeks, cobalt therapy was continued, and the hemoglobin increased to 99 per cent. At that time cobalt therapy was stopped temporarily because of an episode of precordial pain, which recurred a few days later when cobalt was again administered. For this reason, the medication was permanently discontinued. A month later the hemoglobin was still 83 per cent of normal. In the other patient (Case 21) the hemoglobin level prior to the institution of regular transfusions had gradually declined to approximately 50 per cent. Three months later the patient was placed on cobalt and began to receive small amounts of x-ray therapy. The transfusions were discontinued, and the hemoglobin remained above 80 per cent for over a year. In neither patient, unfortunately, were reticulocytes counted at the time of the initiation of the cobalt therapy. In each it is possible to ascribe the increase in red-cell and hemoglobin values either to the previous administration of a nitrogen mustard or to concomitant, though seemingly insufficient, irradiation therapy.

A third patient (Case 22), with chronic lymphatic leukemia, was given two courses of radioactive phosphorus one month and one week respectively before he was placed on 200 mg of cobaltous chloride daily. Cobalt administration was continued for five weeks, during which the elevated white-cell count fell gradually to normal and the hemoglobin increased from 39 to 58 per cent. The dose of cobalt was then reduced to 100 mg daily and was continued for another five weeks, when the hemoglobin had reached 94 per cent. Without further cobalt administration the hemoglobin slowly declined in the next eight months to 74 per cent, and the white-cell count gradually rose to about 80,000. Again, the interpretation of the dramatic hemoglobin response is complicated by the previous administration of radioactive phosphorus.

Two patients with the anemia of chronic nephritis could not tolerate the drug for more than a few days and exhibited no reticulocyte responses. Of 2 patients with hypochromic (iron-deficiency) anemia 1 showed a definite reticulocyte response and rise in red cells and hemoglobin despite the presence of inoperable carcinoma of the stomach. A clear-cut erythropoietic response to cobaltous chloride therapy was obtained in 1 patient (Case 23), a thirty-seven-year-old Italian housewife, with familial microcytic (Cooley's trait) anemia. The pertinent hematologic data are presented in Figure 4. Moderate nausea and vomiting appeared after nine weeks

of therapy and persisted for six days until the medication was discontinued. A patient with moderate anemia due to cirrhosis of the liver was given cobaltous chloride for more than four weeks without detectable effect on reticulocyte or other blood values.

DISCUSSION

On the basis of these observations, it seems clear that cobaltous chloride when administered in man in sufficient doses causes with some regularity increased erythropoiesis in hematologically normal subjects. The reticulocyte responses occurred within ten days of the institution of cobalt therapy, and so resemble in their chronology those resulting from hemorrhage, anoxia or iron or liver-extract administration under circumstances appropriate to each. This is seemingly consistent with the possibility, referred to above, that cobalt interferes with the transport of oxygen in the erythroid cells of the bone marrow because of its ability to form oxygen-binding complexes with certain amino acids such as cysteine and histidine. If so, the agent would be expected to be effective in elevating the hemoglobin level in patients with little or no anemia rather than in those with severe anemia, in whom a powerful anoxic stimulus to erythropoiesis presumably already exists.

Like Orten and Bucciero¹⁰ in their animal experiments, we were unable to demonstrate any abnormalities in the light-transmission curve of oxyhemoglobin using the Beckman spectrophotometer. The pigment was derived from circulating red blood cells removed from a patient (Case 9), nearly all of which had presumably been formed during the previous eleven weeks of treatment with cobalt. As this patient's red blood cells, when transfused into another patient of compatible blood group, survived normally according to identification made by appropriate differential agglutinations, no evidence was obtained that red blood cells produced while the patient was receiving cobalt were defective as vehicles for oxygen transport.

The erythropoietic responses observed in 2 patients with chronic infection confirm the preliminary report of Weissbecker and Maurer¹² and further substantiate the observations of Robinson, James and Kark.²¹ The observations of Waltner,¹¹ of Baxter¹⁸ and possibly of Kato¹⁶ suggest an effect of cobalt in "secondary," presumably hypochromic anemias in children due to iron deficiency with or without infection. In our experience also cobalt was efficient in raising the blood values of 1 of 2 patients with hypochromic anemia due, presumably, to blood loss from an inoperable cancer of the stomach. Iron, however, would be the therapeutic agent of choice in such a patient unless it was rendered ineffective because the cancer was exerting a "toxic" inhibition on erythropoiesis resembling that perhaps existing in chronic infection.¹³ The

definitive erythropoietic response in 1 patient with familial microcytic (Cooley's trait) anemia indicates a possible use for cobalt therapy in a condition that is completely refractory to iron and other substitution treatment.

Because it was the main objective of the study, it was disappointing to find that cobalt was completely ineffective in raising the hemoglobin level in 5 patients with "refractory" anemia of idiopathic origin associated with hypercellular bone marrow.²⁰ The coincidental use of other forms of treatment rendered the results merely suggestive in the 2 patients with anemia associated with reticulum-cell sarcoma and in 1 with chronic lymphatic leukemia. No certain benefit was remarked in any of the other patients with leukemia or lymphoma. In the anemias of chronic nephritis and cirrhosis, our studies, though negative, are perhaps too few to permit conclusions.

The toxicity of cobalt at dosage levels capable of causing polycythemia is difficult to estimate from reports in the literature. When administered orally, cobalt salts are largely excreted in the feces, and even the portion absorbed from the intestinal tract is mostly lost in the urine within a few days.^{22, 23} Thus, at the height of the polycythemia produced in rats, only 40 to 50 microgm of cobalt may be found in the entire body of the animal.²⁴ When cobalt salts are injected, elimination is largely in the urine and bile,^{23, 25} but as much as 5 per cent may be retained by the tissues ten days later.²⁴ Presumably as a result of the poor absorption of the cobalt salts, the production of significant polycythemia in the adult rat requires the daily oral administration of about 40 mg per kilogram of body weight, in contrast to only 2.5 mg of cobaltous chloride daily by injection.²⁶

Early observations in animals showed that when given orally in sufficient dosage to dogs cobalt salts caused irritation of the intestine and death in convulsions. Ten milligrams killed a frog in half an hour, and 300 mg was fatal to a rabbit in three hours. In dogs 200 to 300 mg per kilogram of body weight caused vomiting, diarrhea and sometimes acute nephritis. With larger doses, dyspnea and a fall of blood pressure appear, and death may result from cardiac paralysis.²⁷ On the other hand until a certain daily oral dosage level is reached, which varies in different species and individuals, there may be no signs of toxicity and then only a poor appetite, which promptly improves with the discontinuance of the cobalt.²⁸ In the opinion of LeGoff,²⁹ who has studied the subject of cobalt toxicity both in animals and in man, cobalt is not more dangerous than iron, the immediate toxic actions of which it seems to imitate. The subcutaneous injection of 10 to 50 mg of cobaltous chloride in human subjects caused a sensation of heat in the face and a fall of blood pressure. To one patient LeGoff gave 90 mg daily orally for a

hundred days, and to another 122 subcutaneous injections of 25 mg each during a period of three years, without apparent harm.

The chief manifestations of toxicity from the oral administration of cobalt in our experience were, as reported by others, referable to the alimentary tract: anorexia, heartburn, nausea and vomiting. In many patients receiving 300 mg daily these symptoms were minimal or absent, but in some they were a very real obstacle to the administration of the therapeutic agent. The promptness and consistency with which each of 12 patients with pernicious anemia in complete remission experienced severe symptoms referable to the gastrointestinal tract suggest that the typical achlorhydria or rapid emptying time of the stomach was responsible and may occasionally condition similar undesirable side effects in other patients.

A patient with chronic lymphatic leukemia was given an intravenous injection of 50 mg of cobaltous chloride dissolved in 250 cc of sterile physiologic saline solution on sixteen occasions during a period of thirty-seven days. Whenever a given rate of infusion was exceeded, he experienced burning sensations and flushing of the face. However, if two hours was allowed to elapse for the entire injection, little difficulty was encountered. On one occasion when 75 mg of cobaltous chloride was given to this patient intravenously, an episode of nausea, vomiting and bone pain occurred. No pathologic changes appeared in the urine of this patient or of any of the other patients during the period of cobalt administration.

Two patients, 1 with reticulum-cell sarcoma and the other with giant-follicle lymphoma, after being under treatment continuously with cobalt for one and two months, respectively, complained of severe substernal pain, which they attributed to the drug. In the first patient (Case 20), who was sixty-five years of age, the pain disappeared when cobalt administration was stopped for a few days, only to return when the therapy was resumed. An electrocardiogram was normal at the time, but when autopsy was performed four months later, an old septal infarct was found. In the second patient, aged fifty-eight years, the electrocardiogram was consistent with myocardial infarction. It seems doubtful that the cobalt administration was responsible for the production of the infarct, but it is understandable that the drug could give rise to symptoms in patients who probably already possessed an insufficient blood supply to the myocardium, especially if the fundamental action of cobalt salts is to interfere with intracellular respiration.¹⁰

As with any therapeutic agent, the possibility of injury from cobalt must be balanced against the urgency of the need for the drug. No one questions the use in skilled hands of irradiation or of war gases in the treatment of leukemias or other neo-

plastic conditions. These agents are frequently effective and though dangerous are less so than the uncontrolled disease against which they are directed. With cobalt there is perhaps little evidence of toxicity, at least after oral administration, other than irritation of the alimentary tract. However, we have found that there is also little probability of benefit in severe types of anemia otherwise unamenable to therapy. In mild anemias associated with chronic infections, the benefit due to the slight increase in hemoglobin that can be confidently expected may well be offset by the loss of appetite due to the drug. For these reasons, the clinical use of cobalt should probably be confined to cases of anemia in which other methods of treatment are clearly of no value. Thus, there is no indication for the use of cobalt as an adjuvant to liver extract or iron therapy. Moreover, it is likely that by critical determination of the daily level of reticulocytes during a period no longer than a week, the probable usefulness of the drug during a more protracted exhibition in any given patient can be assessed.

SUMMARY

The daily oral administration of 300 mg of cobaltous chloride to 17 patients without anemia produced slight reticulocyte responses in all within a week. Of the 10 patients given the therapeutic agent for over four weeks, moderate increases in red blood cells, hemoglobin and hematocrit were observed in all but 1.

Similar doses of cobaltous chloride were given for more than four weeks to 20 patients with various types of anemia refractory to other forms of therapy. In 2 of 5 patients with moderate anemia associated with chronic infections, in 1 of 2 patients with hypochromic anemia associated with inoperable carcinoma of the stomach and in 1 patient with familial microcytic (Cooley's trait) anemia, definite reticulocyte responses and rises in red-cell, hemoglobin and hematocrit values were observed.

In only 3 of 10 patients in the lymphoma group — 2 with reticulum-cell sarcoma and 1 with chronic lymphatic leukemia — was even suggestive evidence of ability to maintain higher erythrocyte and hemoglobin levels obtained. In none of 5 patients with refractory anemia and hypercellular bone marrow was erythropoiesis detectably affected. In 1 patient with the anemia of cirrhosis of the liver no response was obtained in an adequate trial. In 2 patients with anemia associated with chronic renal failure, given the drug for only a few days, no evidence of a reticulocyte response was noted.

Red blood cells produced by a patient during eleven weeks of treatment with cobalt contained spectrophotometrically normal oxyhemoglobin and survived normally when transfused into another patient.

In some patients the usual dose employed, 100 mg of cobaltous chloride thrice daily, caused anorexia or mild symptoms referable to the alimentary tract. In a few cases these symptoms developed only after the medication had been administered for several weeks. However, the same amount of drug in each of 12 patients with pernicious anemia in maintained remission at once caused nausea and vomiting sufficiently severe to result in prompt abandonment of the medication. In another patient similar intolerance developed after two weeks when 400 mg had been given thrice daily. Two patients fifty-eight and sixty-five years of age experienced precordial pain while being given 100 mg of cobaltous chloride thrice daily and exhibited clinical evidence suggestive of myocardial infarction. All types of symptoms were relieved within a few hours by discontinuation of the medication.

The possibility that the erythropoietic action of the drug depends upon a fundamental alteration of tissue respiration indicates the need for further studies of chronic toxicity in animals and clearly suggests that cobalt salts should be used in man only in the treatment of anemias resistant to accepted forms of treatment and then with caution.

We are greatly indebted for the opportunity to study some of the patients to Dr. Walter E. Barton and his staff at the Boston State Hospital, Mattapan, Massachusetts, and likewise to Drs. Maurice B. Strauss and Charles R. Blackburn, of the Cushing Veterans Administration Hospital, Framingham, Massachusetts. Appreciation is also due Miss Phyllis Gordon for the performance of many of the blood examinations and to Miss Theo Wood for others, as well as for the preparation of the figures.

METHODS OF INDUCTION IN PEDIATRIC ANESTHESIA*

ROBERT M. SMITH, M.D.†

BOSTON

IN INFANTS and children the technic of induction of anesthesia demands careful consideration, if optimal results are to be obtained.

The success of the induction depends upon several factors, one of the most important of which is the preoperative handling of the child. The first objective is the elimination of fear. Intelligent parents can help in this by instilling confidence in their children, and convincing them that the doctors and nurses are going to help them. Much of this reassurance can be given at home before departure for the hospital. The hospital routine should be planned to avoid frightening the child. He should be admitted to the hospital at least the day before operation. This allows time to recover from being separated from his parents, and to become accustomed to hospital personnel and procedures. It also provides opportunity for adequate, leisurely workup. After a quiet night's sleep the child goes to the operating floor in a far more receptive state of mind than one who has been hurried into the hospital on the morning of operation.

The anesthetist should visit the child at least once before the operation. Receptive children may be told and reassured about what will take place at the time of induction. This calls for careful interpretation, not falsification. Preoperative medication is selected carefully at this time. Preoperative sedation is essential for all children who are old enough to become emotionally disturbed. Gentleness and finesse can do much to gain the co-operation of the frightened child, but a far greater kindness is done the child if adequate medication is relied upon for the major part of the effect.^{1, 2} The dosage of preanesthetic drugs cannot be dictated arbitrarily, since many variable factors are concerned. Approximate dosages for healthy children are presented in Table 1. Children should arrive on

the operating floor calm and drowsy. Here they should await surgery in a quiet room and with an attendant. The sleeping patient should not be disturbed. The others may be watched or quietly amused. Every attempt should be made to prevent them from becoming upset at this time. Such preparation, when successfully carried out, greatly increases the chances for an easy induction.

The choice of the agent and technic of induction depends upon the individuality of the child. Al-

TABLE 1 Approximate Dosage of Preanesthetic Drugs

AGE OF PATIENTS	WEIGHT	ATROPINE	MORPHINE	NEMBUTAL
yr	lb	mg	mg	mg
Newborn	7	0.065	—	—
1	21	0.13	1.0	35
2-4	27-35	0.18	2.0	50
4-6	35-45	0.22	2.7	65
6-8	45-55	0.26	4.0	100
8-10	55-65	0.32	5.4	130
10-12	65-80	0.36	5.0	160

though all children are different, it is possible to make a rough classification into groups that have certain definite characteristics.

INFANTS UNDER ONE YEAR OF AGE

Small babies require relatively little psychology in their handling in the operating room. They are usually hungry, and though they may sense the strangeness of their surroundings, they certainly have no apprehension of the impending procedure. In young infants the metabolic rate is relatively low,³ whereas the threshold of pain is high. Consequently, sedative drugs are not indicated. Atropine is used to prevent excessive secretions and to block vagal reflexes. If the babies cry preoperatively, they may be picked up and comforted so that they will not become tired or emotionally disturbed. It has been found that an infant's stomach may become distended after a crying spell.

*Presented at a meeting of the Philadelphia State Society of Anesthesiology Philadelphia October 9 1948.
From the Department of Anesthesia, Children's Hospital.

†Instructor in anesthesia Harvard Medical School chief of anesthesia Children's Hospital.

Some anesthesiologists advocate the use of such technics as spinal anesthesia, or pentothal and curare on small babies. Although unusual circumstances occasionally indicate the use of one of these methods, their routine usage in the small infant seems, in my experience, to be uncalled for and even dangerous. The smaller and weaker the baby, the simpler should be the methods used. The respiratory reflexes should be depressed as little as possible, and normal function should be encouraged. The most readily controlled drugs should be chosen rather than those of a lasting effect.

Although ether may be used safely for induction of small infants, it is so irritating that it may cause prolonged struggling and breath holding. Ethyl chloride is less irritant and produces rapid induction, but its toxic effect on the heart renders it undesirable. Divinyl ether, or vinethene, although toxic if used over a long period, is a safe inducing agent. It is more potent than ethyl ether and is less irritating. It increases the respiratory exchange, and does not cause reflex spasms. It appears to be the agent of choice for the induction of healthy infants and young children.

At the time of induction, the infant's clothes are loosened so that he may breathe and move freely. Since young patients are frightened if their eyes are covered, this practice is not carried out until they are asleep. A baby Yankauer mask with only four layers of gauze is employed. Holding the mask down over the infant's chin, the operator drops the anesthetic slowly at first, so that this new odor is introduced gradually to the patient. The mask is brought slowly upward over the mouth and nose until full concentration of the agent is reached. There is then usually thirty seconds to a minute of resistance and crying, after which the infant falls into rapid, full, regular, respiration and exhibits increasing muscular relaxation. At this time it is important not to administer the vinethene too rapidly, for such a procedure may cause a characteristic clonic motion. The patient should be held in light anesthesia with vinethene as the ether is gradually introduced. After thirty to sixty seconds a sufficient concentration of ether will have been established, and the vinethene may be discontinued. Vinethene-ether inductions average three or four minutes for infants.

Induction is facilitated if the infant cries and moves his arms and legs, for these activities promote the respiratory exchange. These patients rarely show evidence of passing through an excitement stage, nor do they vomit during induction. Certain members of this younger group, however, will quite confound the anesthetist. Instead of crying and struggling, they lie still, limiting their breathing to a minimal exchange, and even after fifteen minutes under an ether mask, they may still be rigid and awake. Such infants can often be induced to move and cry if the anesthetist gently rubs their

faces, passively moves their arms and legs or lightly massages their ribs. The most difficult patient is the baby who refuses to breathe at all under the anesthetic mask—he simply holds his breath. In such a case cyanosis quickly appears, and it is dangerous to attempt to outlast such a resistant infant. If two or three attempts at induction with a volatile anesthetic are fruitless, one should choose a less irritating agent.

Cyclopropane is very useful for induction of anesthesia in this young age group.⁴ Infants breathe it readily and with little struggling or breath holding. For this reason it is the agent of choice in ill, premature and resistant infants. However, cyclopropane has several characteristics that preclude it from being the first choice in all cases. Respiratory depression may occur, or a marked respiratory spasm with its resultant retraction of the ribs. Once a patient has been induced with a volatile anesthetic, the succeeding anesthesia level is easily stabilized, but with cyclopropane this level is maintained with more difficulty. The explosive hazard of this agent and the management of special equipment for its closed system administration are factors that should influence the anesthetist to elect the simpler methods.

There is a specific type of case worthy of mention—the infant with pyloric stenosis. As the pylorus is obstructed, there is almost always a large residue in the stomach. Not only is induction especially difficult in such cases, but also the operative procedure is made dangerous, for regurgitation and aspiration of stomach contents are frequent. Induction will be much easier and operation safer, if a small tube is passed through the nose and the stomach emptied *before* anesthesia is started. This should be performed on all patients with distention and upon healthy children who are suspected of having eaten recently.

CHILDREN ONE TO THREE YEARS OLD

Children in this age group are relatively sturdy and have elevated metabolic rates. Morphine is indicated for its analgesic effect, as well as for the purpose of lowering the metabolic rate. Although young children will usually not have definite fears concerning an operation, they are easily frightened and hard to control. Barbiturates are tolerated well and may be used to help sedation of active young children prior to induction with inhalation agents. Nembutal may be given an hour and a half before operation, and morphine and atropine forty-five minutes preoperatively.

An earnest attempt should be made to gain the confidence of these children by preoperative attention on the ward and in the waiting room. For patients who appear moderately co-operative, vinethene offers the advantages of simplicity, speed and safety. There will usually be resistance to any method of induction. Needles cause the greatest

disturbance, and the small veins offer targets that are not easy to hit. In general, there is less resistance to the cloth mask and vinylene than to the more bulky closed-system apparatus needed for the less irritating agents. The administration of any agent should be gentle but, once begun, should progress actively. Any faltering or lapse on the way may cause spasm or retching and will result in a prolonged excitement stage and excessive secretions. It is especially important to maintain unobstructed respiratory exchange during this phase of anesthesia. The patient's chin must be supported at all times, and a suitable airway and suction used when indicated. However, since any prolonged removal of the anesthetic mask during induction may allow rapid lightening of anesthesia and further complicate the picture, suctioning and so forth must be performed as rapidly as possible.

Children in this group cannot be reasoned with effectively. If they become frightened they may struggle and scream so actively during induction that sobbing, jerky respiration will continue long after full anesthesia is established. For the child who appears excited and is resistant, rectal anesthesia is undoubtedly the most successful. There is not the pain of the needle, and there is no odor nor mask. A smooth, uncomplicated induction is almost certain. If morphine has not been administered, avertin in doses of 80 to 100 mg per kilogram of body weight will give excellent basal anesthesia with a minimum of respiratory depression.⁵ It should be emphasized that serious respiratory depression may follow the combined use of morphine and avertin. If a sedative has been given with only partial effect, pentothal by rectum can be used to similar advantage.⁶ A 0.6 per cent solution of pentothal is easily prepared by a mixture of 0.5 gm in 75 cc of water, 2 cc of this solution per pound of body weight will quiet an active child, and make induction rapid and easy.

Although rectal anesthesia may seem the technique of choice in most cases, there are definite drawbacks. Children who are to receive avertin should have no other preoperative sedation, therefore, their stay on the operating-floor waiting room is apt to be most upsetting to them, as well as to those nearby. Another point against avertin is that it is mildly irritating and frequently acts as a purgative. Pentothal does not have this quality, but, like other barbiturates, it is not consistent or predictable in sedative effect until large dosages are used.

If the child is receiving an intravenous infusion preoperatively, the anesthetist has an excellent opportunity to inject 2 or 3 cc of 2.5 per cent pentothal into the intravenous tubing, and thereby effect a most pleasant induction. Cyclopropane may be called upon for the same uses as in the youngest age group — namely, for quick, non-irritating induction when indicated by special circumstances.

CHILDREN THREE YEARS OF AGE AND OVER

In the group of healthy children three years of age and over, the preoperative preparation becomes especially important because fear, imagination and previous experiences, either of the patient or those told him by his ward mates, can cause havoc with the child's emotions. In addition to atropine and morphine in suitable dosage, a barbiturate should be given to all these patients who are to have inhalation induction. Comparatively large dosages of barbiturates are required for effective sedation, but these relatively large doses have proved remarkably safe and free from side effects.

This group offers a special challenge to the anesthetist, for it should be possible to put each patient to sleep without making him cry or struggle.⁷ If the child is successfully medicated this can be done readily and with a wide choice of agents. Co-operative older children (five to ten years or over) are easily and pleasantly induced with nitrous oxide and oxygen or cyclopropane and oxygen anesthesia.

Some of these patients are apprehensive even after suitable premedication, and these require the most careful treatment. Five minutes devoted to putting a child into a better state of mind is time well spent. Most children of the preschool and school ages can be reasoned with if the proper avenue of approach is discovered. Those who have specific fears are often easily quieted if the subject of their concern is known and discussed. Many are afraid of being hurt, or of being put to sleep with ether. Others are afraid because they do not know what is going to happen to them, and some know what is going to happen and dread it. After a short attempt at rational reassurance, the anesthetist should actively divert the child's attention from the business at hand. The child's interest is easily turned to pleasant, familiar subjects such as his pets or his favorite hobbies.

The patient should be in a quiet side room for the actual induction. The anesthetic apparatus should be shown to the child and he should handle it, smell it and play with it. If this can be fitted into a game it is more readily accepted by the child. The apparatus may be used as a telephone or it may be described as a dream machine — one valve for dreams about ice cream, one for chocolate cake and so forth. Orange, lemon or peppermint flavors may be added to the apparatus at the patient's choice. If the child still shuns the apparatus, he may be allowed to make his own selection between open or closed mask, or intravenous induction. Frequently the opportunity to decide for himself will change his whole outlook on the procedure. The anesthetist will make it much easier for himself if he can start a story or game that has a definite continuity to it, and carry it throughout the whole induction. A song or story will help with the smaller

Some anesthesiologists advocate the use of such technics as spinal anesthesia, or pentothal and curare on small babies. Although unusual circumstances occasionally indicate the use of one of these methods, their routine usage in the small infant seems, in my experience, to be uncalled for and even dangerous. The smaller and weaker the baby, the simpler should be the methods used. The respiratory reflexes should be depressed as little as possible, and normal function should be encouraged. The most readily controlled drugs should be chosen rather than those of a lasting effect.

Although ether may be used safely for induction of small infants, it is so irritating that it may cause prolonged struggling and breath holding. Ethyl chloride is less irritant and produces rapid induction, but its toxic effect on the heart renders it undesirable. Divinyl ether, or vinethene, although toxic if used over a long period, is a safe inducing agent. It is more potent than ethyl ether and is less irritating. It increases the respiratory exchange, and does not cause reflex spasms. It appears to be the agent of choice for the induction of healthy infants and young children.

At the time of induction, the infant's clothes are loosened so that he may breathe and move freely. Since young patients are frightened if their eyes are covered, this practice is not carried out until they are asleep. A baby Yankauer mask with only four layers of gauze is employed. Holding the mask down over the infant's chin, the operator drops the anesthetic slowly at first, so that this new odor is introduced gradually to the patient. The mask is brought slowly upward over the mouth and nose until full concentration of the agent is reached. There is then usually thirty seconds to a minute of resistance and crying, after which the infant falls into rapid, full, regular, respiration and exhibits increasing muscular relaxation. At this time it is important not to administer the vinethene too rapidly, for such a procedure may cause a characteristic clonic motion. The patient should be held in light anesthesia with vinethene as the ether is gradually introduced. After thirty to sixty seconds a sufficient concentration of ether will have been established, and the vinethene may be discontinued. Vinethene-ether inductions average three or four minutes for infants.

Induction is facilitated if the infant cries and moves his arms and legs, for these activities promote the respiratory exchange. These patients rarely show evidence of passing through an excitement stage, nor do they vomit during induction. Certain members of this younger group, however, will quite confound the anesthetist. Instead of crying and struggling, they lie still, limiting their breathing to a minimal exchange, and even after fifteen minutes under an ether mask, they may still be rigid and awake. Such infants can often be induced to move and cry if the anesthetist gently rubs their

faces, passively moves their arms and legs or lightly massages their ribs. The most difficult patient is the baby who refuses to breathe at all under the anesthetic mask—he simply holds his breath. In such a case cyanosis quickly appears, and it is dangerous to attempt to outlast such a resistant infant. If two or three attempts at induction with a volatile anesthetic are fruitless, one should choose a less irritating agent.

Cyclopropane is very useful for induction of anesthesia in this young age group.⁴ Infants breathe it readily and with little struggling or breath holding. For this reason it is the agent of choice in ill, premature and resistant infants. However, cyclopropane has several characteristics that preclude it from being the first choice in all cases. Respiratory depression may occur, or a marked respiratory spasm with its resultant retraction of the ribs. Once a patient has been induced with a volatile anesthetic, the succeeding anesthesia level is easily stabilized, but with cyclopropane this level is maintained with more difficulty. The explosive hazard of this agent and the management of special equipment for its closed system administration are factors that should influence the anesthetist to elect the simpler methods.

There is a specific type of case worthy of mention—the infant with pyloric stenosis. As the pylorus is obstructed, there is almost always a large residue in the stomach. Not only is induction especially difficult in such cases, but also the operative procedure is made dangerous, for regurgitation and aspiration of stomach contents are frequent. Induction will be much easier and operation safer, if a small tube is passed through the nose and the stomach emptied *before* anesthesia is started. This should be performed on all patients with distention and upon healthy children who are suspected of having eaten recently.

CHILDREN ONE TO THREE YEARS OLD

Children in this age group are relatively sturdy and have elevated metabolic rates. Morphine is indicated for its analgesic effect, as well as for the purpose of lowering the metabolic rate. Although young children will usually not have definite fears concerning an operation, they are easily frightened and hard to control. Barbiturates are tolerated well and may be used to help sedation of active young children prior to induction with inhalation agents. Nembutal may be given an hour and a half before operation, and morphine and atropine forty-five minutes preoperatively.

An earnest attempt should be made to gain the confidence of these children by preoperative attention on the ward and in the waiting room. For patients who appear moderately co-operative, vinethene offers the advantages of simplicity, speed and safety. There will usually be resistance to any method of induction. Needles cause the greatest

avertin and nitrous oxide and local anesthesia will be found most advantageous

MEDICAL PROGRESS

ORAL SURGERY (Concluded)

KURT H. THOMAS, M.D. *

BROOKLINE, MASSACHUSETTS

THE SURGICAL CORRECTION OF JAW DEFORMITIES

In children many jaw deformities can be treated by means of orthodontic procedures. Later in life, or if the deformity is severe, surgical correction may give excellent cosmetic and occlusal results. The deformities referred to are mandibular protrusion (prognathism), mandibular retrusion (underdevelopment or micrognathia) and open incisor bite or apertognathia. These deformities are frequently of congenital origin, often inherited (Hapsburg jaw), or acquired through malunion of a fracture, underdevelopment as in early cases of ankylosis or overdevelopment due to such diseases as acromegaly or leontiasis ossea.

One of two sites may be selected for the operative correction, the ascending ramus and the body of the mandible. For prognathism and mandibular underdevelopment both operations have their champions. For correction of apertognathia, the operation in the ramus is not suitable because closing the occlusion would cause distraction of the osteotomized ramus, and the action of the elevator muscles would cause recurrence.

The operation performed in the ascending ramus is a bilateral osteotomy, whereas in the body of the mandible an ostectomy is used for setting the jaw back in protrusion or closing it in open bite. For advancing the jaw in retrusion, a sliding, Z-shaped osteotomy is recommended.^{1,2} If the jaw is protruding without open bite, a parallelogram is excised, if an open bite is also present, a wedge-shaped or rhomboid-shaped piece of bone has to be removed to allow, through angulation, the closing together of the anterior teeth. Thomas^{1,2} presents a diagram that shows how the size of this piece of bone may be geometrically determined.

The following authors have recommended osteotomy in the ascending ramus for repositioning of the jaw: Babcock,^{1,3} Hensel,^{1,3} Smith and Johnson,^{1,3} Hook and Taylor,^{1,3} Ivy,^{1,4} Traynham,^{1,2} Moose,^{1,3} Lloyd,^{1,4} Stetzer,^{1,5} Peterson^{1,6} and others. Those who prefer an ostectomy in the body of the mandible are New and Erich,^{1,7} Cameron and Stetzer,^{1,5} Dingman,^{1,9} Kemper,^{1,5} Thomas^{1,1} and others. Those who use both procedures are Kazanjian^{1,12} and Waldrom.^{1,13}

An excellent discussion of the advantages and disadvantages of each method was given by Dingman.^{1,4} He wrote that correction of the deformity and repositioning of the teeth may be accomplished by either osteotomy or ostectomy.

Osteotomy is accomplished by a transverse division of the ramus of the mandible and shifting of the bone backward, or forward, where it is held in position during the course of healing. The procedure is simple to execute, avoids the possibility of injury to the inferior alveolar nerve and does not entail sacrifice of useful bone, nor does it damage the mandibular arch or teeth. The operation can be done without contamination from the oral cavity, by means of a Gigli saw, or by open operation with an incision below the inferior border of the mandible. The obvious disadvantages are that a parotid fistula may form. Injury to the facial nerve and serious hemorrhage from the internal maxillary artery may occur. There may be derangement of the muscles of mastication. The possibility of over-riding of the fragments, nonunion, malunion and open-bite deformities must also be considered very serious disadvantages. It is more difficult to adjust bite irregularities when this method is used.

Ostectomy has many advantages. The site of operation is extremely accessible, and the bone section can be removed without interference with the inferior alveolar nerve or its associated structures. The operation also does not interfere with the muscles of mastication, fragments can be repositioned more accurately and satisfactorily. A

children, the older ones may be encouraged to count by threes or fives, or to do a similar task that requires real attention

Restraints should not be used. Instead, children should be encouraged to use their hands to help hold the mask by themselves, or to hold an assistant's hand, but for companionship rather than restraint. An apprehensive child is not a good subject for nitrous oxide, since the relatively slow onset of anesthesia is apt to allow time for him to become frightened. In such cases, the more rapid induction with cyclopropane is an advantage in spite of its slightly greater hazard.

If there is a vein that looks easy of entry, a single needle puncture will effect an easy induction with pentothal (3 to 5 cc in 25 per cent solution). It should be mentioned that although induction of sleep with pentothal is rapid and easy, respiration is depressed, whereas laryngeal reflexes remain active. If full surgical anesthesia is to be obtained later with ether, it is sometimes found that the initial use of pentothal results in slower induction than when other agents, such as nitrous oxide and vinethene, are used.

PATIENTS WITH COMPLICATIONS

Patients who have complicating illnesses or are in poor general condition require special attention. Premature infants should not be subjected to volatile anesthetics. Cyclopropane provides a more gentle induction and gives adequate relaxation. In patients with elevated temperatures anesthesia can be induced with pentothal, and the patients can be maintained on cyclopropane, again with the avoidance of volatile anesthetics. The anesthesia in children with cardiac disease, such as patent ductus arteriosus, coarctation of the aorta and mild rheumatic heart disease, who are not cyanotic or in decompensation, may be induced as that in normal children. Those with cyanotic heart disease or with decompensation provide just cause for considerable concern. Adequate medication is of importance, for as sedation becomes more effective, oxygen demands decrease and the work of the heart is reduced. A marked improvement in the color of the blood is often observed when anesthesia is induced in properly medicated patients, even without the addition of oxygen. Usually, however, when one is dealing with cardiac patients, it is wise to saturate the blood with oxygen before the induction is begun. Then, pentothal-ether or cyclopropane-ether sequences may be administered with minimal excitement and hypoxia, and have proved to be effective methods of induction.

ANESTHESIA FOR OUTPATIENT OPERATIONS

Strangely enough, the group that presents some of the most difficult problems, and perhaps the greatest possibility for tragedy, consists of healthy

children who come into the outpatient clinics for such minor ailments as a cut finger or a fractured wrist. These children may have eaten liberally shortly before admission, and, of course, they are badly upset, both by the accident and by the trip to the hospital with their equally unstrung parents.

The traditional treatment received by such children included their being pricked with a needle, then after a long, fearful wait, being pulled away from their parents and forced down on a table under an ether mask. The noise of the ensuing struggle could easily be heard, and usually was, by the parents in the waiting room. Under such conditions induction was accompanied by intense, prolonged excitement, and also too often by copious vomiting and possible aspiration. The relaxation for surgery was poor, and after the operation the recovery period might involve several hours more of nausea and vomiting.

Unfortunately, relatively few surgical procedures can be done humanely on children under local anesthesia alone. General anesthesia is necessary, but in outpatient surgical operations in children ether should be avoided, owing to the danger of aspiration of vomitus. Although cyclopropane may appear to some to be the agent of choice for such work, its explosive danger seems to contraindicate its routine use for minor surgical procedures. Treatment of patients entering the hospital for operation with a full stomach has long been a serious source of danger. Several courses of action are open. Passage of a stomach tube rarely results in removal of the larger, more dangerous pieces of food. Methods to make the child vomit preoperatively are often terrifying. Waiting a prescribed period for digestion of food is usually ineffective. Still another method is to induce anesthesia rapidly with cyclopropane and pass an endotracheal tube—rather a major anesthesia for a minor operation. I prefer to avoid the use of ether and cyclopropane in such cases. My method of choice is to use a combination of agents that effect an easy induction and maintenance of anesthesia without irritation of the vomiting reflexes. Induction can be accomplished very well with avertin. The parents should be allowed to stand by and witness the gentleness of the procedure. After the child is asleep he may be carried into the operating room. There, light nitrous oxide-oxygen, supplemented, if necessary, by block anesthesia, will be adequate for most such minor procedures. The patient will usually react at the end of operation and be ready for discharge in half an hour, having been subjected neither to discomfort nor to danger. Procedures requiring only momentary anesthesia may be done under vinethene alone. Longer operations on older children may be done under intravenous administration of pentothal with nitrous oxide, but for most outpatients the combination of

reported during the past ten years, a collective review on the subject having been published in 1938¹⁷⁹

Hyperplasia

A large number of the oral tumors are not true neoplasms but are hyperplasias that develop because of chronic irritation from ill fitting dentures and malhygiene

Benign Giant-Cell Tumor

This lesion occurs as the so-called giant-cell epulis, a peripheral tumor found on the alveolar process and as the more important central type. Central giant-cell tumors are not rare in the jaws. They occur less commonly in the maxilla^{180, 181} than in the mandible. In the latter, they are found most frequently in the symphysis,¹⁸¹ but may occur anywhere.¹⁸²

In children a frequent place of development is at the site of resorption of the deciduous teeth.¹⁸³ Conservative curettage is recommended,¹⁸⁴ followed by cauterization with phenol. A review of the literature has been made by Bernick.¹⁸⁵ The relation of these tumors to parathyroid activity is of interest. The statement is unwarranted that all benign giant-cell tumors are due to increased parathyroid activity,¹⁸⁵ but it is essential that there should be a careful investigation of the blood chemistry, and the skeleton should be investigated by x-ray examination. A giant-cell tumor that was caused by hyperparathyroidism and receded after excision of the parathyroid tumor was recently reported.¹⁸³

Fibroblastoma

Oral fibromas are quite common. They occur in any part of the mouth and are also seen as central tumors in the jaws. These are frequently ossifying fibromas. A case involving almost the entire submental area of the mandible was reported in a woman forty-one years of age.¹⁸⁴ She complained of periodic pain but she did nothing about it until her cheek and lip had become numb and her teeth sore.

Fibrosarcoma

Fibrosarcoma is much less common. It occurs as a peripheral and as a central tumor. The malignancy varies somewhat. In a sixty-year-old man, a fibrosarcoma of the mandible, which was of moderate size but caused a pathologic fracture, recurred after resection of the jaw and caused lung metastasis.¹⁸⁶ A similar case,¹⁸⁷ which was of five years' duration and was entirely asymptomatic, was seen in a sixteen-year-old girl. The affected segment of the jaw was resected, and a bone graft was later inserted. There was no recurrence after two years. Not so fortunate was the outcome in a seventeen-year-old boy.¹⁸⁸ The tumor was of six years' duration and was treated by x-ray therapy. When it did not regress, the jaw with a mass extending from the canine to the molar region was excised. After

a year, it recurred locally, extending into the left cheek, nose, temporal region and frontal, sphenoid, and orbital bones. The patient died sixteen years after onset. A rare case of a fibrosarcoma arising from the capsule of the mandibular joint and causing excruciating pain for three years gave a great deal of difficulty in diagnosis. The patient was seen by many specialists. Disease of the ear and Costen's syndrome were thought of, but at an exploratory operation, a fibrosarcoma was found. It was removed by means of a condylectomy and after a year and a half there had been no recurrence.¹⁸³

Myxoma

Thoma and Goldman¹⁸⁹ report that this tumor has hitherto been regarded as similar to those in long bones, which tend to recur and are often malignant. A study based on 7 cases shows the jaw tumor to be benign, perhaps because it is of odontogenic origin. It is often associated with embedded¹⁹⁰ or with missing teeth and may have the x-ray appearance of a dentigerous cyst. It may be regarded as an odontogenic fibroma that has undergone myxomatous degeneration. The x-ray film generally shows a honeycomb appearance,¹⁸⁹ but the tumor may be cystic with an irregular, lobulated outline.¹⁸⁹ A large myxoma expanding the bone was reported in the symphysis mandibulae.¹⁹² The maxilla is also often involved¹⁸⁹; it may involve the entire half.¹⁹³ A very unusual myxoma was reported in the mandibular condyle.¹⁹⁴ It had been found in a forty-eight-year-old woman with Ménière's disease. For four years she had felt a swelling in front of the ear that had caused limitation of motion and pain. X-ray films showed a globular enlargement and trabeculation of the condyle, and after excision a diagnosis of fibromyxoma was made.

Neurofibroblastoma

Benign neurofibromas are peripheral or central tumors forming from the nerves that pass into the bones and supply the teeth. A neuroma has been reported as occurring on the palate of a fifty-five-year-old man.¹⁹⁵ It formed at the site of the larger palatine foramen. A neurofibroma forming a cystic defect, which in the x-ray film was seen to extend in the subapical area from the mental foramen to the ramus, was reported in a man aged thirty-three years.¹⁹⁶ It was diagnosed as a radicular cyst. It healed promptly and uneventfully. Another neurofibroma,¹⁹⁵ developing after a tooth extraction, encroached upon the maxillary sinus and invaded the zygomatic fossa. Martin¹⁹⁷ reported 2 cases. These were both cases of generalized neurofibromatosis with bulky invasion of the oral cavity. In 1 case, that of a three-year-old boy, the diagnosis was plexiform neurofibroma, which was slowly progressing and benign. In the second case, a girl five years old, the local tumor took on malignant, locally invasive characteristics and

dental splint, fitted to the mandible, often holds the fragments in place after very short periods of intermaxillary fixation. The only objections to the procedure are that it necessitates the sacrifice of one or two teeth on each side of the mandible, if an edentulous space does not already exist. It also necessitates the sacrifice of a section of mandibular bony structure. The fact that osteotomy offers almost uniformly successful results with a minimum of effort and only slight possibilities of complications indicates that this is the method of preference in most cases.

Osteotomy in the neck of the mandibular condyle was recommended by Schaefer¹⁵⁵. He performed the operation with a Gigli saw inserted through short skin incisions.

Another operation, called the "bow-back operation," was described by Pettit and Walrath¹⁵⁶. It was originated to correct unilateral prognathism, but can be used for bilateral cases as well. The authors perform an osteotomy in the surgical neck of the condyle that allows the jaw to be set back. The jaw is wired in this position for three weeks if fascia has been inserted between the fragments to form a false joint, or longer if bone union is desired. The advantage of this procedure is that it eliminates most of the objections raised against the other methods, but it seems to me not applicable to the correction of very extreme cases or to cases with open bite. For the correction of prognathism, a similar method was recommended by Smith and Johnson¹⁵⁹ and has since been perfected by Smith¹⁵⁷. In suitable cases he removes a parallel epipedonal section from the region of the sigmoid notch for transpositioning of the condyle.

CYSTS OF THE JAWS

Cysts of the jaws and mouth are generally classified according to their pathogenesis. The most important is the group of developmental cysts formed from odontogenic tissues and called odontogenic cysts. Other cysts occur from nonodontogenic tissue; they are caused by enclaved epithelium (fissural cysts^{158, 159}), or by epithelial remnants such as those found in the nasopalatine duct (incisive canal cysts^{160, 161}). In addition, there are extravasation cysts^{162, 163} of traumatic and non-traumatic hemorrhagic origin. Robinson¹⁶⁴ has recently presented a classification compiled after discussion and consultation with surgeons, radiologists and pathologists of note.

A large literature exists describing not only the various types of odontogenic cysts but also their anatomic distribution. They may be found in the tooth-bearing part of the mandible as well as the ascending ramus. In the maxilla they may encroach upon the nose or displace partly or completely the maxillary sinus. Cysts have often a hereditary history and then occur also in multiple form in the individual person.¹⁶⁵

The neoplastic potentialities of such cysts are important, the epithelial lining having been reported to give rise to adamantoblastoma forming mural thickenings first and invading the jaw widely later.^{166, 167} Cysts in which an epidermoid carcinoma developed were seen by Simmons¹⁶⁸ and Kent.¹⁶⁹

To facilitate roentgenologic diagnosis, aspiration of the cystic fluid and replacement with a radiopaque substance have been recommended as being especially useful for maxillary cysts.^{170, 171}

The treatment consists of complete enucleation of the cyst membrane, though there are some who prefer marsupialization or a modified Parnis operation.^{172, 174}

In these procedures the main part of the membrane is left in situ to protect the roots of involved normal teeth until, because of the evacuation of the cyst fluid, the cavity has become gradually eliminated. This method has the disadvantage of leaving behind pathologic tissue, perhaps with tumor or potentialities to form it, and, therefore, is not accepted as good practice by others. A new procedure combines the complete removal with the preservation of the involved teeth and, since it makes closure of the incision possible, eliminates prolonged post-operative treatments and irrigations to remove food from the recessed area. This procedure consists of space elimination by means of fibrin foam. It was recommended by Thoma¹⁷⁵ and utilized by him¹⁷⁶ and others¹⁷⁷ for filling the bone cavity after removal of the cyst sack with material that prevents the formation of a large blood clot, which would break down and permit healing by the formation of fibrous tissue and bone. The fibrin or gelfoam, soaked in a solution of thrombin and penicillin, is inserted, and the wound closed with closely placed, interrupted sutures. Both involved teeth in dentigerous cysts and adjacent teeth can be saved,¹⁷⁸ and if in a young person a partly formed tooth is accidentally removed with the cyst sac, it may be replanted with success,¹⁷⁶ since the pulp of such teeth with large apical foramina will become revascularized and will continue to develop and erupt.

TUMORS OF THE MOUTH AND JAWS

A great variety of tumors that occur in the mouth may be classified roughly as follows: tumors of the soft tissues of the oral cavity, peripheral tumors of the jaws, osteogenic tumors of the jaws, tumors of the jaws of odontogenic origin, and central tumors of the jaws of nonosteogenic and nonodontogenic origin. Like tumors in other regions, these growths may be benign or malignant, either with local invasive tendency or producing metastases.

To review what has been published on the diagnosis, pathology, treatment and aftercare of these tumors is beyond the scope of this article. The discussion is therefore limited to the more unusual cases

of tissue within the bone. If there is considerable calcification, the radiopacity may suggest an osteomatous growth.²¹⁵ On the other hand, if the replacement tissue has irregularly eroded and distended the cortex resulting in bony ridges on the internal surface, the x-ray picture may look monocystic¹⁹⁴ or multicystic or may resemble a central giant-cell tumor or adamantoblastoma. Schumberger²¹⁵ concludes that ossifying fibroma is a variant of monocystic fibrous dysplasia. The lesion may involve one or both sides of the maxilla or may affect the mandible—in some cases all three. I believe that it is a tumor of medullary origin in which the tumor cells produce, by metaplasia, fibrous connective tissue in which osteoid is deposited irregularly in some²¹⁹ and as trabeculae in other cases.²¹⁵ The tumor is calcified partially in young and completely in older persons when it frequently ceases to grow. Furedi²²⁰ groups these lesions into hypostotic and hyperostotic.

Chondroma

This osteogenic tumor is rather rare. Jacobs²²¹ reported a cystic osteochondroma of the mandible that showed no recurrence three years after excision.

Osteogenic Sarcoma

Cases of both primary and metastatic types have been reported. The former includes a case that occurred in the maxilla²²² of a twelve-year-old girl and involved the antrum and occluded the nostril, and was treated by excision and x-ray irradiation. Another²²³ occurred in a forty-year-old woman, and grew slowly until it filled the entire vault of the palate. It was diagnosed as an osteogenic chondrosarcoma. A case²²⁴ that developed in the mandible was treated by resection of half the mandible. There was no evidence of recurrence a year later.

Of the metastatic cases, 1 was found in the maxilla, and 2 in the mandible. That in the maxilla²²⁵ occurred in a thirteen-year-old girl with a primary osteochondrosarcoma of the right tibia, which was treated by leg amputation, and a secondary tumor of the same type on the left femur, which was similarly treated. Six months later a swelling of the tuberosity of the maxilla appeared that was identical with that of the previously occurring tumors of the extremities.

The first of the mandibular metastases,²²⁶ which occurred in a twelve-year-old boy five months after a diagnosis of primary chondroblastic osteogenic sarcoma had been made, followed an injury (bruise) of the inner aspect of the tibia the month before. He was treated by irradiation. The metastasis occurred below the second molar. When the tooth was extracted the diagnosis was made from tissue attached to it. The other metastasis occurred in an eleven-year-old boy²²⁷ with osteogenic sarcoma of the tibia, which was treated by leg amputation.

Four months later a tumor formed in the third molar region invading the bone and pulp of a tooth.

Odontogenic Tumors

These tumors may be formed either from the epithelial component of the tooth-forming organ or from the mesenchymal part. In some cases—the mixed odontogenic tumors—both are involved. The following types are of interest.

Adamantoblastoma This lesion is considered a benign tumor that is locally invasive. A case with metastases to the lungs has been reported by Schweitzer and Barnfield.²²⁸ An adamantoblastoma was excised by removal of a section of the left mandible. Seven years later the tumor recurred in the ascending ramus and was treated with radium. It continued to grow, and involved the skull. Four years later, x-ray films revealed metastasis to each lung field. Two years later the patient died from local hemorrhages at the age of thirty-six years. An autopsy report was appended to the article.

Of the 16 cases reviewed for this article,²²⁹ 14 occurred in the mandible, and 2 in the maxilla. One of the latter formed a bulky enlargement of the lateral half of the alveolus of a seventy-two-year-old man. It extended to the maxillary sinus and nasal fossa. It was a polycystic tumor that could be completely excised. The other case¹⁶⁷ was that of a seventeen-year-old girl who on roentgenologic examination appeared to have a dentigerous cyst filling the antrum. When enucleated, the growth was found to contain epithelial elements that had formed coarse papillary projections and ill defined cysts.

The mandibular cases were either monocystic or polycystic. The monocystic tumors resembled either a follicular cyst^{196, 230} (without tooth) or a dense dentigerous cyst.^{167, 196} The polycystic tumors may form two or three large compartments or are definitely polycystic (soap-bubble effect).^{153, 196, 198} and may perforate.²³² Generally, the tumor forms in the molar region and invades the ramus,^{196, 229} but it may also occur in the anterior part of the mandible.²⁰⁰ Some of these tumors expand the bone to cause considerable asymmetry of the face,²³³ or an intra-oral mass,²²⁹ and in some cases a large swelling develops, as in that reported by Burford,¹⁹⁵ in which the chin was enlarged by a voluminous tumor the size of a grapefruit.

Recurrence after enucleation is common. Many of the patients were treated for excision of a "cyst," which later recurred as a polycystic tumor.^{153, 229, 232} That recurrence occurs even after resection, was brought out by the cases of Schweitzer²²⁸ and Dingman.²³⁴ Adamantoblastomas sometimes form in the dental follicle of an unerupted third molar,²³⁵ which, therefore, should be removed when the tooth is extracted. Treatment by enucleation is indicated in some cases. Penhale²³¹ shows excellent filling in with bone two years after operation. In polycystic cases, excision of a section or resection of the affected

resulted in death. Autopsy revealed no sign of general dissemination. An adrenal neuroblastoma in a two-year-old child was reported by Burford.¹⁹⁸ Six weeks before examination, a small, nontender lymph node was found in the right submaxillary area. Bilateral orbital ecchymosis developed next, with considerable enlargement of the side and face and neck on the right. Extensive osteolytic and osteoblastic changes were found in the entire skeleton. Biopsy from the buccal mucosa disclosed an unclassified malignant tumor. The patient died eight days later. At autopsy, a neuroblastoma of the right adrenal gland was found, with widespread involvement of lymph nodes, bones and retro-orbital region.

Lipoma

This is an uncommon and perfectly benign tumor, which may form beneath the mucosa and produce a yellowish, soft tumor mass that is sometimes lobulated. More difficult to diagnose are lipomas occurring in the floor of the mouth beneath the sublingual gland, or in the infratemporal fossa. Here they may interfere with the motion of the ramus of the mandible. A case of this type was reported by Thoma.¹⁹⁹

Hemangioma and Lymphangioma

An intraoral nevus, occurring on the maxillary gingiva and of grayish-pink color, was reported by Field and Ackermann.²⁰⁰ Burford et al.^{201, 202} state that cavernous hemangiomas of the oral cavity are relatively common. They are easily recognized by their grayish-blue color. Their report includes a large hemangioma of the lower lip in a thirty-two-year-old woman who was successfully treated with sodium morrhuate (5 per cent) injections. Another case reported from the same clinic²⁰¹ occurred on the upper lip in a nineteen-year-old Negress. This tumor was excised by ligation of two large vessels at the labiolingual fornix that entered the tumor mass. Thoma¹⁸³ described a hemangioma occurring in a fifty-nine-year-old woman and containing phleboliths that could be felt in the cheek and were demonstrable in x-ray examination. Erich²⁰³ reported a central hemangioma of the mandible, which caused intermittent stabbing pain and formed a cystic-appearing lesion that had the x-ray appearance of a giant-cell tumor. Lymphangioma usually occurs on the tongue and is frequently congenital, producing macroglossia,²⁰⁴ which, of course, is not a pathognomonic term. In a case reported by Rigg and Waldapfel²⁰⁵ the tumor occurred in two separate areas.

Hemangioendothelioma

This tumor was discussed by Cheyne and Silberstein,²⁰⁶ who, after reviewing the literature, reported 3 cases in an eight-year-old boy with a tumor on the lower lip, in a fifteen-year-old girl

with a growth on the roof of the mouth, and in a sixty-seven-year-old woman with a mass on the right side of the palate. All were studied pathologically. The authors state that clinically the tumor is generally an infiltrative growth, in some cases slowly growing and benign, whereas other hemangioendotheliomas, which are avascular, show greater metastasizing ability. The lesion is generally amenable to proper surgical removal.

Myoblastoma, Rhabdomyoma and Leiomyoma

These are rare tumors, occurring principally in the tongue. Myoblastomas, known as "rhabdomyoma granulocellulaire" in the French literature, are also found in the lip, soft palate, pharynx, uvula and jaws. Mann and Ash²⁰⁷ reported a case on the gingiva of both the maxilla and the mandible of a two-week-old infant. Thoma²⁰⁸ reported one excised from the tongue of a thirty-year-old woman. Considerable speculation exists regarding the etiology of myoblastomas. The controversy was discussed by Bernier,²⁰⁹ who, analyzing 17 cases,¹⁰ concluded that a number of tumors reported as myoblastomas on closer examination are rhabdomyosarcomas. Myoblastomas are small—seldom larger than 1.5 cm in diameter.

A leiomyoma of the tongue occurring in a thirty-two-year-old Negro was surgically removed and was thought to be derived from the smooth muscle of the blood vessels. It appeared to invade the mandible at the angle.²⁰¹

Osteoma

Some osteomas, which are in reality bony hyperostoses, occur quite frequently on the palate, (torus palatinus) and the mandible (torus mandibularis).²¹¹ The head of the condyle occasionally becomes enlarged—a condition that has been variously reported as hyperplasia and osteoma of the condyle.^{212, 213} True osteomas occur peripherally on the oral²¹⁴ or cutaneous parts of the jaws,²¹⁵ and also as central tumors.¹⁸³ Sometimes multiple osteomas are found, generally in connection with similar formations in other parts of the skeleton.²¹⁶

Fibro-osteoma

This tumor is generally classified as an ossifying fibroma,¹⁹⁸ a term that is often used for a fibroma in which a certain amount of bone is produced but in which the bone plays an unimportant role, whereas "fibro-osteoma" is reserved for a tumor with typical clinical and histologic characteristics. This lesion has been called various names such as osteofibroma and fibrous osteoma, and some pathologists tend to consider it not as a neoplasm but as a bone dystrophy that gives rise to such names as localized osteodystrophia, localized osteitis fibrosa and fibrous dysplasia. Cahn²¹⁷ states that fibrous dysplasia is an expansive lesion with thinning of the cortex and no periosteal reaction. There is a replacement

lesions may destroy the bone around or adjacent to the roots of teeth simulating periodontal abscesses.¹⁵³ In other cases ulceration¹⁵⁶ of the mucosa and the formation of fixed tissue masses on the gingiva and palate¹⁹⁷ are observed and are often of multiple occurrence.^{257, 258} Frequently, adenopathy is present.²⁵⁸ The tumor varies in malignancy and may be a localized process or distributed throughout the lymphatic tissue.²⁵⁴ Extensive destruction of the mandible and maxilla has been observed,²⁵⁷ and neurologic signs may be present, such as anesthesia of the lip.²⁵⁸ A case of a girl three years old²⁰¹ illustrates the remarkable rapidity with which this tumor may grow, involving finally the entire left side of the face. Though these tumors generally respond well to roentgenotherapy, there was no response in the case described. A reticulum-cell sarcoma in a twenty-four-year-old man was reported by Goldman.¹⁹⁶ After being treated for Vincent's stomatitis, it was biopsied and diagnosed. It was treated successfully by irradiation (7200 r). Salmon²⁵⁴ reported 2 cases that ended fatally.

Multiple myeloma A case of plasma-cell myeloma was diagnosed²⁰¹ by biopsy of a mass in the third molar region of an edentulous mandible. It was found to be part of a generalized process. Melov and Gunter²⁵⁹ reported another case of multiple myeloma, in which the largest and first lesion found produced pain and swelling in the mandible. On x-ray examination, a pathologic fracture of the mandible and multiple skeletal involvement were discovered.

Malignant melanoma Melanoma may occur in the mouth, since melanophores and dopa-positive cells are numerous in the oral mucosa, especially among the dark-skinned races, but this tumor is extremely rare. Brown and Byars²⁶⁰ give a good picture of a case occurring on the labial gingiva of a fifty-seven-year-old Negress. Arons²⁶¹ described a case occurring on the palate. Both patients died of metastases. Soderberg²⁶² reported 2 cases occurring in infants one month and two months old. Both were treated with radium, and both patients were free of disease five and six years later. A malignant melanoma of the floor of the mouth associated with an osteogenic sarcoma of the mandible was reported by Thoma²⁶³ in a twenty-four-year-old man. In spite of resection of the mandible and electrocoagulation of the wound, the patient died of a malignant giant-cell tumor seven months later.

Tumor of the retinal anlage This tumor, the first of its kind described, according to the reporter of the case,²⁶⁴ occurred in a six-month-old female infant, forming a firm mass, 5 cm in diameter, protruding from the palate and attached to the anterior part of the right maxilla. Though not malignant, it was radically removed and did not recur.

Metastatic carcinoma Metastasis is not uncommon. The jaws show in most cases radiolucent areas in the x-ray films except in carcinoma from the prostate,

which often causes osteoblastic activity. Adair and Herrmann²⁶⁵ reported 5 cases of cancer of the breast with metastases involving the mandible. Pain or anesthesia and loosening of teeth are early symptoms. Salmon and Darlington²⁵⁴ reported 4 cases, 3 occurring in the mandible causing swelling or pain, the fourth was a hypernephroma that formed on the hard palate two years after a nephrectomy. An embryonal type of metastatic carcinoma from the testicle causing pain and localized in the third molar region of the maxilla was found in a sixty-four-year-old man by Cameron and Stetzer.²⁶⁶

The case reports of some of the malignant tumors reviewed prove that many physicians and dentists continue to be responsible for unpardonable delay in the treatment of these lesions by trying various types of medication and thus postponing the early diagnosis that is essential. In other cases a great deal of harm is done by ineffective treatment or treatment that is too conservative. Malignant tumors should be treated only by those trained in tumor surgery who are familiar with the surgical anatomy of the region involved and are able to perform procedures radical enough to increase the chance of a cure.

CONCLUSION

Oral surgery is a broad field offering a great variety of interests. In this review surgical diseases only have been covered. There are many other conditions that the oral surgeon deals with, which some classify as oral medicine. These are either local lesions treated by nonsurgical means or symptoms of some systemic disorder such as avitaminoses, blood dyscrasias, dermatoses, neuroses or general organic and skeletal diseases, which often require for their elimination close co-operation with the physician or specialists in other fields.

half of the mandible is recommended, followed by restoration of the jaw with a bone graft.^{182 232 233}

Cementoma This tumor is distinguished from odontoma by the fact that only one type of calcified tooth structure is formed. Cementomas occur more often in the mandible than in the maxilla. Bernier,²³⁶ investigating 15 cases, of which only 1 occurred in the upper jaw, found that their structure varied. Ten were trabeculated, and 5 were composed of cementicles. Many cases show multiple occurrence.²³⁷

Mixed tumor These are made up of epithelial and mesenchymal elements. Thoma and Goldman,^{238 239} in a review of 75 cases, distinguished three types: soft odontoma, soft and calcified, and completely calcified. The last is known as odontoma.

Odontoma is made up of masses of tooth tissue that has become calcified. It is considered a very benign tumor that ceases to grow after all soft tissue has been replaced. A case has been reported of a tumor that caused a gradual increase in size of the jaw, with alteration of the occlusion.²⁴⁰ Ordinarily these tumors are asymptomatic, even if large.²⁴¹ The excision is attended by the danger of fracture of the jaw. Therefore, in cases of extensive tumors, a two-stage operation is recommended by Callahan.²⁴²

The soft and partly calcified odontogenic tumors, on the other hand, may continue to grow. Both the epithelial components and the mesenchymal part have the ability of neoplastic proliferation. Thus the adamantoma-odontoma forms, in which, besides dentine and cementum, epithelial cells are present, both as differentiated cells (ameloblasts), which form enamel, and as undifferentiated adamantine epithelium, which is neoplastic and locally invasive.^{215 243} In other cases the mesenchymal part may take on malignant characteristics (fibrosarcoma), and form a so-called adamantino-sarcoma.²⁴⁴

Mixed tumor of salivary-gland type This tumor, also composed of epithelial and mesenchymal structures, is much more frequently malignant (adenocarcinoma) than the mixed odontogenic tumor. Being most common in the parotid and submaxillary gland, it occurs in the oral cavity. Ash²⁴⁵ reports the following distribution in 683 cases: parotid, 503, submaxillary, 55, sublingual, 2, lip, 40, palate, 80, and tongue, 3. The tumor also occurs in the mandible, forming what appears in the x-ray picture as a cystic lesion.^{197 246} It may invade the bone from an adjacent neoplasm.²⁰¹ An excellent collective review of the subject, with an analysis of 50 cases, has recently been presented by Cheyne et al.²⁴⁷ For differential diagnosis from inflammatory lesions, sialography has been recommended.²⁴⁸

Carcinoma

A long chapter could be written on the clinical appearance, complications and treatment of oral cancer, and many individual case reports and series

of cases in special regions of the mouth and jaws may be found in the literature. Epidermoid carcinoma is more common than the transitional-cell lesion and the adenocarcinoma, which is found in the palate, cheek and lip.²⁴⁹ Though the tumor is more common in the later part of life, no age is exempt. Two cases of malignant embryonal carcinoma have been reported — one in a child three years of age with a malignant epithelial tumor expanding the mandible and giving the appearance of an osteogenic sarcoma²⁵⁰, the other, in a nine-year-old child, probably was, like most of these tumors, formed from odontogenic epithelium in the jaw.²⁵¹

Epidermoid carcinoma varies greatly in its appearance, origin, clinical course, histologic structure and complications. It may form an ulcerating, papillomatous exophytic, fungating, indurated lesion often associated with leukoplakia, and careful inspection and palpation are necessary in the examination. Woodbury²⁵² gives examples of cases that are constantly observed in the outpatient clinic of the Massachusetts General Hospital because of persistent sores, swellings or lymph-node enlargement that the patient regards as being due to dental conditions. Secondary involvement of the mandible occurs for various reasons. Buirge,⁴³ analyzing 71 cases, states that delay before diagnosis is made is the most frequent reason. Only 10 per cent of the patients were promptly referred by the dentist or physician to an appropriate source of therapy, in the other cases, there was an average delay of 8.4 months before definitive treatment was instituted.

More uncommon are other malignant tumors, which often give even the expert great difficulty in diagnosis. Fibrosarcoma and osteogenic sarcoma have already been discussed.

A Ewing tumor was reported as a possible primary lesion in a fifteen-year-old boy²⁰¹ complaining of a gradually increasing swelling of the body of the mandible, which responded dramatically to radiotherapy. In another case,²⁰¹ which showed striking radiologic changes in the mandible and involved the lateral wall of the left orbit and adjacent malar bone, a primary tumor involved the radius. Two cases were reported by Salman and Darlington.²⁵³ One, in a seventeen-year-old boy, caused a large swelling extending from the premolar area to and including the anterior border of the ramus of the jaw, after resection of the jaw, multiple bony metastases formed. The other occurred in a thirty-six-year-old woman who, after pregnancy, noticed numbness in the right mandible and pain. After a tooth extraction, which brought no relief, metastases occurred.

Lymphosarcoma

Stout²⁵⁵ discussed some of the reported cases and stated that 26 of 218 cases were primary in the mouth, pharynx or salivary glands. The gingival

lesions may destroy the bone around or adjacent to the roots of teeth simulating periodontal abscesses¹⁵³. In other cases ulceration²⁵⁶ of the mucosa and the formation of fixed tissue masses on the gingiva and palate¹⁹⁷ are observed and are often of multiple occurrence²⁵⁷⁻²⁵⁹. Frequently, adenopathy is present²⁵³. The tumor varies in malignancy and may be a localized process or distributed throughout the lymphatic tissue²⁵⁴. Extensive destruction of the mandible and maxilla has been observed,²⁵⁷ and neurologic signs may be present, such as anesthesia of the lip²⁵⁵. A case of a girl three years old²⁶⁰ illustrates the remarkable rapidity with which this tumor may grow, involving finally the entire left side of the face. Though these tumors generally respond well to roentgenotherapy, there was no response in the case described. A reticulum-cell sarcoma in a twenty-four-year-old man was reported by Goldman¹⁹⁶. After being treated for Vincent's stomatitis, it was biopsied and diagnosed. It was treated successfully by irradiation (7200 r). Salmon²⁵¹ reported 2 cases that ended fatally.

Multiple myeloma A case of plasma-cell myeloma was diagnosed²⁶¹ by biopsy of a mass in the third molar region of an edentulous mandible. It was found to be part of a generalized process. Melov and Gunter²⁵⁹ reported another case of multiple myeloma, in which the largest and first lesion found produced pain and swelling in the mandible. On x-ray examination, a pathologic fracture of the mandible and multiple skeletal involvement were discovered.

Malignant melanoma Melanoma may occur in the mouth, since melanophores and dopa-positive cells are numerous in the oral mucosa, especially among the dark-skinned races, but this tumor is extremely rare. Brown and Byars²⁶⁰ give a good picture of a case occurring on the labial gingiva of a fifty-seven-year-old Negress. Arons²⁶¹ described a case occurring on the palate. Both patients died of metastases. Soderberg²⁶² reported 2 cases occurring in infants one month and two months old. Both were treated with radium, and both patients were free of disease five and six years later. A malignant melanoma of the floor of the mouth associated with an osteogenic sarcoma of the mandible was reported by Thoma²⁶³ in a twenty-four-year-old man. In spite of resection of the mandible and electrocoagulation of the wound, the patient died of a malignant giant-cell tumor seven months later.

Tumor of the retinal anlage This tumor, the first of its kind described, according to the reporter of the case,²⁶⁴ occurred in a six-month-old female infant, forming a firm mass, 5 cm in diameter, protruding from the palate and attached to the anterior part of the right maxilla. Though not malignant it was radically removed and did not recur.

Metastatic carcinoma Metastasis is not uncommon. The jaws show in most cases radiolucent areas in the x-ray films except in carcinoma from the prostate,

which often causes osteoblastic activity. Adair and Herrmann²⁶⁵ reported 5 cases of cancer of the breast with metastases involving the mandible. Pain or anesthesia and loosening of teeth are early symptoms. Salmon and Darlington²⁵¹ reported 4 cases, 3 occurring in the mandible causing swelling or pain, the fourth was a hypernephroma that formed on the hard palate two years after a nephrectomy. An embryonal type of metastatic carcinoma from the testicle causing pain and localized in the third molar region of the maxilla was found in a sixty-four-year-old man by Cameron and Stetzer.²⁶⁶

The case reports of some of the malignant tumors reviewed prove that many physicians and dentists continue to be responsible for unpardonable delay in the treatment of these lesions by trying various types of medication and thus postponing the early diagnosis that is essential. In other cases a great deal of harm is done by ineffective treatment or treatment that is too conservative. Malignant tumors should be treated only by those trained in tumor surgery who are familiar with the surgical anatomy of the region involved and are able to perform procedures radical enough to increase the chance of a cure.

CONCLUSION

CASE 35191

PRESENTATION OF CASE

A thirty-eight-year-old French-American fish-cutter was admitted to the hospital because of jaundice

The patient was perfectly well until four months before admission, when he had an episode of vomiting food recently eaten. This was followed by the onset of flatulence and a sensation of upper abdominal fullness and anorexia, which persisted until the time of entry. There were occasional cramps and increased urge to defecate. Three months prior to admission the urine became darker. Two weeks later it was "reddish" for a period of three days,

this change was unassociated with pain, chills or fever. One week later jaundice and pruritus, associated with dark urine and clay-colored stools, developed. Two months before admission he noted the onset of a dull ache in the right upper quadrant, which became increasingly more severe, finally requiring an injection by his physician. Following this he was admitted to another hospital, where he remained for one month. During the first week in the hospital he was febrile, the temperature going as high as 102.5°F, but without chills or leukocytosis. Pain did not recur after the first hospital day, although jaundice persisted. Following a course of penicillin and aureomycin the temperature became normal, and the patient's appetite returned. A cephalin-flocculation test was negative. During the five weeks before entry he was on limited activity at home but despite a high-calorie, high-carbohydrate, high-protein, low-fat diet he became progressively worse. Jaundice persisted, flatulence, belching and "gas pains" became more severe, and it was noted that his weight, which before the onset of the illness had been 165 pounds, was now 130. During the week before admission he vomited just before each meal the food he had eaten at the previous meal. There was no history of hematemesis, although there were two questionable episodes of tarry stools three weeks before admission and on the day of admission, re-

spectively Although jaundice had been constant, the color of the stools varied greatly from dark brown to light tan to clay

Although his job was that of fish-cutter, he often supplemented his earnings by doing odd painting jobs and had been thus engaged, using a silver paint, shortly before the onset of the illness There was no past history of jaundice or other serious disease, and he used alcohol only moderately

Physical examination revealed a thin, jaundiced, middle-aged man lying comfortably in bed in no distress No spider angiomas were noted, and the chest and heart were normal The liver edge, on inspiration, was palpable 2 cm below the costal margin and was smooth and nontender No other organs or masses were felt, and there was no tenderness

The temperature was 100°F, the pulse 80, and the respirations 15 The blood pressure was 130 systolic, 90 diastolic

Examination of the blood showed a red-cell count of 4,900,000, with a hemoglobin of 15 gm, and a white-cell count of 8400, with 54 per cent neutrophils The total protein was 7.25 gm per 100 cc, with 5.02 gm of albumin and 2.23 gm of globulin (albumin-globulin ratio of 2.3) The cholesterol was 320 mg and the cholesterol esters 216 mg per 100 cc The van den Bergh test was 8.4 mg per 100 cc direct and 10.6 mg indirect The cephalin-flocculation test was negative in twenty-four and forty-eight hours, the thymol turbidity was 1.0 units, the prothrombin time 17 seconds (control, 15 seconds), and the alkaline phosphatase 9.3 units The urine gave a +++ test for bile on repeated examinations The stools varied in color from dark brown through yellow brown to metallic gray and, with a single exception, gave ++ or +++ guaiac tests

In the hospital the patient seemed somewhat improved and ate extremely well, complaining that the diet given him was inadequate On the sixth hospital day the urinary urobilinogen was 3.7 Ehrlich units The serum amylase was 123 units and lipase 3.4 units per cubic centimeter The fasting blood sugar was 103 mg per 100 cc A plain film of the abdomen was negative for gallstones and showed no enlargement of the liver or spleen A roentgenogram of the chest was within normal limits A gastrointestinal series revealed no abnormality in the esophagus, stomach or duodenal cap There was slight narrowing of the duodenum in the post-bulbar region, but this was not constant The remainder of the duodenum showed no defect or displacement, and no stones were identified in the region of the common duct

On the tenth hospital day an operation was performed

DIFFERENTIAL DIAGNOSIS

DR EARLE M. CHAPMAN When one tries to reconstruct the story of jaundice the record says,

"the jaundice was constant" I cannot tell whether the jaundice was of three weeks' duration or longer I suppose it persisted throughout his illness

DR ALFRED KRANES The jaundice was constant but fluctuated in degree, not only clinically but also by chemical tests When the patient was discharged from the other hospital the icteric index was considerably below that of admission The jaundice never completely disappeared

DR CHAPMAN That is helpful The record states that the patient used alcohol only moderately Did you decide that it was moderate?

DR KRANES I did not know about that

DR CHAPMAN Was his temperature rectal or by mouth? I assume it was by mouth since it is not stated If so, he had a fever

DR KRANES He had no fever in this hospital except for one period of twenty-four hours

DR CHAPMAN I think we had better see the x-ray films at this point The record states that they were normal except for what is described as slight narrowing of the duodenum in the post-bulbar region

DR STANLEY M. WYMAN The films of the chest are not remarkable The liver shadow as described appears within the limits of normal There is no evidence of intrinsic disease in the stomach The narrowing of the post-bulbar region of the duodenum is seen at this point, and it appears on the spot films It does seem to change somewhat in caliber

DR CHAPMAN Compression from something external?

DR WYMAN Pressure from something extrinsic The mucosal pattern is perfectly normal in the entire area There is no evidence of convergence of folds It looks as if something is pressing on the distal portion of the duodenal cap, causing a narrowing rather than something intrinsic in the duodenum There is another finding of considerable value, and that is what I believe to be compression of the second portion of the duodenum on its medial aspect about at the junction of the middle and distal thirds over an area measuring 2.5 cm in length This is also seen on this spot film, in which there is a filling defect at this point It is not reproduced on all the films

DR CHAPMAN That lies in the region of the head of the pancreas anatomically

DR WYMAN Yes Although it is well visualized on only two or three films, and not on all films, the filling defect is a valid finding

DR CHAPMAN I think it is more significant than I was led to believe from reading the record There is more mischief in this area from looking at the film than I thought from the description What was found at operation is what they are asking me I will start by saying that I have no idea really It is a difficult diagnostic problem Since this man was a fish-cutter, we have to consider

Weil's disease It probably is a "red herring" Davidson* reported Weil's disease in fish-cutters in Scotland, who acquired it in their occupation This man did not have an acute disease and was almost afebrile, so I think we can exclude Weil's disease However, the illness started with dark urine

DR KRANES The dark urine noted the week before the jaundice was hematuria It had a good many red cells in it

DR CHAPMAN That is interesting The record said 'dark' urine, it did not say "bloody" urine

DR KRANES I did not see it His family said that microscopically it was full of red cells

DR CHAPMAN I thought of the possibility of Weil's disease The patient was a fish-cutter, and we have seen the disease among people with that occupation in Boston Yet this seemed like a chronic disease If it was a complication of Weil's disease we ought to find something like abscess in the region of the head of the pancreas This bothered me a little, but I decided to exclude it because the progress of the illness did not seem to fit the diagnosis and someone should have made a diagnosis of Weil's disease But there it is—he was a fish-cutter, with a febrile illness to start with Why did it take so long? I did not think of it last night when I first read the record, but now that I have seen the films I am thinking of the possibility of abscess I have to change my thinking of 11 30 last night

The laboratory evidence is confusing, but from it one gathers that there is no good evidence on which to base the diagnosis of intrinsic liver disease I do not see how we can support cirrhosis or infectious hepatitis All the laboratory changes are consistent with the intermittent type of obstruction to the outflow of bile The clinical description Dr Kranes gave us and the laboratory changes all fit together

We are faced with the question of what would lead to an intermittent obstruction in the region of the head of the pancreas What lesion would fit with the x-ray evidence? Of course the commonest thing in this location, even though thirty-eight years of age is a little young, is carcinoma of the head of the pancreas We know that carcinoma in the head of the pancreas can erode the ampulla of Vater and lead to blood in the stools and it can lead to intermittent obstruction and cause the type of distortion seen in the x-ray film That is the likeliest possibility, but there is one thing strikingly against the diagnosis of cancer I cannot believe that a man who had cancer and who died of it, let us say, would complain that the diet in the hospital was inadequate and want more food That is a clinical fact against carcinoma of the head of the pancreas That is the one state-

ment that I underlined as being against that diagnosis

Could he have had a stone, a so-called silent stone, in the head of the pancreas? A large non-opaque stone does not cause a shadow and could have bored in there and got mixed in with the pancreatic duct and eroded the whole area and caused mischief

If we go back to the beginning of the history, he had occasional cramps and increased urge to defecate when the illness started If we try to reconstruct the events from the beginning of the illness we have to consider silent stone in the head of the pancreas, not reflected here in the x-ray films, and then consider inflammatory reaction around it There must have been considerable inflammatory reaction around this area whatever it is, because the serum amylase was high (123 units), which is evidence of destruction of the pancreas The upper limit of normal is 40 units I might say in passing that jaundice has been described as coming on after penicillin and also described after pentothal anesthesia He did not have any such things injected into him, did he, Dr Kranes?

DR KRANES Penicillin was given by the family physician after the patient had become jaundiced because he was running a septic fever

DR CHAPMAN But he had had no operative procedure, before the onset of the illness I wondered if it might be related to an infected syringe or anything of that sort There was nothing of that nature antecedent that you know of?

DR KRANES No

DR CHAPMAN Was this, then, a stone, a tumor or an inflammatory mass? I am beginning to change my mind Last night I was all for cancer of the head of the pancreas or ampulla of Vater Having seen the films and reconstructed the story, however, I am now thinking that this mass was inflammatory and that is about as far as I can go I do not see how an area of constriction across this region such as Dr Wyman described can come from a vascular structure I had thought of aneurysm of the abdominal aorta, but that does not fit this, does it?

DR WYMAN No, but it fits with dilated common duct pressing on the duodenum

DR CHAPMAN I cannot do any better than this We might give someone else in the audience a chance

DR JACOB LERMAN What did the X-ray Department think it was?

DR BENJAMIN CASTLEMAN They thought it was inflammatory

DR CHAPMAN I did not mention retroperitoneal lymphoma I considered the possibility of a tumor of the lymphoma series involving the head of the pancreas and pressing on the duodenum

DR HOWARD B SPRAGUE Could it have started with pancreatitis?

*Davidson L S P and Smith, J Weil's disease in fishworkers. clinical chemical and bacteriological study of 40 cases *Quart J Med* 5 263 286 1936

DR CHAPMAN An inflammatory mass subsequent to ordinary pancreatitis? Yes, that is perfectly possible. My first choice is an inflammatory mass, with pancreatic destruction. That fits the laboratory evidence best, and what lies behind that remains to be seen.

DR WYMAN There is a suggestion that this is well localized, so that I should place more emphasis on common-duct stone with secondary dilatation of the common duct or a tumor of the ampulla of Vater or the distal end of the common duct. However, a carcinoma of the pancreas or, I suppose, an inflammatory mass could look exactly the same.

DR CASTLEMAN Have you any comment, Dr Boyd?

DR WILLIAM BOYD (Toronto) I think pancreatitis of some type might be all right.

DR LYMAN DUFF (Montreal) The possibility of pancreatic cyst might be suggested, that is no more impossible than any of the other suggestions made.

DR KRANES I saw this patient on only one occasion about one month after he became ill in the other hospital. At that time he was on the mend, the jaundice diminishing, his appetite, which had previously been very poor, had increased enormously, and in general he was a great deal better. The history at the time—jaundice, nausea and fever, followed by the subsidence of the jaundice and the return of the appetite—was fairly characteristic of acute hepatitis. I might say in further support of that diagnosis that he was rather tender in the right upper quadrant. That is not brought out well in the history. The only thing that disturbed us was the fact that the fever occurred about two or three weeks after the onset of the jaundice rather than preceding the jaundice, and the laboratory tests were those of obstructive jaundice. Since he was improving it was decided to let him go home and see if he continued to improve. As the history brings out, although the appetite remained good he continued to lose weight, his jaundice grew more intense and repeated cephalin-flocculation tests done during this period were negative. So he was readmitted to the hospital with a diagnosis of obstructive jaundice. When he arrived on the ward everyone who saw him from students to house officers and visiting physicians all thought he had hepatitis until the results from the laboratory work were returned and the impressions were changed.

CLINICAL DIAGNOSIS

Infectious hepatitis?
Obstructive jaundice?

DR CHAPMAN'S DIAGNOSIS

Inflammatory mass in region of head of pancreas

ANATOMICAL DIAGNOSIS

Adenocarcinoma (low grade) of ampulla of Vater

PATHOLOGICAL DISCUSSION

DR CASTLEMAN The operation on the tenth day was an aspiration of the liver, which showed evidence of biliary obstruction. The bile ducts were all distended with bile. There was no doubt of an obstructive jaundice, and with that diagnosis Dr Linton operated. He found a large, distended gall bladder, the head of the pancreas felt pretty hard, but a rush frozen section on a biopsy showed normal pancreas. The common duct was markedly thickened and dilated, probably two or three times the normal size, this was strong evidence that there was an obstruction at the ampulla. The duodenum was therefore opened, disclosing a papillary lesion surrounding the papilla of Vater. A Whipple operation, which consisted in removing the head of the pancreas and duodenum and anastomosing the end of the common duct into the jejunum, was then performed.

The specimen we received showed a papillary tumor measuring $\frac{1}{2}$ cm in diameter probably arising in the duodenum, completely surrounding the ampulla and producing complete obstruction. The center of the tumor was at the ampulla. Histologically this was a slowly growing adenocarcinoma with very little invasion. We found one spot where it had gone beyond the muscularis mucosa, but there was no invasion of the pancreas at all.

Following operation the patient developed a localized abscess which was drained, and he is apparently doing well. A dozen regional lymph nodes were examined, and they were all normal. I am quite certain that there are no metastases.

CASE 35192

PRESENTATION OF CASE

First admission A seventy-five-year-old man was admitted to the hospital complaining of occasional abdominal pain and gaseous eructations.

Ten to twelve months previously he began having intermittent bouts of aching right-lower-quadrant pain, usually occurring at night. Six months before admission these pains became sharp and crampy and were severe enough to interfere with his sleep. They usually lasted two or three hours and were relieved somewhat by enemas. He had always been somewhat constipated, and he noted no change in the character of the stools. A system review was negative except for occasional slight ankle edema and some urinary frequency. Approximately one month before entry a complete checkup, including a gall-bladder and large-bowel x-ray series, was reported as negative in an outside hospital. A pulsating mass in the left upper

quadrant was found, and he was referred to this hospital

Physical examination was entirely negative except for a pulsating, 10-cm, rounded mass in the left upper quadrant, presenting just below the costal margin

The temperature was 98.6°F, the pulse 60, and the respirations 20. The blood pressure was 140 systolic, 80 diastolic

Laboratory studies showed a cloudy urine, with a specific gravity of 1.012, with 4 white blood cells per high-power field in the spun sediment. The hemoglobin was 11.8 gm

Chest x-ray films disclosed enlargement of the heart in the region of the left ventricle and a tortuous, elongated aorta. Plain films of the abdomen demonstrated a smooth mass, extending from the level of the twelfth thoracic vertebra about 9.5 cm to the left of the midline. There was some calcification about the periphery of the mass. The left kidney was possibly displaced slightly laterally. The right kidney was not remarkable. On the third hospital day wiring of the abdominal aneurysm was done by means of a trocar needle inserted through the back. He was discharged one week later.

Final admission (six months later) The patient continued to have daily attacks of severe abdominal pain, which was sometimes burning, sometimes sharp and crampy and sometimes aching. He gradually developed increasing constipation, progressing to almost complete obstipation, and had episodes of vomiting two or three times a week. His appetite gradually diminished, and he lost considerable weight.

Physical examination showed slight icterus, a hard, irregular liver edge, extending four finger-breadths below the costal margin, and an 8-cm mass in the right lower quadrant. There was, again, the 10-cm, pulsating mass in the left upper quadrant. The abdomen was distended and tympanitic, with high-pitched peristaltic gurgles. There was ++ edema of the ankles. The patient became increasingly jaundiced and more listless and died.

DIFFERENTIAL DIAGNOSIS

DR RICHARD J. CLARK We are given the history of a seventy-five-year-old man whose symptoms started out approximately eighteen months prior to his final admission to the hospital. He had crampy abdominal pains all through this period, which were apparently somewhat related to constipation—not too definitely at first, but quite definitely later on. Various studies were made, including gall-bladder x-ray films and a barium enema, which were said to have been negative at that time. A pulsating mass was found in the left upper quadrant. He came into the hospital, and the diagnosis of aneurysm was apparently made. We are told that this was wired. We have to be suspicious when given such a flat-footed diagnosis,

but there seems little reason to doubt that the patient had an abdominal aneurysm. In spite of the wiring of this aneurysm, he had no relief of pain, and he went on developing increasing constipation, weight loss, anorexia and finally vomiting. He returned to the hospital following a progressively downhill course and on the second entry presented a mass in the right lower quadrant and a liver that had become enlarged and nodular. He died without any sudden dramatic event.

The problems presented here are twofold: the nature of the pulsating mass in the left upper quadrant and its relation to symptoms, and the nature of the mass in the right lower quadrant and its association with the abnormal liver and the course of events. May we see the x-ray films?

DR STANLEY M. WYMAN The films of the chest are not remarkable except to demonstrate a heart that is prominent in the region of the left ventricle and a somewhat tortuous thoracic aorta. The films of the abdomen show the wired aneurysm, and the soft-tissue mass extending peripherally to the right is well seen. The lateral view discloses calcification in the walls of the aneurysm itself. The only other thing of particular note is the increase in the size of the liver from the first admission to the second, when it appears to be definitely larger.

DR CLARK Is there any appreciable change in the appearance of the lesion?

DR WYMAN Both these films are taken after the wiring, about six months apart, and there is no definite change that I can see.

DR CLARK Can you follow the course of the abdominal aorta at all?

DR WYMAN The calcification here lies in the aneurysm. It is impossible to follow it with accuracy, but it seems to extend in this fashion. Down below, it is readily seen where it comes out to more or less normal caliber at the level of the fourth lumbar interspace. The aneurysm itself lies apparently between the twelfth thoracic and the fourth lumbar vertebra.

DR CLARK Dr Wyman has been kind to us in granting that this is an aneurysm. He has left relatively little doubt about that particular point.

This man obviously had arteriosclerosis. We have no record over the course of time of his having had hypertension. Possibly he had it at some time in the past, but he was not in congestive failure. I see no definite indication for making a diagnosis of hypertensive heart disease. Lacking evidence for any other etiologic factor, we may reasonably assume that this patient had an arteriosclerotic form of heart disease, with arteriosclerosis of the aorta. Certainly from the descriptions given we may assume that he also had an abdominal aneurysm. The question arises just where the aneurysm was located. The three commonest locations are the abdominal aorta, the splenic artery and the hepatic artery. From the description we might have suspected origin

from the splenic artery, but it seems quite definite from the size of the aneurysm and the x-ray appearance in relation to the abdominal aorta that the aneurysm arose from the aorta. The next question is, What was the etiology of the aneurysm? While many aneurysms are syphilitic in origin, those of the thoracic aorta are more apt to be syphilitic, whereas I believe it has been shown in this laboratory that the majority of intra-abdominal aneurysms are arteriosclerotic. Was a serologic test done?

DR TRACY B MALLORY Yes, and it was negative.

DR CLARK That would be further evidence that this probably was an arteriosclerotic aneurysm of the abdominal aorta. What relation did this aneurysm have to the patient's presenting symptoms? Aneurysms by themselves do not ordinarily produce pain. Pain and other symptoms of aneurysm are almost entirely caused by their effect upon adjacent structures, from erosion, pressure and the like. Symptoms from aneurysm in the abdomen are apt to be notably absent because there is plenty of room for expansion, and pressure symptoms are less likely to occur. I toyed with the thought of involvement of the ostia of various branches of the aorta leading to the mesentery. Could this symptomatology have been related to what has been described as abdominal angina secondary to arteriosclerosis of abdominal vessels? It seems to me that in view of subsequent evidence there is no need to bring in any such supposition. I do not believe that the aneurysm had any important relation either to the patient's death or to the patient's symptoms, although symptoms of nausea, anorexia and so forth have been attributed to such lesions.

On the final entry we are given very few facts and almost no specific data on which to confirm or establish a diagnosis. Apparently no x-ray studies were done and no laboratory data are at hand. We do have the appearance of a tumor that had arisen in the right lower quadrant, and we have evidence of involvement of the liver. There are no data on which to substantiate a diagnosis of infection; nothing is said about tenderness in the mass or in the liver, there is no record of fever or leukocytosis. This leads us almost certainly to a neoplastic lesion. We might go through all the neoplasms in the lower abdomen that could metastasize to the liver, but in view of the rather definite symptoms of increasing constipation, weight loss

and so forth, without further ado we might just as well make the assumption that this patient had carcinoma of the colon, most likely in the region of the cecum, with metastases to the liver, and that he probably died as a result of this. The lesion was likely present but undiscovered at the time of the first x-ray examination. I cannot reasonably relate the aneurysm with the right-lower-quadrant mass or the liver. That leaves me with a diagnosis of arteriosclerotic heart disease, arteriosclerotic aorta, with an arteriosclerotic aneurysm of the abdominal aorta together with carcinoma of the colon and metastases to the liver.

CLINICAL DIAGNOSES

Carcinoma of colon, with metastases to liver
Abdominal aneurysm
Arteriosclerosis

DR CLARK'S DIAGNOSES

Carcinoma of colon, with metastases to liver
Arteriosclerotic aneurysm of abdominal aorta

ANATOMICAL DIAGNOSES

Carcinoma of ascending colon, with metastases to liver, regional lymph nodes, lungs and kidney
Arteriosclerotic aneurysm of abdominal aorta, wired
Arteriosclerosis, generalized, severe
Bronchopneumonia,
Pulmonary emboli, small
Thrombosis, periprostatic plexus of veins

PATHOLOGICAL DISCUSSION

DR ROBERT R LINTON I would like to compliment Dr Clark on his presentation of this case. He has described everything that I know about it. I will show some color slides, which will confirm his diagnosis. This first slide is a view of the abdomen when it was opened at autopsy. It shows a huge liver. Here is the left lobe with the metastatic nodules in the liver itself. There is nothing else of note in that view. This is the cut section of the liver. Much of the liver tissue was replaced or pushed aside by this tremendous infiltration of metastatic disease. The next slide shows the aorta and the aneurysm, the abdominal aneurysm, which has been wired. The next view shows the aorta when it has been opened. We have been unable to obtain many such specimens after wiring. There is a dark area that contains many of the loops of wire and

fresh blood clot, which is post-mortem clot. This portion out here is a gristle-like, partially organized thrombus. The wiring did what it was supposed to do—that is, it strengthened the wall of the aneurysmal sac so that it did not perforate and through it a channel led whereby blood could flow freely to the lower part of the body in spite of numerous coils of steel wire. The next is a closer view, showing the channel through which the blood flowed.

I became interested in the wiring of aneurysms because of the fact that we have a certain number of arteriosclerotic aneurysms that are the cause of a patient's death. Having watched a number of them perforate or rupture, and watched the patient suddenly expire, it seemed that one was justified to try almost anything to save their lives. Wiring of aneurysms dates back many years. I do not know who was the first courageous surgeon to attempt it, but it fell into disrepute chiefly because surgeons did not have the proper type of wire to use. The difficulty with the wire used formerly was that it was too stiff and rigid and followed the path of least resistance and ended up where one did not want it to go. The wire I have used is stainless steel, No 30 gauge, and very flexible so that it coils around without traveling up and down the aorta.

We must rely on preoperative x-ray studies to determine the cause of many patients' symptoms. If an abdominal arteriosclerotic aneurysm is found on examination I would like to warn that very often it is nothing but a red herring, and the cause of the symptoms is some other disease. In the case under discussion I unfortunately relied on a single x-ray examination taken at another hospital. The patient had had a barium enema and a gastrointestinal series, and the x-ray studies were reported as negative. I took that to be true and, as a result, decided to wire this aneurysm from a lumbar approach, which necessitates only a nick of the skin to insert the wiring trocar, and with this approach one can wire the abdominal aorta just as well from behind as in front. I did the wiring last June thinking that the aneurysm was the cause of the symptoms, as did his local physician. It was not until the patient developed a mass in the right lower quadrant that we decided to reinvestigate his gastrointestinal tract, and on a more careful search we found a lesion in the cecum, which Dr Wyman also demonstrated by roentgenologic examination a short time before the patient's death.

The lesson I learned from this case was not to rely on a single gastrointestinal series in a patient who has symptoms that do not seem typical of an abdominal aneurysm. I thought I was very smart a little while later because I had another patient come to me the latter part of last year. This patient was sixty-three years old, he was referred to me because of a mass in the abdomen, which obviously was the same kind of lesion, an arteriosclerotic abdominal aneurysm, which one can see in the x-ray films has been wired. His symptoms were those of obstruction—for six years he had had discomfort after eating heavy, fatty meals. The aneurysm was noted about one month before he came to me and during the last two weeks had increased in size. It seemed to me that his symptomatology suggested something wrong with his gastrointestinal tract, so I had a gastrointestinal series performed. The report came back that this mass was a prepyloric ulcer on the lesser curvature. Do you agree, Dr Wyman?

DR STANLEY M. WYMAN: It looks like it.

DR LINTON: I believe there was no question of correctness of this diagnosis since we all thought this man's symptoms were due to the prepyloric ulcer, so I transferred him to an internist for treatment of the prepyloric ulcer and determined to forget about the aneurysm for the present. A few days after the internist saw him the patient began to complain of terrific pain in the back, radiating to the groins. The aneurysm increased in size, and it was obvious that it was beginning to rupture and for that reason we did an emergency laparotomy and wired the aneurysm. Since then the pain in the groin and back disappeared. Here was a man with two lesions—the one that brought him to the hospital was the abdominal aneurysm, although the history was that of prepyloric ulcer. I have another that I would like to show. This is a sixty-five-year-old man who came to me in December. The chief complaint was indigestion. I took one look at him and said, "This man is not coming to me because of his aneurysm, he is coming to me because he has something else wrong with him." Examination revealed a large arteriosclerotic abdominal aneurysm. It was my opinion, however, that the man had a gastric lesion, and I thought that it probably was malignant. I referred him to the hospital, and the first thing done was a gastrointestinal series, which was reported negative. Because the pain was atypical for aneurysm, we thought of doing a Graham test, which showed a

number of calculi in the gall bladder. We finally decided to operate on him to take out the gall bladder and wire the aneurysm at the same time. To my consternation, when I opened his abdomen I found that he had a huge carcinoma of the stomach involving the fundus, which necessitated a total gastrectomy. So I ended up by doing that and let the aneurysm alone. I did not think it was justifiable to do both procedures at the same time. Another patient, referred to me by Dr. Arthur W. Allen, said that he was lying in bed one night, reading a book, and he noticed that it jumped up and down with every heart beat, and he became interested and found that he had an aneurysm. He had no symptoms whatever except the mass that kept bouncing up and down. In his case the aneurysm was successfully wired. Even after a most careful x-ray workup I still think that if one is going to wire an abdominal aneurysm (and I believe they should be wired because they probably will rupture sooner or later) it should be done through an abdominal exploratory incision rather than through the back with a small incision. In that way one can pick up a certain number of these patients who have other diseases and correct them and perhaps later on take care of the aneurysm.

DR. CLARK: Was the original lesion in the cecum?

DR. MALLORY: It was in the ascending colon, just above the cecum — there were extensive metastases to the liver and generalized, diffuse arteriosclerosis.

DR. CLARK: Did the heart show anything more?

DR. MALLORY: Nothing except diffuse coronary sclerosis without infarction.

DR. LINTON: In defense of the original barium-enema examination, I do not believe anyone would have found the tumor at the time it was done. Even before death the lesion was not too obvious or large at autopsy.

DR. WYMAN: In defense of the first examiner who saw the patient, the lesion must have been small because when I saw the films seven months later, before death, it was only 5 cm. in length.

DR. LINTON: I even shudder to think that I might have missed it had I done an exploratory laparotomy.

DR. CLARK: How much hazard is there involved in doing a wiring of this sort — do you have any way of knowing what the results are? Have you followed enough patients over a period to know how much good is accomplished?

DR. LINTON: I think that is hard to answer. I had a long letter from Dr. Cole, of England, who developed a wiring apparatus, and he said that he had spent his life trying to determine whether wiring of aneurysms prolonged life, and he was going to die without accomplishing it. It is difficult to say. There is a man from Atlanta, Georgia, in the hospital now with an abdominal aneurysm. The aneurysm began to leak while he was motoring through Connecticut. He was rushed to a hospital and referred here for treatment. I think, without question, that he would not have lived if the aneurysm had not been wired at that time. The thing that encourages me most to continue this treatment is that the autopsy in the case under discussion today showed that one can strengthen the wall and prevent it from perforating by this method.

DR. CLARK: What is the risk of the procedure?

DR. LINTON: The mortality is zero. I have done about 15 or 20 operations, which brings it down to a fairly reasonable risk. However, I am sure I will never do another through the back, no matter how sure we are by preoperative studies that that is the only trouble the patient has.

ALL ROADS LEAD TO WORCESTER

THE one hundred and sixty-eighth annual meeting of the Massachusetts Medical Society will be held at the Worcester Memorial Auditorium on May 24, 25 and 26. This will be the first meeting away from Boston in a decade, the last out-of-town meeting having been held in Worcester in 1939.

The quality of the meetings of the Society has improved steadily since the war, and their popularity has increased out of all proportion to the increase in the Society's membership. In 1947, 1521 fellows and guests registered their attendance, and in 1948, 2436. While a meeting outside Boston does not ordinarily attract the numbers that a meeting in the more densely populated section

of the state can draw, every effort is being made to secure an especially large attendance this year.

As usual, the Council of the Society will meet on Monday evening, the day before the sessions begin, at the Hotel Sheraton. On the following morning, at 8:55, the first general session will convene in the Little Theater of the Memorial Auditorium. General sessions will continue to be held each morning and afternoon through Thursday, May 26.

The annual meeting of the Society will take place in the Memorial Auditorium at 11:00 on Tuesday morning, May 24. The annual oration, "Some Responsibilities of Medical Education," by Dr. C. Sidney Burwell, dean of the Harvard Medical School, will immediately follow. At the close of the oration the annual luncheon will be served. The Worcester District Medical Society has invited all members of the Massachusetts Medical Society to "Worcester Hofbrau Night" that evening, in the ballroom of the Sheraton. As if any inducements to attend were necessary, free entertainment will be furnished, and free beer will be served.

The Shattuck Lecture, always an event of great interest, will be delivered on Wednesday morning at 11:05 by Dr. Paul D. White, clinical professor of medicine at the Harvard Medical School, consultant in medicine at the Massachusetts General Hospital, and executive director of the National Advisory Heart Council. His subject is "La médecine du coeur."

The high point of the meeting will be the annual dinner on the evening of May 25, to which ladies may be invited. Tickets for the dinner, the fellows are warned, MUST be procured in advance. The speaker of the evening will be Roscoe Pound, LL.D., University Professor Emeritus, Harvard University, and former dean of the Harvard Law School, on the subject, "The Professions in the Society of Today."

The usual section meetings and luncheon will round out the program, and as usual the scientific and technical exhibits and the exhibition of works of art by members of the Massachusetts Physicians' Art Association will be well worth visiting.

This year, also, the Woman's Auxiliary will be on the scene as a full-fledged, functioning organ-

number of calculi in the gall bladder. We finally decided to operate on him to take out the gall bladder and wire the aneurysm at the same time. To my consternation, when I opened his abdomen I found that he had a huge carcinoma of the stomach involving the fundus, which necessitated a total gastrectomy. So I ended up by doing that and let the aneurysm alone. I did not think it was justifiable to do both procedures at the same time. Another patient, referred to me by Dr. Arthur W. Allen, said that he was lying in bed one night, reading a book, and he noticed that it jumped up and down with every heart beat, and he became interested and found that he had an aneurysm. He had no symptoms whatever except the mass that kept bouncing up and down. In his case the aneurysm was successfully wired. Even after a most careful x-ray workup I still think that if one is going to wire an abdominal aneurysm (and I believe they should be wired because they probably will rupture sooner or later) it should be done through an abdominal exploratory incision rather than through the back with a small incision. In that way one can pick up a certain number of these patients who have other diseases and correct them and perhaps later on take care of the aneurysm.

DR. CLARK: Was the original lesion in the cecum?

DR. MALLORY: It was in the ascending colon, just above the cecum — there were extensive metastases to the liver and generalized, diffuse arteriosclerosis.

DR. CLARK: Did the heart show anything more?

DR. MALLORY: Nothing except diffuse coronary sclerosis without infarction.

DR. LINTON: In defense of the original barium-enema examination, I do not believe anyone would have found the tumor at the time it was done. Even before death the lesion was not too obvious or large at autopsy.

DR. WYMAN: In defense of the first examiner who saw the patient, the lesion must have been small because when I saw the films seven months later, before death, it was only 5 cm. in length.

DR. LINTON: I even shudder to think that I might have missed it had I done an exploratory laparotomy.

DR. CLARK: How much hazard is there involved in doing a wiring of this sort — do you have any way of knowing what the results are? Have you followed enough patients over a period to know how much good is accomplished?

DR. LINTON: I think that is hard to answer. I had a long letter from Dr. Cole, of England, who developed a wiring apparatus, and he said that he had spent his life trying to determine whether wiring of aneurysms prolonged life, and he was going to die without accomplishing it. It is difficult to say. There is a man from Atlanta, Georgia, in the hospital now with an abdominal aneurysm. The aneurysm began to leak while he was motoring through Connecticut. He was rushed to a hospital and referred here for treatment. I think, without question, that he would not have lived if the aneurysm had not been wired at that time. The thing that encourages me most to continue this treatment is that the autopsy in the case under discussion today showed that one can strengthen the wall and prevent it from perforating by this method.

DR. CLARK: What is the risk of the procedure?

DR. LINTON: The mortality is zero. I have done about 15 or 20 operations, which brings it down to a fairly reasonable risk. However, I am sure I will never do another through the back, no matter how sure we are by preoperative studies that that is the only trouble the patient has.

group than in the controls. The typhoid strain responsible for the outbreak was no more resistant to the action of penicillin and sulfathiazole than other strains with which it was compared *in vitro*. Bevan and his co-workers therefore considered it necessary to warn against the indiscriminate use of penicillin and sulfathiazole in the treatment of typhoid fever.

McSweeney was sufficiently impressed with the bacteriologic effects of the penicillin and sulfathiazole therapy in his cases to suggest that the same regime be tried in attempts to clear up typhoid carriers. Comerford,⁶ following this lead, used both sulfathiazole and penicillin on 2 known carriers who regularly excreted typhoid bacilli even after cholecystectomy. He used 2 gm of sulfathiazole followed by 1 gm every 4 hours by mouth, and 500,000 units of penicillin intramuscularly at the same interval. This was continued for seven or eight days, and in both patients the stool cultures remained free of typhoid bacilli for a follow-up period of about four months. In another study, however, Fry and his associates⁷ used the same regime in 17 chronic fecal carriers. There were only 3 apparent successes. In 2 of the cases in which the usual doses had failed, doses of 40,000,000 units and 12 gm of sulfathiazole per day were given on three occasions and proved unsuccessful. These workers concluded that the therapeutic results of the penicillin and sulfathiazole treatment in typhoid carriers were not encouraging.

The introduction of streptomycin raised new hopes for effective therapy in typhoid fever because of the susceptibility of the organisms to this antibiotic *in vitro*. Reimann, Elias and Price⁸ treated 5 patients with severe typhoid fever, and on doses of 1 to 4 gm per day intravenously or intramuscularly obtained levels of streptomycin in the blood and urine that were more than sufficient to kill the organisms *in vitro*. Small quantities of the antibiotic were also excreted in the feces. Both parenteral and oral administration of streptomycin was considered desirable, the former to control the bacteremia and bacilluria and the latter to sterilize the feces and prevent reinfection and the carrier state. There was no evidence of the development of increased resistance during exposure of the or-

ganisms to streptomycin in the body. However, only 3 of the 5 patients recovered, and, in addition, bacilemia and positive stool cultures persisted in some cases in spite of the exposure of the organisms to concentrations of streptomycin greater than that required to kill the organisms *in vitro*.

Since this study of Reimann and his associates, it has been amply demonstrated that streptomycin has little if any favorable effect on the clinical and bacteriologic course of typhoid fever. The 169 cases collected by Keefer and Hewitt⁹ seemed to bear this out.

Of interest is the failure in most cases of typhoid fever to demonstrate the development of resistance in organisms that persist in the blood and stools during treatment with streptomycin. Comparable observations have been made by Hall and Spink¹⁰ in cases of brucellosis. Such findings suggest either the failure of the antibiotic to obtain access to the bacteria or possibly a difference in the genetic constitution of these organisms that affects the mutations concerned in the development of streptomycin-resistant flora. Of additional interest is the demonstration of "hormesis" (an increase in the mortality rate) among mice infected with typhoid bacilli and treated with subeffective concentrations of either penicillin¹¹ or streptomycin.¹² The immunity that followed the typhoid infection in the streptomycin-treated mice that recovered suggested that when the small doses of drug were used, there was actually multiplication of the organisms *in vivo*.

It is natural that new antibiotics that are relatively nontoxic and have a definite effect on gram-negative bacilli *in vitro* and in experimental infections should receive a clinical trial in the treatment of typhoid fever. Preliminary trials of two such antibiotics have appeared recently. Ten cases of typhoid fever were treated with chloromycetin¹³ in Kuala Lumpur during the course of clinical trials with this agent in scrub typhus. The course of the typhoid fever was markedly shortened in comparison with that in untreated cases, and the febrile stage of the illness was terminated in an average of three and a half days after treatment was begun. These patients were treated orally with an initial dose of 50 mg per kilogram of body weight,

ization, with all but one or two districts participating. With a year's experience since its organizational meeting, it will hold its first annual meeting on May 24 at the Worcester Woman's Club.

All roads lead to Worcester, come one, come all!

ANTIBIOTIC THERAPY OF TYPHOID FEVER

TYPHOID fever is one of the few acute bacterial infections in which modern chemotherapy has not yielded very brilliant results. It is generally agreed that the sulfonamide drugs have no effect whatever on the course of this disease, although they exert a definite bacteriostatic effect on the causative organisms *in vitro*. There have, however, been some conflicting claims concerning the effects of the combined use of penicillin and sulfonamides, and there are indications that some of the newer antibiotics may be beneficial. Since this disease, because of its possible severity in the individual patient and because of its public-health aspects, may assume importance out of proportion to its frequency, it may be of interest to review some of the recent reports on the effects of chemotherapy.

It is now generally appreciated that many gram-negative bacilli and particularly the typhoid bacilli are not totally resistant to the action of penicillin. They are essentially like the less sensitive strains of staphylococci in that they require relatively high concentrations to inhibit their growth. Evans¹ found that most strains of this organism were inhibited by 5 to 10 units of penicillin per cubic centimeter, and Welch and Randall² reported that all but 1 of 29 strains of typhoid bacilli tested were inhibited by 12 units or less of penicillin G, and all 29 were inhibited by 6 units of penicillin X.

In vitro studies carried out by Bigger³ showed that penicillin in concentrations up to 8 units per cubic centimeter reduced but did not prevent the growth of *Eberthella typhosa* in broth. Sulfathiazole in concentrations up to 10 mg per 100 cc inhibited the multiplication of these organisms, but a bactericidal effect was obtained only when small numbers of bacteria were exposed. The combination of penicillin and sulfathiazole, however, had a pronounced bactericidal effect. Thus, a concentration of 4 units of penicillin per cubic centimeter

and 10 mg of sulfathiazole per 100 cc sterilized a culture inoculated with 70,000 typhoid bacilli per cubic centimeter, and 1 unit of penicillin with the same amount of sulfathiazole sterilized a culture inoculated with 7000 organisms per cubic centimeter. On the basis of his findings, Bigger suggested a tentative therapeutic regime for the treatment of typhoid fever. This consisted of full doses of sulfathiazole in addition to penicillin in doses of 2,500,000 to 3,000,000 units per day by continuous drip for five to seven days. This dosage would be expected to maintain a concentration of 2 units of penicillin per cubic centimeter of blood. Both these agents would be given again if typhoid organisms reappeared in blood or stools.

Following this suggestion, McSweeney⁴ treated a series of 6 severe cases. One of his patients who received doses of penicillin appropriate for ordinary staphylococcal infections showed no appreciable effect on the pyrexia or blood cultures, although the toxemia was much lessened. The other 5 patients were treated intensively with penicillin and sulfathiazole and received two courses, each comprising 10,000,000 units of penicillin and 34 gm of sulfathiazole in four days. Speedy disappearance of toxemia, subsidence of pyrexia and disappearance of organisms from the blood, feces and urine followed the end of the second course in 4 of these 5 patients. McSweeney regarded the clinical effects observed as confirming the laboratory findings of Bigger.

In a later and somewhat more extensive study, Bevan and his co-workers⁵ treated 39 patients with penicillin and sulfathiazole in doses comparable to those used by McSweeney. The cases all occurred in a single outbreak. These workers did not observe the speedy disappearance of toxemia and subsidence of fever described by McSweeney. In the cases treated by this method, there was no evidence of any appreciable clinical effect of the drug treatment when compared with comparable cases in which the patients did not receive this therapy. Furthermore, a considerable proportion of the patients yielded positive blood cultures shortly after completion of the course of penicillin and sulfathiazole, and fecal excretion of typhoid bacilli during convalescence was not shorter in the treated

MASSACHUSETTS MEDICAL SOCIETY ANNUAL MEETING OF THE COUNCIL

The annual meeting of the Council of the Massachusetts Medical Society will be held at the Sheraton Hotel, Worcester, on Monday, May 23, 1949, at 7:00 p m

Business

- 1 Call to order at 7 00 p m
- 2 Presentation of record of meeting held February 2, 1949, as published in *The New England Journal of Medicine*, issue of April 2, 1949

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender Books that appear to be of particular interest will be reviewed as space permits Additional information in regard to all listed books will be gladly furnished on request

Abdominal Operations By Rodney Maingot, F R C S, surgeon to the Royal Free Hospital, London, and to the Southend General Hospital Second edition, 8° cloth, 1274 pp, with illustrations New York Appleton-Century-Crofts, Incorporated, 1948 \$16 00

This treatise on surgery of the abdomen and its organs is the joint work of Dr Maingot and eight collaborators Although the treatise is written by English surgeons with the exception of Dr Dragstedt, of the University of Chicago, and Dr Harrington, of the Mayo Foundation, the book was printed in the United States The whole text has been thoroughly revised and brought up to date since the publication of the last edition Many illustrations for new and revised operations have been added Pertinent references have been interpolated throughout the text The material is well arranged A very good large type has been used, and the illustrations are excellent The book is recommended for medical libraries and should be available to all persons interested in surgery of the abdomen It should be recognized as a standard treatise in its field

Diseases of the Ear, Nose and Throat By William W Morrison M D, professor of otolaryngology and attending otolaryngologist, New York Polyclinic Medical School and

Hospital senior assistant surgeon in otolaryngology, New York Eye and Ear Infirmary, and associate clinical professor of otolaryngology, New York University College of Medicine 8°, cloth, 772 pp, with 359 illustrations New York Appleton-Century-Crofts, Incorporated, 1948 \$8 50

This new textbook, written for the undergraduate medical student and the general practitioner, is based on a long period of teaching The text is divided into eight parts The first is devoted to general considerations, including history taking equipment for examination and chemotherapy in otolaryngology The other parts, in order, deal with diseases of the ear diseases of the external nose and the nasal cavities allergic diseases of the respiratory tract, and diseases of the paranasal sinuses, of the throat, of the larynx, and of the trachea, bronchi, esophagus and mediastinum An appendix comprises a formula of prescriptions for medications to be used by patients The volume concludes with two indexes of subjects and symptoms The material is well organized, and the text well written Lists of selected references are appended to the chapters The illustrations are original with the author The book is well published and should prove useful as a reference source

Streptomycin and Tuberkulose Herausgegeben von G Fancioni und W Löffler unter Mitwirkung von J Barth et al 8°, p per, 357 pp, with 233 illustrations Basel, Switzerland Benno Schwabe and Company, 1948 30 Swiss francs

This monograph is comprehensive and well written The text is well arranged and consists of introduction and four major sections The first discusses general problems influence on cellular respiration, the experimental groundwork, cytotoxic action, and the use of streptomycin, para-aminosalicylic acid and sulfone in experimental tuberculosis The second deals with hematogenous spreading in tuberculous meningitis, miliary tuberculosis in the aged and in children and tuberculosis in infants and children The third, comprising about half the text, considers tuberculosis of the various organs and of the lymph nodes, as well as fistulas The fourth is devoted to the pathological anatomy of tuberculous meningitis and miliary tuberculosis after streptomycin treatment, and a description of 3 cases of osteomalacia occurring in tuberculous meningitis treated with streptomycin The text is concluded with a large bibliography The publishing is excellent in every way There is an adequate table of contents, but the lack of an index detracts from the reference value of the book The monograph is recommended for all medical libraries and to all persons interested in the subject

Zinsser's Textbook of Bacteriology, The application of bacteriology and immunology to the diagnosis, specific therapy and prevention of infectious diseases for students and practitioners of medicine and public health 8°, cloth, 992 pp, with 250 illustrations Revised by David T Smith, M D, professor of bacteriology and associate professor of medicine, Duke University School of Medicine, Donald S Martin, M D, M P H, professor of preventive medicine and public health and associate professor of bacteriology, Duke University School of Medicine, Norman F Conant, Ph D, professor of mycology and associate professor of bacteriology, Duke University School of Medicine, Joseph W Beard, M D, professor of surgery in charge of experimental surgery, Duke University School of Medicine Grant Taylor, M D, associate professor of bacteriology and associate professor of pediatrics, Duke University School of Medicine, Henry I Kohn, Ph D, M D, surgeon, United States Public Health Service, and assistant professor of physiology and pharmacology (on leave), Duke University School of Medicine, and Mary A Poston, M A, instructor in bacteriology, Duke University School of Medicine Ninth edition 8°, cloth, 992 pp, with 251 illustrations New York Appleton-Century-Crofts, Incorporated, 1948 \$10 00

This standard textbook was first published in 1910 Through eight editions Drs Hiss, Zinsser and Bayne-Jones were responsible for the text This edition has been thoroughly revised and brought up to date The sections on bacterial metabolism, immunology and fungous and viral diseases have been rewritten entirely A chapter on pleuropneumonia-like organisms and a section on the antibiotics have been added, and the material on the sulfonamides has been expanded

followed by 0.25 gm every three or four hours and smaller doses after the temperature had been reduced. Concentrations of chloromycetin that were many times the bacteriostatic levels for the organisms were obtained in the serum.

Even in this small group of chloromycetin-treated cases, however, some of the reported observations indicate that the beneficial results were far from optimal. Positive stools were obtained in 2 patients during convalescence, 2 other patients had relapses of fever with positive blood cultures after being afebrile for ten to sixteen days, 1 patient had an intestinal perforation two days after the temperature had returned to normal, and another had a large hemorrhage from the bowel after being afebrile for four days.

Aureomycin is the most recent antibiotic to receive a trial in typhoid fever. This agent is effective against typhoid bacillus *in vitro*¹⁴ and in experimental infections.¹⁵ With this agent, although the results of treatment in some patients with typhoid fever seemed encouraging, the results in other patients were quite equivocal.¹⁴

Of these new agents chloromycetin appears to be more beneficial during the acute illness, but neither of these antibiotics, according to a number of unpublished reports, has any influence on the carrier state.

STILL THE AMERICAN WAY

VOLUNTARY health insurance needs only time in which to earn the nation's full confidence. By the end of 1948, according to Blue Shield national headquarters, the enrollment in Associated Medical Care Plans had reached 10,370,819, having experienced its greatest quarterly gain, of 1,057,274 members, in the last quarter of the year. This increment represents a growth of 11.35 per cent for the short period mentioned.

Enrolled in this same period were approximately a quarter million Ford Motor Company employees. The majority of these joined Michigan Medical Service, which continues to be the largest plan in the country, with a peak 1948 enrollment of 1,311,811. The New York City Plan ranks second with 1,128,967 members listed.

Varying as Blue Shield plans must in different localities and under a variety of background conditions, there is nevertheless an average or "typical" plan. The average plan is described as providing "complete surgical and obstetrical care including delivery, fractures and dislocations, medical care for hospitalized cases, limited diagnostic x-ray, and anesthesia."

Average subscription costs are \$1.17 per month for a single subscriber, who is provided with the above mentioned benefits on a service basis if his annual income is less than \$2050, \$2.26 for a man and wife and \$2.75 for a family. The benefits are provided on a service basis for families with incomes less than \$3100.

A criticism directed against voluntary prepayment plans for medical care is that they do not provide complete coverage. This, in fact, should be considered as one of the chief points in their favor. Calculated on an actuarial basis they balance the benefits against the cost, operating on as economical a basis as possible. Like Blue Cross they do not absorb all the costs of illness but cushion the shock, making it possible for the average earner to meet the obligations that have been tempered by his insurance.

Until a real majority of the American people may decide otherwise this form of independence and self-reliance must still be considered as a vital part of the American heritage.

HYPERCALCEMIA WITHOUT HYPERCALCURIA OR HYPOPHOSPHATEMIA, CALCINOSIS AND RENAL INSUFFICIENCY*

A Syndrome Following Prolonged Intake of Milk and Alkali

CHARLES H. BURNETT, M.D.,† ROBERT R. COMMONS, M.D.,‡ FULLER ALBRIGHT, M.D.,§
AND JOHN E. HOWARD, M.D.¶

BOSTON AND BALTIMORE

BECAUSE of our interest in the parathyroid glands our attention has been directed to a number of diseases with which primary hyperparathyroidism may be confused. These include acute osteoporosis,¹ hypervitaminosis D,^{2,4} sarcoidosis,⁵ myelomatosis,⁶⁻⁸ carcinomatosis with extensive bone involvement,⁶ polyostotic fibrous dysplasia,⁹ renal osteitis fibrosa generalisata¹⁰ and osteomalacia.¹⁰ By clinical and laboratory observations it is usually possible to differentiate these conditions from primary hyperparathyroidism. However, when the latter condition is complicated by secondary renal damage the diagnosis, in our experience, may be very difficult.^{6, 11} This report describes a syndrome observed in 6 patients that has many features in common with primary hyperparathyroidism and secondary kidney damage but that we now believe has an entirely different etiology.

The characteristic features in these patients are a history of prolonged and excessive intake of milk and absorbable alkali, hypercalcemia without hypercalcuria or hypophosphatemia, normal serum alkaline phosphatase level, marked renal insufficiency with azotemia, mild alkalosis, calcinosis manifested especially by an ocular lesion resembling band keratitis, and an improvement in the clinical state on an intake low in milk and absorbable alkali.

CASE REPORTS

CASE 1. A. McA. (M. G. H. 235557) a 44-year-old caretaker was first admitted to the hospital in February 1940, complaining of pruritus of 3 years' duration. Since the age

of 11 he had suffered from epigastric pain relieved by food and sodium bicarbonate. Three years before admission, a peptic ulcer had been found on x-ray examination; subsequently he had been almost constantly on a regimen of several quarts of milk daily and large quantities of absorbable alkalis. Five years before admission, during a period of 3 months, he had had three attacks of renal colic with passage of gravel and stones. On a high fluid intake there had been no recurrence of these symptoms. Other significant points in the past history were spinal meningitis at the age of 21, and a heavy alcoholic intake for 30 years.

Physical examination disclosed a well developed and well nourished man. The corneas showed band keratopathy, the fundi were normal. The liver edge was just felt at the costal margin. The blood pressure was 140/80.

Routine urinalyses revealed a maximal specific gravity of 1.012, acid reactions and a ++ test for albumin. The sediment contained 10 to 15 white cells per high-power field, an occasional red cell and rare granular casts. Urine culture was negative. The phenolsulfonphthalein test demonstrated 15 per cent excretion of the dye 1 hour after intravenous injection. The Sulkowitch test showed no increase in calcium. A test for urinary Bence-Jones protein was negative. Examination of the blood disclosed a red-cell count of 4,350,000 with a hemoglobin of 85 per cent and a white-cell count of 9,700 with a normal differential. There were no abnormal cells in the sternal bone marrow. The serum calcium was 12.4 mg, inorganic phosphorus 4.0 mg, alkaline phosphatase 5.3 Bodansky units, and nonprotein nitrogen 58 mg per 100 cc. The carbon dioxide combining power was 27.4 milliequiv per liter and the protein 9.8 gm per 100 cc.

A gastrointestinal series revealed a nonobstructing duodenal ulcer. Films of the skull showed normal bones.

A definite diagnosis was not made, but the patient was discharged on a reduced milk intake and advised to take no alkalis.

On his second and third admissions, both in October 1941, he complained of great weakness, continuing pruritus, polydipsia and polyuria. The ulcer had been asymptomatic, milk intake had averaged 2 or 3 glasses daily, and he had taken no alkalis. The physical examination revealed no changes from the previous admission. Examination of the urine was unchanged. The serum calcium was 12.0 to 14.6 mg and the phosphorus 4.0 to 4.7 mg per 100 cc. The alkaline phosphatase was 1.7 Bodansky units, the carbon dioxide content 31 milliequiv and the chloride 84.5 milliequiv per liter. The nonprotein nitrogen was 80 mg and the total protein 9.2 mg per 100 cc, with an albumin of 5.6 gm and a globulin of 3.6 gm. Calcium and phosphorus balance was negative. The average urinary excretion of calcium was 87 mg per 24 hours.

Further x-ray studies demonstrated no evidence of decalcification in the skeleton. The lamina dura about the teeth was preserved.

*From the Evans Memorial Hospital, the Department of Medicine, Boston University School of Medicine, the Massachusetts General Hospital, the Department of Medicine, Harvard Medical School, and the Johns Hopkins University School of Medicine and Hospital.

†Assistant professor of medicine, Boston University School of Medicine.
‡Senior fellow, National Institute of Health, assistant in medicine, Boston University School of Medicine.

§Associate professor of medicine, Harvard Medical School.

¶Associate professor of medicine, Johns Hopkins School of Medicine.

Likewise, 182 new illustrations, including many electron micrographs, have been included. Lists of pertinent references have been added to the various chapters. A good index concludes the volume. The book is recommended for all medical and public-health libraries and to all persons interested in bacteriology.

NOTICES

SOUTH END MEDICAL CLUB

A luncheon meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, May 17, at 12 noon. Dr. Francis J. Wenzler will speak on the subject "Pediatric Aspects of Erythroblastosis and Its Treatment."

Physicians are cordially invited to attend.

VERMONT STATE MEDICAL SOCIETY

The University of Vermont College of Medicine will be host to the Vermont State Medical Society for its annual meeting to be held in Burlington on May 19. The morning session will be held at the Bishop DeGoesbriand Hospital, and lunch and the afternoon sessions will be at the Mary Fletcher Hospital. Papers will be presented by various members of the university faculty.

MASSACHUSETTS GENERAL HOSPITAL

A special research meeting will be held in the Bigelow Amphitheater of the Massachusetts General Hospital on Monday, May 23, at 4:30 p.m. Dr. W. F. H. M. Mommaerts, of the Department of Biochemistry, Duke University School of Medicine, will speak on the subject "Fundamental Problems in Muscular and Cardiac Biochemistry."

NEW ENGLAND DIABETES ASSOCIATION

The annual meeting of the New England Diabetes Association will be held in Thayer Hall, City Hospital, Worcester, Massachusetts, on Monday, May 23, at 4 p.m.

CLINICAL PROGRAM

Neuropsychiatric Aspects of Diabetes. Dr. Foster L. Vibber.
Potential Diabetes. Dr. Joseph A. Lundy.
Necrotizing Papillitis in Diabetes. Dr. Edward F. Ramsdell.
Pathology of Necrotizing Papillitis. Dr. Raymond H. Goodale.
Experience with Diabetic Coma at Worcester City Hospital. Dr. Albert E. Hall.
Optimism and Diabetes. Dr. George Ballantyne.

The clinical program will be preceded by the annual business meeting including the election of officers and four directors. This meeting is planned in conjunction with the annual meeting of the Massachusetts Medical Society, May 23 to 26. The meeting will be completed in time so that councilors of the Massachusetts Medical Society can attend the Cotting supper at 6:00 p.m.

CONFERENCE OF PRESIDENTS AND OTHER OFFICERS OF STATE MEDICAL ASSOCIATIONS

The fifth annual Conference of Presidents and Other Officers of State Medical Associations will be held at Atlantic City on Sunday afternoon, June 5. The meeting, which will be held in the Rose Room of the Traymore Hotel on the day preceding the opening of the American Medical Association general sessions, will be open to all physicians. The meeting will be devoted to a discussion of compulsory health insurance plans for medical care and disability compensation.

CONFERENCE OF COUNTY MEDICAL SOCIETY OFFICERS

The fifth national Conference of County Medical Society Officers will be held in the Rose Room of the Hotel Tray-

more, Atlantic City, on Sunday, June 5. The conference will consist of three panel discussions on emergency calls, local places for medical care of the indigent and the national health campaign. At a session in the Trimble Room of the Claridge Hotel, Atlantic City, at 8 p.m., Mr. Clem Whitaker, director of the National Education Campaign of the American Medical Association, and the Honorable John L. McClellan, United States Senator from Arkansas, will be the speakers.

AMERICAN SOCIETY FOR THE STUDY OF STERILITY

The fifth annual conference of the American Society for the Study of Sterility will be held at the Hotel Strand, Atlantic City, on June 6 and 7. The two-day program will be divided into general discussions on the physiology of the uterus, new and known facts concerning reproduction and recent advances in reproduction and a round-table discussion on male sterility.

Additional information may be obtained from the program chairman (Dr. Fred A. Simmons, 330 Dartmouth Street, Boston 16, Massachusetts), the local arrangements chairman (Dr. Abner I. Weisman, 1160 Fifth Avenue, New York City) or the registration secretary (Dr. Walter W. Williams, 20 Magnolia Terrace, Springfield, Massachusetts).

INTERNATIONAL ACADEMY OF PROCTOLOGY

The first meeting of the International Academy of Proctology will be held at the Marlborough-Blenheim in Atlantic City, New Jersey, on Friday, June 10.

The scientific portion of the program will consist of the presentation of papers and motion-picture films of interest to all physicians as well as to those specializing in proctology.

Further information and a copy of the program may be obtained by application to Dr. Alfred J. Cantor, International Academy of Proctology, 43-55 Kissena Boulevard, Flushing, New York.

(Notices concluded on page xv)

not change. Symptomatically he was slightly improved on discharge.

He was not seen again at the Massachusetts General Hospital, failed progressively after discharge and died in July, 1945. No autopsy was performed, and the nature of the terminal illness is unknown.

CASE 3 C McC (M G H 324826), a 44-year-old married man, was first seen in October, 1941, complaining of intermittent claudication. A diagnosis of thromboangitis obliterans was made, and a left lumbar sympathectomy performed. Three routine urine specimens were entirely normal, the specific gravities varied between 1.002 and 1.014. A bi-

and duodenum. The bones of the hands and skull were normal. In the abdomen there was extensive calcification of both iliac arteries and calcification in the region of both kidneys, probably in the renal arteries, and in the aorta.

On a low calcium diet and high fluid intake the patient was much better subjectively, and the pruritus diminished remarkably. Coincident with the clinical improvement the serum calcium fell to 11.4 mg and the nonprotein nitrogen to 52 mg per 100 cc.

In May, 1947, on a follow-up visit, the serum calcium was 10.6 mg, the phosphorus 2.3 mg, and the nonprotein nitrogen 64 mg per 100 cc. During several visits between December, 1947, and February, 1948, the serum nonprotein ni-

*Glomerular filtration rates were measured with mannitol in Cases 4 and 5 and with inulin in Case 6. Effective plasma flow and maximal tubular excretory capacity were determined with sodium para amino hippurate. (We are indebted to Dr W P Boger of Sharp and Dohme Inc. for generous supplies of mannitol and sodium para amino hippurate.)

opsy taken from the left kidney at the time of operation revealed normal renal tissue.

The patient had been told 25 years previously that he had a peptic ulcer. Since then milk and antacids had been frequently employed to control symptoms.

In May, 1943, he entered another hospital in uremia. A serum nonprotein nitrogen of 198 mg per 100 cc, a low urine specific gravity and a + test for albumin were reported at this time. With parenteral administration of fluids he improved and was discharged.

In November, 1946, the patient again entered the Massachusetts General Hospital because of exacerbation of ulcer symptoms, nervousness, fatigue, nausea and intractable pruritus. He had continued to take large quantities of milk and variable amounts of alkalis.

Physical examination showed a thin haggard man with a sallow complexion. The eyes disclosed band keratopathy and normal fundi. The only arterial pulsation palpable in either leg was that of the right femoral artery. The left arm and leg were warmer than the right. The blood pressure was 175/105.

Routine urinalysis demonstrated a maximal specific gravity of 1.011, a ++ test for albumin and a pH of 6.0 to 7.5. The sediment contained rare hyaline and granular casts and occasional red cells and white cells. Urine cultures revealed a moderate growth of *Staphylococcus albus* and *aureus*, but were negative for pleuropneumonia-like organisms. The urine calcium excretion was 109 mg per 24 hours. The results of renal-function studies are presented in Table 1.

Examination of the blood showed a red-cell count of 4,050,000 with a hemoglobin of 10 gm and a white-cell count of 9800, with a normal differential. The serum calcium was 12.4 to 12.8 mg, inorganic phosphorus 5.5 to 6.6 mg, nonprotein nitrogen 90 mg and alkaline phosphatase 7.2 Bodansky units per 100 cc. The chloride was 90 to 105 milliequivalents and the carbon dioxide content 30 to 35 milliequivalents per liter, and the total protein 7.7 gm per 100 cc, with an albumin of 4.96 gm and a globulin of 2.12 gm. Gastric analysis disclosed 4 units of free and 11 units of combined hydrochloric acid.

A gastrointestinal series gave evidence of an old duodenal ulcer, probably still active, with accompanying gastritis,

trogen was 48 to 75 mg, calcium 10.6 mg, phosphorus 2.0 to 2.3 mg, and alkaline phosphatase 3.0 to 3.4 Bodansky units per 100 cc, and the carbon dioxide content was 37.3 milliequivalents and the chloride 107 milliequivalents per liter. The results of laboratory studies between November 1946, and February, 1948, are presented in Figure 1. When last seen in February, 1948, the only symptoms were those referable to an obstructing duodenal ulcer. The patient had remained on a low milk and alkali and high fluid regimen since discharge.

CASE 4 T W (J H H 204618), a 38-year-old physician, entered the hospital in July, 1940, for surgical therapy of intractable ulcer symptoms. He had had symptoms of peptic ulcer, which had begun while he was in medical school in 1928. There was then a period during which he was relatively asymptomatic until 1937, when symptoms recurred and x-ray examination demonstrated a duodenal ulcer. From this time until admission he took 6 or more teaspoonfuls of sodium bicarbonate and drank 2 or 3 quarts of milk daily. Two years prior to admission nocturia and polyuria had begun and had been increasing. He had never had symptoms of nephrolithiasis.

Physical examination showed normal fundi, with conjunctival crystals and band keratopathy bilaterally. The blood pressure was 140/80.

Routine urinalysis was entirely negative. The urea clearance was 16 per cent of normal. The phenolsulfonephthalein excretion was 8 per cent in the first 1/2 hour, and 28 per cent in 2 hours. The serum nonprotein nitrogen was 78 mg, calcium 12.5 and 12.7 mg, phosphorus 6.5 and 7.3 mg, and protein 6.5 and 6.8 gm per 100 cc, and the carbon dioxide combining power was 26.8 milliequivalents, and the chloride 100 milliequivalents per liter.

A gastrointestinal series demonstrated a duodenal defect characteristic of ulcer.

Parathyroid exploration was carried out on July 10, and enlargement of all four parathyroid glands was found. Three glands and about three quarters of the remaining one were removed. The pathological diagnosis was hyperplasia of the chief and chief types. On July 24 hypercalcemia was still present, the blood calcium determination being 13.5 mg per 100 cc. The serum phosphorus was 5.9 mg per 100 cc.

An exploration for parathyroid adenoma was carried out. Three parathyroid glands were located, which on biopsy proved to be normal.

During the next 2 years the patient again remained on a low calcium intake and took no alkali. He re-entered the hospital in June, 1942, because of bleeding from the duodenal ulcer. Laboratory studies were essentially the same as those on previous admissions, with the addition of a serum sodium of 135 milliequiv per liter. A plain x-ray film of the abdomen showed small kidneys and areas of calcification in the lower pole of the left kidney.

The fifth admission, in October, 1943, was for another episode of bleeding from the ulcer. Urinalysis demonstrated a +++ test for albumin. The serum calcium was 10.1 mg, the phosphorus 10 mg, and the total protein 8.6 gm per 100 cc, the chloride was 71.7 milliequiv, and the carbon dioxide content 25.6 milliequiv per liter. X-ray films of the bones were normal.

The final admission was in April, 1944, terminating in death from renal insufficiency. Laboratory studies performed shortly before death revealed a serum calcium of 7.7 mg and a phosphorus of 9.4 mg per 100 cc, a phosphatase of

There had been no urinary symptoms except nocturia, (twice) for about 2 years. Urinalysis 20 months before admission had shown a slight trace of albumin.

Physical examination revealed a very emaciated young man with marked atrophy of the skin and muscles. The eyes were prominent, and the corneas demonstrated changes consistent with band keratopathy. The fundi were normal. The skin was dry and scaly, with brownish pigmentation over some of the keratotic areas. The blood pressure was 88/70.

Routine urinalysis disclosed a maximal specific gravity of 1.008 and a +++ test for albumin, with a pH 6.5 to 7.5. The sediment contained white cells, frequently in clumps, and occasional granular casts. Urine cultures showed a moderate growth of *Staphylococcus aureus* and colon bacilli in one, and no growth in another. Phenolsulfonephthalein excretion was 3 per cent in 1 hour. The Sulkowitch test demonstrated no calcium. A test for Bence-Jones protein was negative. The urinary 17-ketosteroid excretion was 27 and 3.0 mg per 24 hours.

Examination of the blood revealed a red-cell count of 2,250,000 with a hemoglobin of 45 per cent, and a white-cell count

LOW CALCIUM, PHOSPHORUS, and ALKALI INTAKE

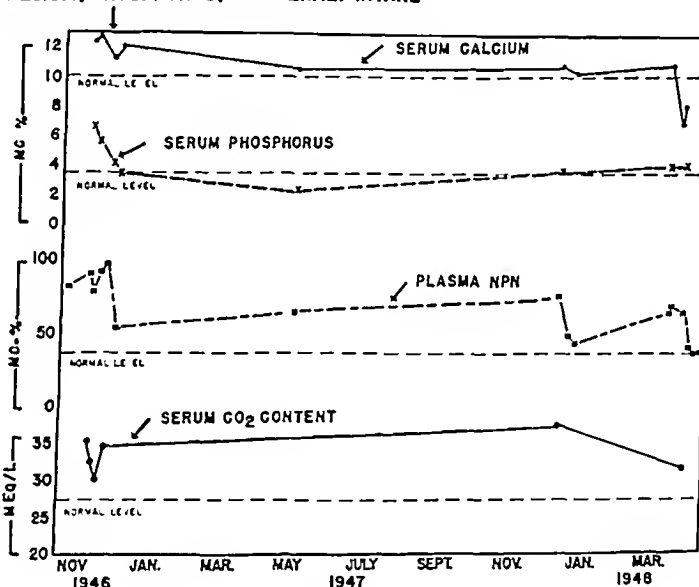

FIGURE 1 Laboratory Findings in Case 3

18.0 Bodansky units and a chloride of 84 milliequiv, a sodium of 128 milliequiv and a carbon dioxide content of 9.5 milliequiv per liter. The nonprotein nitrogen was 150 mg and the total protein 7.87 gm per 100 cc, with 5.17 gm of albumin and 2.70 gm of globulin.

The diagnoses at autopsy were as follows: chronic pyelonephritis, nephrocalcinosis, calcification of the dura mater, diaphragm, costal cartilages, tendons and blood vessels, bronchopneumonia of all lobes, gastric ulcer, well healed, and prostatic abscess. No parathyroid glands were found, but it is not known whether a careful search for them was made.

CASE 2 A C (M G H 267258), a 25-year-old man, first entered the hospital in September, 1940, complaining of vomiting and eructations for 2 1/2 years. Epigastric pain relieved by food and soda had started while he was a senior in college and worrying about examinations. A milk and alkali regimen was prescribed, and until his admission, because of persistent gastrointestinal symptoms, he was almost constantly on such a program. He had lost 50 pounds since the onset of his illness. Repeated x-ray films of the gastrointestinal tract were reported to have shown no abnormalities.

of 8500, with a normal differential. There was marked variation in the size and shape of the erythrocytes. The serum calcium was 12.0 to 12.8 mg, the alkaline phosphatase 2.8 to 6.8 Bodansky units, the protein 7.1 gm, the nonprotein nitrogen 85 mg, the cholesterol 184 mg, and the fasting blood sugar 83 mg per 100 cc. The carbon dioxide combining power was 23.3 to 30.2 milliequiv, and the chloride 89 to 95 milliequiv per liter. The basal metabolic rate was -6 per cent. In the sternal bone marrow there was no evidence of leukemia or multiple myeloma.

A gastrointestinal series gave no evidence of disease. X-ray films of the long bones showed extensive periosteal new bone formation about the humeri, radii, metacarpals, pelvis, femora, tibiae, fibulae, tarsals, and metatarsals. Films of the skull demonstrated extensive calcification of the tentorium, the falx and the dura over the cerebral hemispheres. In the chest there was extensive calcification of the bronchial tree. On a plain film of the abdomen, the kidneys were poorly outlined but appeared smaller than normal, without unusual areas of calcification within them.

On a low calcium diet the serum calcium fell to 11.2 mg, and the nonprotein nitrogen to 40 mg per 100 cc, the phosphorus, chloride and carbon dioxide combining power did

with 311 gm of albumin and 154 gm of globulin, the calcium 10.9 mg, the phosphorus 2.7 mg, and the alkaline phosphatase 3.66 Bodansky units per 100 cc. The carbon dioxide content was 29 milliequiv, the chloride 103 milliequiv, the sodium 135 milliequiv, and the potassium 4.1 milliequiv per liter.

In June a posterior gastroenterostomy was performed because of recurrent pyloric obstruction. The patient withstood the operation well. Laboratory studies shortly before discharge disclosed a serum nonprotein nitrogen of 71 mg, calcium of 9.1 mg, and phosphorus of 2.7 mg per 100 cc, with a carbon dioxide content of 29 milliequiv and a chloride of 96 milliequiv per liter.

He has remained relatively asymptomatic since discharge.

CLINICAL FEATURES

The clinical features of these cases are shown in Table 2 and 3. All 6 patients gave a similar history of having suffered symptoms characteristic of peptic ulcer for many years, in excess of ten years with the exception of 1 patient (Case 2), who had had symptoms for only two years. In 4 cases duodenal ulcer was demonstrated by x-ray examination, in a fifth (Case 5) the presence of a peptic ulcer seems almost certain although the diagnosis was never definitely established by x-ray study.

Treatment of each patient had consisted of almost continuous ingestion of large quantities of milk and absorbable alkalis, usually sodium bicarbonate, for periods of a few to many years. Nephrolithiasis had occurred in 1 case several years previously (Case 1). In 2 patients (Cases 5 and

with hypercalcemia from any cause, and have been described in a previous report,¹² which includes Cases 1, 2, 3 and 4 in this series. Cases 1, 2, 3, 5 and 6 will also be included in another report now in press.¹³ In brief, these changes are of two types. In one there are corneal changes consisting of hazy, granular and subepithelial deposits running con-

6), there was a history of previous hypertension. In no case was there a history suggestive of preceding acute glomerulonephritis or pyelonephritis.

The primary complaints were exacerbation of ulcer or gastrointestinal symptoms in 4 cases, intractable pruritus in 1 and arthritic complaints in 1. Pruritus was an important secondary complaint in 3 others.

A moderate hypertension was present initially in 5 patients, and as the disease progressed, the physical findings usually became the expected ones of hypertension and renal failure.

Early in the course, the physical finding that was most striking and the only one common to all patients was that found in the eyes (Table 3^{12, 14}). The ocular lesions were believed to be associated

sumably a calcium salt beneath the conjunctival membrane. In all patients in the present series, band keratopathy was demonstrated, in 2 the conjunctival lesions were also present.

The combination of elevated serum calcium and a slightly elevated or normal serum phosphorus present in this syndrome theoretically should favor metastatic calcification. In addition to those uniformly present in the eyes, such changes were present elsewhere in 5 of the 6 patients, but they were extremely irregular in their anatomic distribution (Table 3). They varied from widespread soft-tissue calcification (subcutaneous, lungs and falx cerebri) to a few calcified mesenteric lymph nodes.

In 2 patients significant abnormalities of the bones were demonstrated. extremely dense can-

At the next admission, on October 30, the patient felt very much better and had been carrying on an active practice. The serum calcium was 12.2 mg, and the phosphorus 4.5 mg per 100 cc. The nonprotein nitrogen had fallen to 45 mg per 100 cc. He now had a secondary anemia that had not been present on the first admission.

When next seen in March, 1942, he was improved in every respect. He had no further symptoms of ulcer, and had remained on a milk-free diet without alkalis. Nocturia had diminished from five times to two times. For 2 months he had noticed tingling in the toes if pressure were made on the posterior aspects of the thighs. Trousseau's sign was positive in 90 seconds, although Chvostek's sign was negative. These symptoms of tetany were relieved by calcium acetate. The conjunctival lesions had partially cleared.

Laboratory studies demonstrated a serum nonprotein nitrogen of 52 mg, calcium of 6.4 mg, phosphorus of 6.4 mg and protein of 6.0 gm per 100 cc. The carbon dioxide combining power was 20 milliequiv, and the chloride 107 milliequiv per liter.

The patient was seen again in 1944, when retinal hemorrhages and narrowing of the retinal arteries had developed. The blood pressure had risen to 150/100. The phenolsulfonephthalein excretion was 10 per cent in the first 30 minutes, the serum nonprotein nitrogen was 64 mg per 100 cc. The calcium and phosphorus values were unchanged. The blood showed a moderate anemia.

By October, 1946, there was marked progression of the renal disease and evidence of congestive heart failure. The blood pressure was 140/100. The nonprotein nitrogen ranged between 145 and 160 mg per 100 cc. The serum calcium was 7.5 mg, the phosphorus 7.7 mg, and the protein 5.6 gm per 100 cc.

The patient died in January, 1947, an autopsy was not performed.

CASE 5* E McD (W R V A H 12467), a 55-year-old carpenter, first entered the hospital in September, 1946. One grandmother was an American Indian.

He had had symptoms and x-ray signs suggestive of ulcer since 1930 although a definite x-ray diagnosis had never been made. Treatment had consisted almost continuously of 4 or 5 quarts of milk daily and large quantities of sodium bicarbonate. Hypertension had been noted in 1930. For 5 years he had had nocturia (once or twice,) and dribbling of urination. He had complained of aching of the ankles, knees and hips for 4 years, for 6 months the ankles and lower legs had been swollen. A prominent secondary complaint was severe generalized pruritus. He had never been given vitamin D for his arthritic complaints.

Physical examination revealed an elderly appearing man whose skin was dark brown. Dime-sized, movable, firm, subcutaneous nodules were noted on the extensor surface of the forearms. Examination of the eyes disclosed white plaques on the conjunctivas and crystalline opacities along the medial edge of the corneas, there was tortuosity of the vessels of the fundi and arteriovenous nicking. A Grade II systolic murmur was heard in the aortic area. Edema of the feet, ankles and lower legs was present. The prostate was enlarged. The blood pressure was 150/80.

Routine urinalyses demonstrated a maximal specific gravity of 1.011 and a +++ to ++++ test for albumin. The sediment contained occasional white cells and red cells. The phenolsulfonephthalein excretion was 5 per cent in 1 hour. Examination of the blood showed a hemoglobin of 10.0 gm and a white-cell count of 7100, with a normal differential. The serum calcium was 11 to 14 mg, the phosphorus 4.1 to 5.9 mg, the nonprotein nitrogen 89 to 100 mg, the total protein, 7.6 gm, with 4.68 gm of albumin and 2.92 gm of globulin, and the cholesterol 320 to 550 mg per 100 cc.

A gastrointestinal series was normal. X-ray films revealed cancellous bone and a very dense skull and long bones. The falx, cerebrum and soft tissues of the knees, elbows, hands and lungs were calcified. Retrograde pyelograms disclosed slight clubbing of the calyces of the kidneys.

An electrocardiogram demonstrated myocardial disease, with right bundle-branch block and auriculoventricular block, probably on the basis of arteriosclerotic heart disease.

The patient was discharged on December 7, on a low protein and low salt diet. During the next 6 months clinically his condition remained essentially unchanged, neces-

sitating three readmissions during April, May and June, of 1947, with the same general complaints. It is questionable whether during this period he adhered to his diet, and hence whether his milk and alkali intake was much reduced.

Between April and July routine urinalyses were unchanged. The urinary calcium was 77.8 and 77 mg per 24 hours. The results of renal-function studies are presented in Table 1.

Examination of the blood showed a red-cell count of 4,300,000, with a hemoglobin of 73 per cent. The serum nonprotein nitrogen was 90 to 137 mg, the calcium 10.8 to 12.8 mg, the phosphorus 4.2 to 5.4 mg, the alkaline phosphatase 3.2 to 5.9 Bodansky units, and the cholesterol 415 mg per 100 cc. The chloride was 91 to 101 milliequiv, and the carbon dioxide content 32 milliequiv per liter. A biopsy of a subcutaneous nodule demonstrated calcified material embedded in large areas of dense fibrous tissue. A bone biopsy revealed dense cortical bone of normal architecture, with granular basophilic deposit in the periphery of the Haversian canals.

From July, 1947, to June, 1948, the patient was maintained on a regimen low in milk, sodium and protein. Subjectively he was somewhat improved, but continued to complain of joint pains, weakness and pruritus. On readmission in June, 1948, the physical findings were unchanged. There was also no change in the urine or in renal function (Table 1). The serum nonprotein nitrogen was 125 mg, the calcium 10.7 mg, and the phosphorus 2.8 mg per 100 cc, the chloride was 110 milliequiv, the sodium 138 milliequiv, and the potassium 4.3 milliequiv per liter. The protein was 7.2 gm per 100 cc, with 4.39 gm of albumin and 2.81 gm of globulin.

He was not seen again in the hospital and died at home in December, 1948. The nature of his terminal illness is unknown. Permission for autopsy was not obtained.

CASE 6 M J L (E M H 329,496), a 54-year-old fireman, was admitted to the hospital in January, 1948, because of hematemesis. Ulcer symptoms had been present for over 30 years, and treatment had almost always included several quarts of milk daily and large quantities of sodium bicarbonate. In November, 1946, the diagnoses of active duodenal ulcer and chronic nephritis had been made at the Massachusetts General Hospital.

The past history revealed a heavy alcoholic intake. Nocturia (up to five times) had been present for 5 years, and mild pruritus for 2 years. The right eye had been removed at the Massachusetts Eye and Ear Infirmary in 1945 because of changes secondary to glaucoma and chorioretinal degeneration.

The blood pressure was 130/70 after the initial hypotension due to blood loss had been relieved. The left cornea showed band keratopathy, the fundus was normal.

Routine urinalyses demonstrated a maximal specific gravity of 1.016, no albumin and a normal sediment. The results of renal-function studies are presented in Table 1. The hemoglobin was 10 gm per 100 cc. The white-cell count and differential were normal. The stools were guaiac positive during the 1st week of hospitalization. On admission the nonprotein nitrogen was 131 mg, the calcium 11.5 mg, the phosphorus 4.6 mg, and the alkaline phosphatase 4.4 Bodansky units per 100 cc, and the carbon dioxide content was 33 milliequiv, and the chloride 95 milliequiv per liter.

A gastrointestinal series revealed a duodenal defect consistent with peptic ulcer. An x-ray film of the abdomen disclosed an area of irregular density at the level of the fourth lumbar vertebra, probably representing calcified mesenteric nodes.

The bleeding stopped spontaneously, and the pyloric obstruction was treated with gastric suction. While the patient was on suction considerable alkalosis developed, with a serum carbon dioxide content of 38 milliequiv per liter and a chloride of 89 milliequiv per liter. After relief of the obstruction and parenteral administration of physiologic saline solution and the serum carbon dioxide content fell to 27 milliequiv, and the serum chloride rose to 106 milliequiv per liter, and the serum nonprotein nitrogen stabilized at 60 to 80 mg per 100 cc. He was discharged on a low milk and alkali regimen considerably improved.

In March, 1948, he was readmitted for further renal-function studies. Physical examination was unchanged. Examination of the urine was also unchanged. The results of renal-function tests are presented in Table 1. The serum nonprotein nitrogen was 62 mg, the total protein 4.64 gm,

*We are indebted to Dr A. S. Zdanis for asking us to study this patient.

explanation because of certain atypical features of the syndrome, no one of which is insurmountable but which taken as a group could hardly be explained by primary hyperparathyroidism. These features are lack of hypophosphatemia accompanying the hypercalcemia, lack of hypercalcuria, lowering of the serum calcium on a low calcium intake, and absence of skeletal demineralization or its laboratory manifestation, elevation of serum alkaline phosphatase.

Renal failure associated with hypercalcemia in diseases other than hyperparathyroidism has been observed in acute osteoporosis,¹ hypervitaminosis D,²⁻⁴ sarcoidosis,⁵ myelomatosis,⁶⁻⁸ and generalized carcinomatosis with metastatic bone involvement.⁶ All these conditions seem to have been adequately excluded in this series. A special search was made in each case for a history of excessive intake of vitamin D, none was elicited.

In chronic Bright's disease with uremia, there are usually hypocalcemia, hyperphosphatemia and metabolic acidosis,¹⁶⁻¹⁸ a very different biochemical pattern from that described above.

The possibility that ulcer regimens employing milk and absorbable alkalis adversely affect kidney function has been suggested repeatedly. There is little question that acute alkalosis may cause a temporary and sometimes marked diminution in renal function, and that a subsequent striking improvement may occur after correction of the alkalosis.¹⁹⁻²² Some observers have found no evidence of antecedent renal disease in their patients.²³⁻²⁴ Definite proof that alkalosis can cause any permanent renal damage is still lacking.²¹⁻²²

The present series of cases is somewhat different from previously reported ones, in that no episodes of acute alkalosis with accompanying severe dehydration, hypochloremia and azotemia were known to have occurred. All patients were found to be suffering from chronic renal failure, usually incidental to other complaints. In the 2 patients who are still living and in the 3 who died on whom autopsies were not obtained, the histories gave no evidence of previous renal disease, although 2 were known to have had hypertension. The case in which a post-mortem examination was performed showed a renal lesion diagnosed as pyelonephritis and nephrocalcinosis. From this case alone, one might hypothesize that for the production of the syndrome the presence of underlying renal disease is necessary, on which is superimposed the harmful effect of milk and alkalis on the kidneys. On the other hand in Case 2 urinalyses were normal, as was a kidney biopsy only two years before renal insufficiency developed, so that there is little evidence of antecedent kidney disease in this case. The final answer clearly must await more extensive observations.

The abnormalities of calcium metabolism as evidenced by calcinosis and hypercalcemia are extremely puzzling, and no complete explanation

for them is evident from our data. Hypercalcemia has previously been observed during episodes of acute alkalosis associated with excessive intake of alkalis and calcium.²⁴⁻²⁵ To our knowledge cases of prolonged hypercalcemia and renal failure such as those observed in this series have not been recorded. The absence of hypercalcuria and the lowering of the serum calcium level following low calcium intake suggest an interference with the renal excretion of calcium. The exact mechanism of this interference with excretion cannot even be speculated upon until the normal mechanisms for the renal excretion of calcium are elucidated.

The mechanism of a slight persistent alkalosis after relief of vomiting and withdrawal of alkali is equally difficult to explain. There may have been, of course, vomiting or alkali ingestion of which we were unaware when the high serum carbon dioxide contents were observed, but this explanation seems unlikely. When serum sodium determinations were done they were normal or slightly low, and the alkalosis was not invariably accompanied by hypochloremia. The association of intracellular potassium deficiency and alkalosis suggests itself.²⁶⁻²⁸ However, there is no reason to believe that there was such a deficiency in any of these patients, and the serum potassiums when measured were normal.

The observation of high serum proteins with the elevation chiefly in the albumin fraction is also most unusual. They were determined in several different laboratories, by the usual Howe technic, and appear consistent enough to exclude artifacts or errors in measurement.

Each of these patients showed evidence of improvement after institution of low milk, low alkali and high fluid intakes. Subjectively they felt better, chemically, the azotemia diminished in all patients, and hypercalcemia diminished in the 5 cases in which it was demonstrated. This therapeutic response strengthens our conviction that the deranged homeostasis was in some manner associated with the excessive ingestion of milk and alkalis.

SUMMARY

A syndrome observed in 6 male patients, all of whom gave the common history of peptic ulcer or ulcer symptoms treated by excessive intake of milk and alkalis for many years, is described.

The syndrome is characterized by a history of prolonged and excessive intake of milk and absorbable alkali, hypercalcemia without hypercalcuria or hypophosphatemia, normal serum alkaline phosphatase levels, marked renal insufficiency with azotemia, mild alkalosis, calcinosis manifested especially by an ocular lesion resembling band keratitis, and improvement on an intake low in milk and absorbable alkali.

Although primary hyperparathyroidism could not be excluded positively in all patients, the evi-

cellous bone in Case 5, and extensive periosteal new bone formation in Case 2. The bones in the remaining 4 cases were normal.

Four patients have died, the other 2, although they still show evidence of renal insufficiency, remain symptomatically improved.

LABORATORY FINDINGS

The laboratory findings are summarized in Table 1 and 4. The biochemical abnormalities in the blood and urine were usually unsuspected and always puzzling. In general they were at first inspection those of advanced renal insufficiency,

TABLE 4 Summary of Laboratory Findings

FINDING	No. of Cases
Renal insufficiency	6
Azotemia	
Fixed urinary specific gravity	
Depression of renal function tests	
Hypercalcemia	5
No hypercalcuria	5
Mild alkalosis	5
Albuminuria	3

but with definite differences from the pattern usually seen in uremia.

Azotemia was always present, the nonprotein nitrogen level varied from 50 to 150 mg per 100 cc. Under treatment the nitrogen retention usually diminished.

Definite hypercalcemia was present in 5 patients, the serum calcium level varying between 12.0 and 14.5 mg per 100 cc. In Case 6 only a moderate hypercalcemia was demonstrated (11.2 mg per 100 cc) after the patient came under observation. However, in several of the other patients, the serum calcium fell as renal failure progressed. We have assumed that a more severe hypercalcemia had been present in the past in this patient since he showed all the other characteristics of the syndrome.

The serum phosphorus typically was normal or high, varying from 3.0 to 7 mg per 100 cc. Except for a terminal level of 10 mg in Case 1, none of the patients ever exhibited the degree of hyperphosphatemia usually present in uremia, nor was the hypophosphatemia of hyperparathyroidism present at the time when the serum calcium was elevated. Another puzzling feature of the syndrome is the fall in serum phosphorus in some cases after withdrawal of milk and alkali. Thus, in Cases 3 and 5, although the serum calcium levels fell from 12.8 and 14 to 10.6 and 10.7 mg per 100 cc respectively, the serum phosphorus levels fell from 6.6 and 5.9 to 2.0 and 2.6 mg per 100 cc respectively. In Case 5 (in which only moderate hypercalcemia was demonstrated), the serum calcium levels remained at 11.5 and 10.9 mg per 100 cc, whereas the serum phosphorus levels fell from 4.6 to 2.7

mg per 100 cc. It appears that the high phosphate, as well as the high calcium content, of milk is a factor in this syndrome.

Urinary calcium excretion was not shown to be increased by quantitative measurements in 3 patients or by the Sulkowitch test in 2.

Instead of the acidosis (as evidenced by low serum carbon dioxide content) usually seen in renal insufficiency, 5 patients had at some time slightly high carbon dioxide contents of the serum, ranging from 30 to 36 milliequiv per liter. At times this was associated with alkali ingestion and vomiting, but the tendency toward alkalosis occasionally persisted so far as could be determined even after these factors had been removed. In 1 fatal case (Case 1) acidosis eventually developed during the terminal phase of the illness.

The serum protein levels were not so low as might have been expected in view of the degree of renal insufficiency present, indeed, in 3 patients (Cases 1, 3 and 5) actual hyperproteinemia was demonstrated. On fractionation this elevation appeared to be chiefly in the albumin in each case.

Albuminuria was present in all but 1 patient. The urinary sediment contained no abnormal constituents in 2 patients, in the other 4 it contained occasional to rare hyaline and granular casts, infrequent red cells and occasional to many white cells. Urine cultures were negative in 1 patient, grew *Staph aureus* and *Esch coli* in 1 and *Staph aureus* and *albus* in 1, and were not done in 3 patients.

The results of the various renal-function measurements, which are presented in Table 1, indicated advanced renal disease. Ability to concentrate the urine was uniformly absent. From the renal clearances in 3 patients it is apparent that all portions of the nephron were impaired. The high filtration fraction and the high ratio of glomerular filtration rate to maximal tubular excretory capacity suggest relatively greater insufficiency of tubular as compared with glomerular function. The recognized limitations of clearance technics in advanced renal disease, however, render such a conclusion only tentative.

DISCUSSION

The presence of primary hyperparathyroidism was suspected in each of these cases. In 1 patient who died the parathyroid glands were not located at autopsy. This is the same patient (Case 1) in whom three years previously normal parathyroid glands had been found at operation. One other patient (Case 4) who was explored showed parathyroid hyperplasia of the chief and oxyphil cell variety thought to be characteristic of secondary hyperparathyroidism.¹⁵ In the other 4 patients it is admittedly impossible to state that primary hyperparathyroidism was not present in addition to renal failure. We have been led to seek another

least 7 gm of solid potassium permanganate, the post-mortem findings and subsequent investigations are judged to have been of sufficient interest to warrant presentation

CASE REPORT

A 21-year-old single woman, pregnant for the second time, entered a general hospital in a state of acute collapse with slight to moderate vaginal bleeding and brownish staining of the perineum. Death occurred about 8 hours later. The total duration of illness was said to have been about 12 hours. The history given by her sister, a nurse, was that the decedent had attempted abortion by douching herself with a solution of potassium permanganate. This solution is said to have been prepared by the addition of about 2 ounces of permanganate crystals to 3 ounces of water.*

Post-mortem examination, conducted 6 hours after death, showed the body of a well developed and well nourished woman of about the stated age. The entire skin surface was a uniform, light-mahogany brown, although prior to the fatal illness, it was learned, the skin had appeared a normal white. The uterus could be palpated as a soft freely movable intra-abdominal mass extending from the pubis almost to the umbilicus. There was focal and confluent superficial hemorrhagic necrosis of intravaginal cervical epithelium, and a small amount of liquid blood oozed from the dilated cervical canal.

On internal examination the principal abnormalities were to be found in the soft and boggy uterus, which measured 18 by 14 by 10 cm and showed a diffusely hyperemic serosal surface. The cervix was soft and flattened in its infero-superior aspect. The os was dilated to about 1.0 cm in diameter. Upon opening, the inner aspect of the uterus showed diffuse superficial hemorrhagic necrosis, the cavity contain-

ing there was focal and confluent hemorrhagic extravasation. The sinusoids were dilated, and in and about them were a few inflammatory cells, chiefly polymorphonuclear. In the cervical epithelium there was focal and confluent erosion

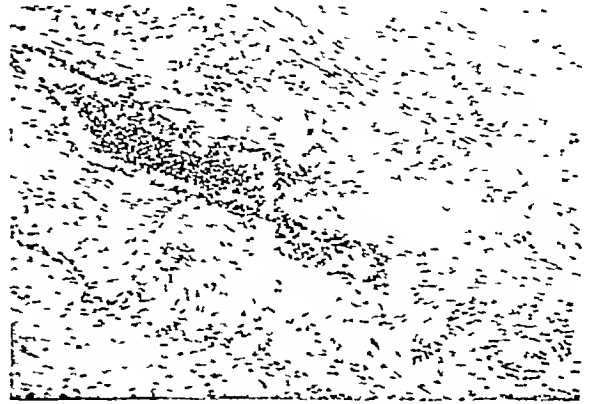

FIGURE 1 Exudative Reaction in a Dilated Vessel of a Superficial Section of the Cervix (Hematoxylin and Eosin Stain $\times 200$)

The superficial cervical stroma contained foci of hemorrhage. There was a marked perivascular and intraluminal (Fig. 1) accumulation of exudative cells, mostly polymorphonuclear leukocytes, in the vessels in this location. This irritative re-

FIGURE 2 Pigment Casts in Lower Portions of the Nephron (P.T.A.H. Stain $\times 50$)

ing masses of purplish-red coagulum. No definite evidence of fetal components could be identified grossly.

The other organs showed nonspecific changes, principally hyperemia. There was no evidence of exsanguination.

On microscopical examination of the uterus the disorganized remnants of a decidual reaction could be identified in the decidua and in the poorly staining superficial myometrium.

*A saturated solution of potassium permanganate contains 6.38 gm. per 100 cc. at 20 C. How much, if any, of the undissolved permanganate was carried along in the process of injecting the solution could not be determined.

action was much more prominent than it was in comparable areas in the uterus. Although the kidneys grossly were not regarded as showing significant changes, microscopical examination revealed the presence of numerous pigmented casts, chiefly in the lumen of the tubules designated as "lower nephron" (Fig. 2). The vasculature were engorged. There was no significant alteration of the tubular epithelium. None of the other viscera showed changes of note except for hyperemia and moderately severe pulmonary edema.

dence, in our opinion, suggests that the abnormalities observed in the calcium and phosphorus metabolisms were a result of the following sequence of events excessive intakes of milk (a foodstuff high in calcium and phosphorus) and alkalis, kidney damage, tendency to fixation in urinary calcium excretion, hypercalcemia, tendency to supersaturation in respect to calcium phosphate, and calcinosis. The improvement resulting from a low intake strongly supports this sequence.

DEATH FROM ATTEMPTED ABORTION WITH A POTASSIUM PERMANGANATE DOUCHE

WALTER W. JETTER, M.D.* AND FRANCIS T. HUNTER, M.D.†

BOSTON

ALTHOUGH potassium permanganate is commonly employed as a disinfectant and deodorant and for local application in the treatment of dermatitis, fatal poisoning from its use is rare. As evidence of this, Green and Warr,¹ in reviewing the literature from 1899-1941, were able to find only 8 fatal cases. On the other hand, these authors reported 31 cases in which potassium permanganate was ingested, none of which resulted fatally. Except in children, the poison was invariably swallowed with suicidal intent, since the intense blue color of even a very dilute solution tends to make disguise difficult.

Within recent years, necrotizing injury of the vagina and cervix due to the use of potassium permanganate tablets (0.3 to 1.0 gm.) as an abortifacient has been reported in increasing numbers of cases, mostly from European countries.²⁻¹⁴ That the practice occurs also in this country has been stressed by McDonough,¹⁵ who reviewed 65 cases,

in all of which admission of the use of potassium permanganate as an abortifacient was sooner or later obtained from the patient. Actually, only 6 patients were successful in the attempt to terminate the pregnancy. The chief clinical evidence was bleeding, which usually occurred within two hours of the insertion of the tablet. Although none of the cases reported by McDonough ended fatally, operative intervention by suturing at bleeding sites was necessary in 10 cases, and in 34 others close packing of the vagina for forty-eight hours was necessary to control the hemorrhage. Twelve patients required treatment for shock, with multiple transfusions. There was no evidence of toxemia that was thought to be attributable to systemic absorption of the chemical itself.

The case presented below is the first to our knowledge in which death has occurred after the use of potassium permanganate as an abortifacient. Although the circumstances are unusual in that the abortive procedure consisted in the intravaginal instillation of what was apparently a saturated solution of potassium permanganate containing at

*Assistant professor of legal medicine, Harvard Medical School, pathologist, Massachusetts Department of Mental Health.

†Associate in medicine, Harvard Medical School, associate physician and clinical pathologist, Massachusetts General Hospital.

reveal the form in which manganese was distributed systemically, it seems highly probable that the compound present in the tissues post mortem was a reduction product of permanganate. This does not necessarily imply that the permanganate molecule as such did not enter the blood vessels during life. Certainly, the local environment was favorable for permanganate to enter the uterine circulation through the widely dilated sinusoidal channels of the richly vascular decidual tissue. Since potassium permanganate acts so quickly, hemolysis may have taken place in the small uterine sinusoids before this blood moved on into the venous circulation.

Apparently, it has not been generally appreciated that permanganate may act as an acute hemolytic agent, although the hemolytic effect of a somewhat similar oxidizing agent, potassium chlorate, is well known. Homma¹⁹ states that permanganate causes methemoglobin formation *in vitro* but not *in vivo*. Palmieri,²⁰ in a fatal case caused by the suicidal ingestion of about 25 gm of potassium permanganate, could not demonstrate methemoglobin in the post-mortem blood*. However, photomicrographs of the kidney of this case showed pigment in the lumen of collecting tubules resembling that seen in the case reported above. Concerning the presence of pigment casts in the kidney, it is probable that our patient would have developed the syndrome of lower-nephron nephrosis had she lived sufficiently long.

The formation of abnormal blood pigments *in vivo* can be brought about in a number of ways, but the particular hemoglobin derivative produced depends on mechanisms not yet well understood. Many chemicals, particularly the aromatic amino and nitro compounds, have the capacity of converting intracellular hemoglobin to methemoglobin without necessarily causing hemolysis. The spectrum of such a blood laked with distilled water *in vitro* shows methemoglobin chiefly in the "neutral" form. On the other hand, intravascular hemolysis may or may not cause the formation of methemoglobin. As examples, a patient recently seen with blackwater fever showed a large amount of "neutral" methemoglobin in the serum whereas in 12 cases of intravascular hemolysis due to the entrance of water into the circulation, not one showed evidence of methemoglobin in the serum; instead, the serum pigments consisted of oxyhemoglobin, alkaline hematin and bilirubin in varying proportions.²¹

The production of methemoglobin by permanganate, however, differs from the foregoing in that both hemolysis and pigment formation are caused by a strong oxidizing agent. With rupture of the red cell, the hemoglobin is freed and is instantly oxidized to methemoglobin. But since the amounts of permanganate used in the animal experiments increased the serum pH to only a slight extent

(maximum, 7.65), it is difficult to see just why such a large proportion of the methemoglobin thus formed was in the alkaline form.

In addition to intravascular hemolysis, other types of systemic intoxication potentially may occur in acute permanganate poisoning. The first of these is hyperkalemia. An increase in plasma potassium may have occurred in two ways in our case

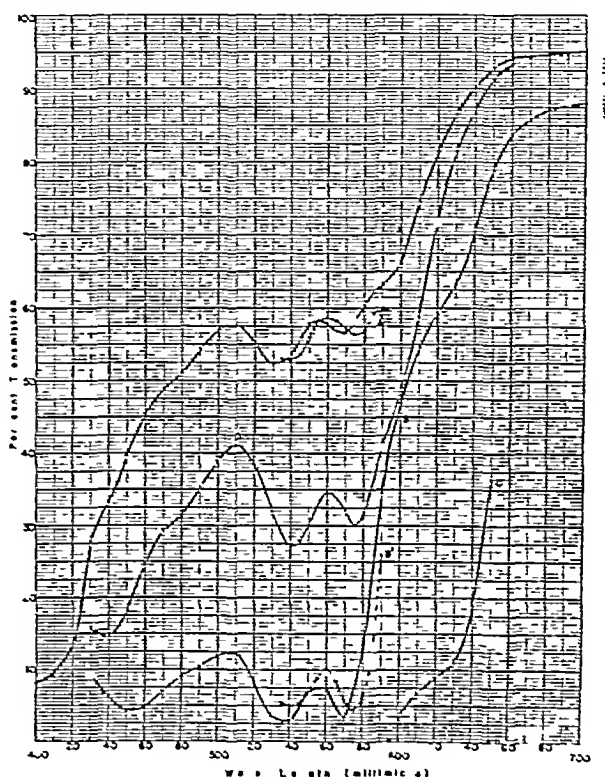

FIGURE 5. Spectrophotometric Transmittance Curves. A and B represent serum from a rabbit injected intravenously with 5.0 cc of 10 per cent potassium permanganate and killed half an hour later, diluted respectively 1:21 with 0.1 per cent sodium carbonate, 1:5 with water and undiluted (wave-band width, 14.0 millimicrons). A and B' demonstrate corresponding curves with a wave-band width of 4.5 millimicrons. D shows pure methemoglobin, 72.5 mg per 100 cc, at a pH of 10.7.

by absorption of potassium ions after breakdown of the permanganate molecule in the reproductive canal, and by the release of potassium incident to intravascular hemolysis. Although it is entirely possible that hyperkalemia contributed to death, we have no objective chemical or other evidence of this. Potassium determinations in post-mortem plasma are unreliable in predicting the ante-mortem level because of the progressive increase in the potassium ion taking place after death.²²

A second possible cause of systemic poisoning is the reduction product, manganese dioxide. Local absorption of this substance is highly limited because of its insolubility. Parenteral administration

*The author demonstrated sulfhemoglobin which is often present in blood after death.

For spectrographic examination for manganese* a specimen of heart blood and about half the uterus were submitted. Samples of these were separately ashed at low temperatures, and the resulting ashes were separately examined on the spectrograph. Manganese was detected in both the specimens, but the spectral lines of manganese from the uterus sample were more intense than those from the blood. A control specimen of normal blood showed very faint lines of the manganese spectrum, evidently representing the small trace of manganese normally present in this material.

The heart blood was fluid and dark purple. On exposure to air it turned to what appeared to be the usual normal red. Upon centrifuging, however, the serum was medium brown. The intensity of the color was far in excess of that which could possibly be accounted for by the presence of manganese dioxide alone. It was decided, therefore, to investigate this pigment further. With a visual (Zeiss) spectroscope, the serum specimen showed two absorption bands of about the same width, — but without sharp margins, — at 540 and 575 millimicrons. These observations were regarded as indicative of the presence of either oxyhemoglobin or alkaline methemoglobin, more likely the latter. The addition of strong sodium hydroxide and a crystal of sodium hydrosulfite (lykapon) produced characteristic bands at 535 and 560 millimicrons of hemochromogen — indicating that the pigment was a hemoglobin derivative. To establish definitely the nature of this pigment the following experiments were carried out.

In Vitro Experiments

To 10 cc of heparinized normal whole human blood, 0.2 cc of 10 per cent potassium permanganate was added. After centrifugalization, the plasma showed a deep brown color, and on comparison with an untreated specimen of the same blood, the hematocrit value was reduced from 44 to 35 per cent, indicating a hemolysis of approximately 20 per cent.

To normal human blood diluted and laked with distilled water, a drop of dilute potassium permanganate was added. This instantaneously converted the oxyhemoglobin to a brownish-red pigment, showing absorption bands at 540 and 575 millimicrons, *similar in all respects to those observed in the serum of the decedent*. Moreover, in a concentrated solution, a faint but definite absorption band was seen at 630 millimicrons. Upon reduction with crystalline sodium hydrosulfite (lykapon), this pigment was converted to reduced hemoglobin. These observations were explicable only if the brownish-red pigment were alkaline methemoglobin with merely a trace of the "neutral" form. Since methemoglobin in aqueous solution behaves as an indicator, both forms (neutral and alkaline) are present in varying proportions at pH values between 5 and 10. That the pigment was *not* hematin was shown by its reduction to reduced hemoglobin rather than to hemochromogen.

In Vivo Experiments

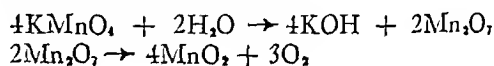

Rabbits were injected via the ear veins with a 1 per cent solution of potassium permanganate in amounts ranging from 1 to 5 cc. Immediately after injection the ear veins were outlined by a brownish discoloration, and in the animals allowed to survive, these veins became thrombosed and ischemic necrosis resulted. After injection there was an initial short period of minor collapse, but with this exception the clinical course of these animals was uneventful. In 2 animals killed at the end of 1 and 2 weeks there was no evidence of pathologic change. The kidneys of animals killed 24 hours after injection, however, showed pigment casts in the lumens of many tubules.

Serum was obtained from animals killed at periods ranging from 30 minutes to 2 days after injection. In all cases, alkaline methemoglobin was the principal abnormal pigment present. Continuous transmission curves made in the spectral region between 400 and 700 millimicrons showed the presence of alkaline methemoglobin, with only a trace of methemoglobin in "neutral" form. These curves are demonstrated in Figure 3. The steep rise of the transmission curves as they approach the longer wave lengths and the bands at 540 and 575 millimicrons are produced by alkaline methemoglobin. However, the slight "plateau" at 630 millimicrons is caused by the neutral form of the pigment. Although the pH of the serum in all cases was

considerably below 8.0, spectrophotometric quantitation showed over 90 per cent of the pigment to be in the alkaline form. At present no explanation of this observation can be offered.

DISCUSSION

Potassium permanganate is a strong oxidizing agent reacting promptly with protoplasm and most organic material, and at the same time undergoing reduction to the brown, almost completely insoluble oxides of manganese. Brown staining of tissues due to the formation of this oxide at sites of reaction may be regarded as pathognomonic of the injury produced by permanganate. Since the interreaction of the chemical and tissue is so prompt, the local necrotizing effect of permanganate is initially confined superficially to the site of surface contact. Further corrosive injury due to the formation of potassium hydroxide may take place, however, assuming that the reaction given below is a representative one.

A characteristic of a strong alkali is to penetrate into deeper tissues, leading to progressive injury. Death in the case reported above probably occurred too soon for significant manifestations of potassium hydroxide penetration to take place. Two fatal cases of permanganate poisoning cited in the literature, however, may demonstrate the occurrence of deep-seated damage by secondarily formed potassium hydroxide. In 1 case¹⁶ death occurred several days after permanganate ingestion from erosion of a gastric vessel and subsequent fatal acute hemorrhage. In the other,¹⁷ after intra-urethral instillation of 200 cc of 10 per cent potassium permanganate solution, perforation of the urinary bladder occurred and finally death from peritonitis. In some of the nonfatal cases described by McDonough,¹⁵ scar-tissue deformation of vagina and cervix occurring as late complications are more easily explained by the deep-seated injury due to potassium hydroxide than they are by the more superficial injury caused by the permanganate molecule per se.

After ingestion, the clinical features of permanganate poisoning are those of local corrosive injury. The occurrence of secondary shock when sufficiently large amounts are taken (lethal dose 10 to 20 gm)¹⁵ has usually been regarded as a nonspecific general manifestation of the severe local injury rather than as systemic toxicity of permanganate per se. By the same rationale, no different interpretation is needed to explain collapse following permanganate injury of the reproductive canal.

A critical appraisal of the case presented indicates that, in contradistinction to the conventional opinion, permanganate may act as a systemic poison. Spectrographic examination of heart blood revealed the presence of a manganese compound, suggesting that absorption had taken place. Although the spectrographic examination did not

CLINICAL NOTE

HEREDITARY MULTIPLE EXOSTOSES

JOSEPH ROSE, M D,* AND PAUL D DOOLAN, M D †

WASHINGTON, D, C, AND BOSTON, MASSACHUSETTS

HEREDITARY multiple exostoses are a distinct clinical entity more frequently encountered than is generally appreciated

We have recently had the opportunity of studying 4 members of a Negro family who had the condition. Few cases occurring in Negroes are reported in the American literature.^{1,2} To our knowledge this is the first Negro family studied and reported.

The cases were typical in both the clinical and roentgenologic aspects, varying, of course, in degree. It was our intention originally to include total protein, dextrose tolerance, calcium, phosphorus and other hormonal excretion studies in the investigation. Owing to circumstances beyond our control it was not possible to do so.

CASE REPORT

CASE 1. M C, a 40-year-old Negress, the mother of the family, demonstrated completely asymptomatic growths about the knees with genu valgus. She was unaware of them up to the time x-ray films were taken. Consanguinity was denied and no further genealogy could be elicited. The creatinine excretion was 0.96 gm, and the 17-ketosteroid excretion was 3.9 mg. Both values were low, but their significance, if any, is unknown.

CASE 2. A C, a 19-year-old daughter, first noticed the growths about the knees when 9 years old. There was involvement of the extremities, and full extension of the forearms was not possible. The tumors progressed in size until the age of 13, after which they remained quiescent. She had some aching in the feet and ankles for a week or more after even trivial trauma, but otherwise was completely asymptomatic. A urinalysis, hemogram and blood sugar, alkaline phosphatase, serum calcium and phosphorus determinations were normal. We were unable to obtain total 24-hour urine specimens.

CASE 3. In S C, a 14-year-old son, the exostoses first appeared at the age of 6 and had continued to increase in size. There was shortening of the forearms, with lack of full extension, as well as some limitation in movement of the legs. The laboratory procedures enumerated above gave normal values.

CASE 4. In S C, a 9-year-old daughter, the protuberances were noted within the past year with seemingly no progression. There were no symptoms.

DISCUSSION

As Ehrenfried⁴ stated, the disease is a distinct clinical entity with the following characteristics: the occurrence of multiple, more or less symmetric cartilaginous and osteocartilaginous overgrowths

within and on the skeletal system, the presence of certain typical distortions and deformities of the skeleton, and the demonstration of inheritance in a large proportion of the cases. The appearance of the knees of the members of the family under discussion is shown in Figure 1.

The hereditary nature of the condition was most extensively studied by Stocks and Barrington,⁵ who reported that out of a total of 1189 cases a definite familial history was elicited in 76.5 per cent, 69.6 per cent of the patients were males. The disease probably cannot be transmitted through an unaffected male but can definitely be transmitted through an unaffected female, and the suppression

FIGURE 1 Photograph of the Family at First Examination

or latency of the disease in one generation does not involve any weakening in the power to transmit it to the next generation. The association of multiple exostoses with multiple enchondromas is more frequent in patients with a hereditary history.

Congenital exostoses and a case discovered shortly after birth have been described,⁵ but, by and large, the condition is mostly frequently detected during the periods of growth up to puberty, and few cases are reported in which the tumors appeared after the age of twenty.

There may be no signs or symptoms so that the condition is detected only on x-ray study, usually for some unrelated condition. In other cases the growths may be visible and palpable but cause no other complaints. In typical cases there are certain characteristics: shortness of stature due to defective growth of the lower extremities whereas the trunk is normal, forearm deformities, including shortening, bending and inability to extend the forearms fully (asymmetry of the extremities may be obvious), and genu valgum (scoliosis, kyphosis and

‡The determinations were made in Dr. Lawrence Kyle's laboratory at Georgetown University Hospital.

leads to convulsive seizures and terminal coma in animals²³—symptoms that did not appear in the fatal case described above

SUMMARY

A case of a twenty-one-year-old pregnant woman who died approximately twelve hours after a potassium permanganate douche used as an abortifacient is presented. So far as can be ascertained, no similar case has been described.

The principal morphologic findings were extensive superficial hemorrhagic necrosis of the uterus, pigmented casts in the collecting tubules of the kidney, and evidence of acute intravascular hemolysis. The blood serum contained alkaline methemoglobin. The skin was discolored brown because of the presence of this pigment in the peripheral vascular bed.

On the basis of this case and of the experimental work reported herein, it is postulated that in acute permanganate poisoning death may be caused by one or any combination of the following processes: circulatory collapse (secondary shock) incident to severe local injury, intravascular hemolysis, hyperpotassemia due to local absorption of potassium ions, and potassium ion release incident to acute hemolysis.

Potassium permanganate in vivo and in vitro leads to lysis of red blood cells and to spontaneous conversion of released hemoglobin to methemoglobin, chiefly in the alkaline form.

Since the above report was written, another almost identical case has come under investigation in which an ante-mortem catheter specimen of urine was deep brown. The pigment showed the spectroscopic characteristics of methemoglobin, it was converted by sodium hydrosulfite to reduced hemoglobin, and then by a strong solution of sodium hydroxide to hemochromogen. This methemoglobin was chiefly in the alkaline form, and spectrophotometric quantitation showed total pigment concentration to be 16.7 gm per 100 cc.

The post-mortem blood was likewise deep brown and showed only about 10 per cent of red cells after centrifuging, and the plasma had the same appearance and gave the same reactions as the urine. Quantitated as alkaline methemoglobin, the plasma concentration was 14.9 gm per 100 cc. Since post-mortem blood samples frequently show high con-

centrations of red cells, this figure (indicating almost complete hemolysis) is not so unreasonable as it seems at first sight. Evidently hemolysis and oxidation of hemoglobin to methemoglobin continued after death.

Although it was impossible in this case to obtain information about the chemical used in the douche, potassium permanganate was doubtless employed since the spectrographic examination of uterine tissue showed definitely a larger amount of manganese than normal.

A COMPARISON OF PTEROYLGLUTAMIC ACID AND LIVER EXTRACT MAINTENANCE THERAPY IN SPRUE*

HERBERT J. FOX, M.D.†

DURHAM, NORTH CAROLINA

THE effects of synthetic folic acid in sprue have been studied by several groups of investigators. Both Darby et al.¹ and Suarez and his associates² reported that the substance had a prompt and dramatic clinical and hematologic effect with remissions comparable or superior to that which follows liver therapy. A daily dose of 2.5 to 5 mg was considered to be adequate although in many cases the periods of observation were brief. Davidson and his co-workers,³ on the other hand, treated 10 cases of sprue with folic acid with only moderately good hematologic results, noting that macrocytosis persisted.

The present report deals with hematologic and certain clinical changes observed in 7 patients with sprue receiving maintenance dosage of synthetic folic acid for a period of at least one year. All these patients had chronic disability in spite of years of nutritional therapy, liver and vitamin supplements. This report deals with an appraisal of the comparative effects of liver and folic acid as maintenance therapy in such cases. Results of fat-balance tests and roentgenographic and biochemical studies are being presented elsewhere.

All patients were white adults native to the Carolinas, and had been under observation at this hospital for a number of years. A report on many of them has appeared in the study made by Hanes.⁴ Careful and continued follow-up observations on this group ranged from four to eighteen years, during which time they were hospitalized for treatment of sprue. All had symptoms and signs typical of the sprue syndrome: recurrent diarrhea, steatorrhea, meteorism, progressive loss of weight, glossitis, anemia and abnormal x-ray patterns of the small intestine. Two to four hospital admissions had been

required because of recurrent relapses during the preliminary time of study. The patients had all returned to the clinic at intervals of three months or less, because of a variety of complaints and disabilities.

Seven patients, 4 of whom were males and 3 females, with chronic sprue were chosen for study. Before the beginning of folic acid therapy, all of them had received prolonged treatment with low-fat diets, various vitamin preparations, and purified liver extract, dosage of 30 units to 60 units, administered parenterally once a week. These measures had failed to restore to normal the weight, stools and blood values.

Two of the patients included in this report were not having diarrhea and had not taken parenteral liver for several months. They were given folic acid because they were underweight, had abdominal distention and lacked a sense of well-being. That folic acid is beneficial in such cases can be noted in Cases 2 and 3 (Table 1).

For more than a year, these 7 patients have been closely observed while receiving synthetic folic acid⁵ orally as the sole specific therapeutic agent. All were rehospitalized for complete fat-metabolism studies and were examined in the clinic once a month. The dosages as well as the hematologic and clinical findings before and after treatment with folic acid are given in Table 1 and 2. The values for the white-cell count and differential formula and reticulocyte percentage were within normal limits in these cases and therefore are not included.

DISCUSSION

Hematologic Features

Table 2 shows the blood values before the start of folic acid therapy compared to the values one

⁵Through the generosity of Dr. Stanton M. Hardy of the Lederle Laboratories we obtained all supplies of synthetic folic acid. Folivite used in this study.

talipes valgus occur, but there is no alteration in the physiognomy)

The patient may have complaints referable to joint interference or pressure phenomena on nerves or blood vessels, or the new growths may cause pain. Growths in the pelvis are a cause of dystocia.

The condition is primarily limited to the long bones, where the tumors may appear anywhere along the bone but are more frequent at the juxta-epiphyseal regions. Furthermore, it has been shown

dromas. The ends of the bones may fail to develop, giving the femur a squared-off shape. When this happens in the radius and tibia there is bowing of the adjacent bone—namely, the ulna and fibula. Synostoses of the upper end of the fibula with the tibia and fusion of the lower end of the ulna with the radius can occur. The Madelung deformity of the radius may be present.

Grossly, the exostoses are firm, lobulated tumors covered by a glistening, fibrous envelope that, on cutting, reveals a thin outermost layer of connective tissue beneath which, and appearing more prominently, is a zone of cartilage. The innermost regions are occupied by bone. Microscopically the surface envelope is seen to be composed of fibrous connective tissue, which in places blends almost imperceptibly with bone, whereas elsewhere it joins the subadjacent cartilage. The cartilage in its deeper layer becomes calcified and may either abut on spicules of laminated bone or merge into a region of cartilage removal and bone deposition. In the latter areas osteoblasts and osteoclasts may be seen. The bone is cancellous in structure, and the interspaces are occupied by fatty marrow.

Malignant degeneration is rare, being more common in cases of the single than of the multiple type.^{6,7} If neoplastic changes arise in the multiple cases they will do so from one growth so that an increase in size in a previously dormant osteochondroma should alert one to the possibility. Osteogenic sarcoma, chondrosarcoma, chondromyosarcoma and spindle-cell sarcoma are the malignant lesions that have been described. Osteogenic sarcoma arising from an exostosis is less malignant and bears a better prognosis than that of the primary type.

Many theories⁷⁻¹⁴ have been put forth in an attempt to explain the etiology. The fundamental cell in exostoses of enchondral or intramembranous origin, as well as enchondromas, is the mesenchymal cell. This cell, depending on the stage of its differentiation when stimulated as well as the duration of stimulation, can give rise to connective tissue, cartilage or bone. The stimuli that may initiate the progress are as follows: hereditary diathesis and defect in bone growth itself, growth, with its concomitant stresses and strains, metaplasia due to alteration in the physicochemical environment induced by hormonal or other metabolic factors, and trauma or infection in certain cases of single growth.

We are indebted to Dr. Charles F. Geschickter, professor of pathology, and Dr. Murray Copeland, professor of oncology, Georgetown University School of Medicine, and Dr. Donald G. McKay, assistant in pathology, Mallory Institute of Pathology, Boston City Hospital, for their help.

that the most actively growing end of the bone bears the brunt of the involvement. The growing ends of the lower-extremity bones are nearest the knee, whereas in the upper extremity they are located at the shoulder and wrist, which explains the frequency of osteochondromas around the knee and their comparative rarity near the elbows.

The characteristic roentgenologic picture is that of numerous osteochondromas in the metaphyseal region of the long bones (Fig. 2). The metaphysis is wider and somewhat longer than normal, and the cortex is thin. The exostoses vary in configuration, usually point in the direction of muscle pull and may arise from a broad base of cancellous bone or from a pedicle. There may be associated enchon-

A progressive gain in weight was enjoyed by 4 patients, 2 showed no essential weight change, and 1 (Case 7) had a marked drop in weight. All but 1 admitted to an improvement in appetite and sense of well-being. Glossitis disappeared within a week. Diarrhea, a persistent complaint in 4 patients, was much better controlled by folic acid than by liver. Within two weeks of starting folic acid, the patients exclaimed upon the decrease in number as well as bulk of stools. Those who had suffered diarrhea at night as well as in the daytime were improved until they could sleep without interruption. Diarrhea ceased completely in 1 severe case. The other patients began to enjoy periods of normal bowel habits alternating with periodic recurrences of diarrhea. Such recurrences were at long intervals and were preceded by ingestion of foods high in fat. The relief of abdominal distention was pronounced in the majority. All patients but 1 were enabled to perform normal work and earn a living. No neurologic disease or evidence of any harmful effect from the folic acid administration was seen. With the exception of Case 7, there were no relapses.

Regarding the chronicity of sprue, it has been our experience that about half the patients go into remission after initial treatment, and remain well for many years. On the other hand, there are a number of patients, like those in this report, whose histories of sprue extend back for several years and who have suffered various degrees of disability. These patients have been difficult to control. They have required close supervision of diet and specific therapy. Prior to the assay of folic acid in this group, purified liver extract given parenterally had been relied upon fairly satisfactorily as the chief mode of control. Injections of 30 to 60 units were given once to three times each week. Exacerbations occurred in the women during pregnancy despite maintenance liver therapy, and relapses were suffered by the men when an attempt to prolong the interval between injections of liver was made.

Folic acid, by comparison with liver extract, has proved to be of equal value, and perhaps superior in some cases, in the treatment of 6 of the 7 patients of this group. These patients followed essentially the same dietary regime while receiving folic acid as when taking liver extract. They were not

given supplemental vitamins, since, in our experience, these have proved worthless. Neither folic acid nor liver extract alone can be expected to be a cure-all in sprue. Folic acid can be given orally. This is a great convenience to the patient. Also, most of them dislike injection therapy.

By definition, the term sprue as used here designates the sprue syndrome as described by Hanes,⁴ and there seem to be no cogent reasons for attempting to differentiate the tropical and nontropical forms.

SUMMARY

Observations on the effects of folic acid given for at least a year to a group of sprue patients are presented. Folic acid has a beneficial effect in general, but does not produce complete remission in all types of cases. The majority of patients gained weight and had less diarrhea. One patient relapsed, with the development of weight loss, diarrhea and glossitis while receiving 60 mg daily. This case, however, was also refractory to purified preparations of liver extract and responded only to crude liver extract given intravenously.

Blood values were not quite so well maintained by folic acid as by liver extract, an experience encountered in a number of cases of pernicious anemia so treated. Three of the patients in whom folic acid was substituted for liver extract showed a drop in blood values over a period of a year. Despite this fact, they all experienced definite clinical benefits that had not been enjoyed while they had been on liver therapy.

The dosage requirements of folic acid varied from one patient to another. Whereas 15 mg daily sufficed for some, it was observed that increasing this dosage to 30 mg in other cases was followed by gain in weight and considerable relief of gastrointestinal symptoms.

year later. Severe anemia was not a feature in any of the cases of this group. The blood picture in the majority was macrocytic, as judged by the stained films and the elevated mean corpuscular volume. In a patient who had at one time had a macrocytic anemia a hypochromic anemia developed. In our experience, which confirms that of others,⁵ the anemia associated with the sprue syndrome in many

to have multiple absorptive deficiencies. These included hypoproteinemia associated with edema, hypocalcemia accompanied by tetany, a flat glucose tolerance curve, subnormal levels of blood potassium and very low levels of plasma vitamin A, which did not rise after the administration of a large test dose of the vitamin. Not only was she refractory to folic acid but also purified preparations of paren-

noted that the hemoglobin, red-cell count and hematocrit were lower in Cases 5, 6 and 7 after a year of folic acid. In Case 7, despite a daily dosage of 60 mg, folic acid proved a complete failure. The patient steadily lost weight, her appetite declined, steatorrhea and diarrhea continued, she developed glossitis, and her state of relapse was so severe that she was hospitalized. She was found

patients received the same preparation of folic acid in tablets orally. Contrary to reports by certain other investigators that doses as low as 5 mg daily suffice for most cases, that amount was totally inadequate in our cases. On such small doses, the patients exhibited only a fraction of the degree of improvement seen after an increase to 30 mg daily.

acquires reactivity to what is a variant of LH or is a new pituitary gonadotropin, luteotropin. Hisaw's fourth stage of development, that of the corpus luteum, begins.

Meanwhile the ovum has matured and, in its first mitotic division, has split its chromosomes longitudinally and extruded half their substance in a polar body. The follicle ruptures, floating out the mature ovum on the liquor folliculi (described below). With rupture the luteinization that started the third stage of follicular maturation continues. More progesterone, as well as estrogen, is secreted. As estrogen continues to suppress FSH production by the anterior pituitary body, LH and its successor, the luteotropic hormone, acquire ascendancy and establish the corpus luteum. For about ten days this produces gradually increasing amounts of estrogen and of progesterone. After the first week it starts morphologic regression, for it loses susceptibility to further stimulation by pituitary gonadotropins. Only chorionic hormone, secreted by the trophoblast of the differentiated conceptus, can revive this declining gland.

Meanwhile, what has happened to the several other graafian follicles that by estrogen had been sensitized to FSH and had begun to grow? They reached that degree of maturity at which they were ready to start luteinization — Hisaw's third stage of development. They failed to qualify at this point because of a delicate species quality. In the human subject there seems to be just enough LH in co-operation with FSH to evoke effective amounts of progesterone and increased estrogen in only the most receptive follicle. This most sensitive follicle takes all there is, and its resultant endocrine activity diminishes the hypophyseal product below the reactive threshold of the other follicles or progesterone desensitizes them to the FSH and LH present. It is known that these other thecated follicles regress, leaving only those with well developed antra but without well luteinized thecae internae.

Thus it is in human beings that, typically, only one follicle ruptures, other competing follicles regress. Time is required after the corpus luteum involutes for more follicles, by their own estrogen, to become successively responsive to FSH and to LH that gradually increase when the regressing corpus luteum diminishes its production of estrogen and progesterone, which respectively had inhibited the very hypophyseal activity that evoked each of them.

OVULATION

The accumulation of liquor folliculi within the distended granulosa and theca of the maturing follicle may increase the internal pressure. Were this so, something must give or the granulosa and the ovum would be crushed. Perhaps the pressure is transmitted through the concentric muscled laminations of the thecae interna and externa to the less organized stromal connective tissue, surround-

ing the follicle. This would then recede before the stress of the follicle and its supporting thecae. At all events, unless only superficial follicles mature, the whole growing graafian unit moves toward the surface. It bulges as the cortical germinal layer and the underlying thecal layers as well become thinner. Finally, the continuity of these surface layers is broken, and the fluid escapes. Floating out with it are the disrupted portions of the granulosa and cumulus. In the latter is the ovum within its zona radiata of more cohesive granulosa cells. Recently, Kraus⁷ experimented with rabbit follicles in an attempt to determine the factors of rupture. From these experiments it was deduced that not internal pressure, local enzymatic action, muscular force in the theca or "pull" of the cilia of the fimbria was involved. It was therefore postulated with proper serenity that there occurred a 'morphologic change in the stigma' of unknown nature and caused by unknown agents.

Time of Ovulation

As is common, with only rare exceptions, to all species of animals studied, a short individual life is the lot of human germ cells. To serve their function those of the two sexes must unite within a number of hours after being freed, the ovum from the ovary and the sperm from the male genital tract. The chance of conception in human beings is exceedingly slight, indeed perhaps impossible, if the nearest *preceding* coitus occurs more than forty-eight hours before ovulation, and the first *succeeding*, more than twelve hours after escape of the egg. Once meiosis, the process of diminution of chromosomes, has begun, as it does usually in the follicle with the first polar division, it progresses steadily. When terminated in the tube, probably at most twenty-four hours later, more chromosomes, to complete the species number, must soon be added or life processes cease. Furthermore, it seems likely, from studies such as that of Blandau and Young⁸ in the guinea pig and those of several others in different species, that if ova approaching deicide do become activated, or if an aged sperm succeeds in fertilizing an ovum, the resultant conceptus is very likely to be defective. It is of great practical importance, therefore, to know just when in the menstrual cycle ovulation takes place.

The number of independent biologic factors involved in the whole process of ovulation from beginning luteinization of the theca interna to the final rupture of the mature follicle makes evident the probability that no sign of the exact moment of ovular release will ever be recognizable. Ovulation is the result of the interplay among hormonal agents such as carefully adjusted proportions of FSH and LH, physical agents such as accumulation of fluid in the follicle and migration of this enlarging cyst to the cortex, and possibly enzymatic agents or even the more obscure internal "cell organizers"

MEDICAL PROGRESS

PHYSIOLOGY OF HUMAN CONCEPTION*

JOHN ROCK, M D †

BOSTON

ALTHOUGH simple parthenogenesis is not at all uncommon in invertebrates — for instance, in ants and bees — it does not, as far as is known, occur in human beings, who must produce eggs and sperm and then effect their conjugation. The following discussion concerns itself only with the somatic aspects of this complicated process since the beguiling psychologic motivation and mechanisms lie in a mixture of too much fancy with too little fact.

Among various vertebrate species the sequential involvement of the primordial oocyte, within its epithelial capsule, to the mature ovum, in the rupturing follicle, is impressively similar, although the duration of the successive phases may be very different. We are thus led to believe that, in human beings, factors identical with those recognized in laboratory animals are involved in the growth process. There is no specificity of pure hormones, for those from one animal are effective in others. The degree of their potency and the susceptibility of the target organs, however, vary widely among species. Of the gonadotropic hormones found effective in animals some are known to be produced likewise in human beings, and others are reasonably assumed to be. Doubtless their effects in human beings are the same, in kind, if not in degree.

In the human ovary at puberty there are said to be, distributed through the stroma, more than 10,000 ova in various stages of development.¹ Some are small oocytes surrounded by a single layer of epithelial cells. These nurse cells, the precursors of the granulosa, and the central oocyte are believed to be derived from the mesothelium that covers the original formative gonad. This mesothelial derivative becomes the germinal epithelium. Whether in human beings all primitive ova are present at birth or new ones, from time to time, descend from the germinal layer into the cortex is not known. Hartman² has shown that oogenesis continues in the rabbit, and Allen³ that this is so in the mouse, and Mossman⁴ states that it occurs in the pocket-gopher. Although Hertig⁵ has not incidentally seen mitotic activity in the germinal layer of any mature ovary it seems at least possible that production occurs, albeit infrequently, in adult life.

This report arises from research aided in part by grants from the American Cancer Society and also from the Committee on Human Reproduction, both of the National Research Council.

†Clinical professor of gynecology, Harvard Medical School, visiting surgeon and director of Fertility and Endocrine Clinics, Free Hospital for Women, Brookline, Massachusetts.

MATURATION OF THE FOLLICLE

Hisaw⁶ has recently reviewed pertinent follicular biology in animals and from his discussion one may plausibly theorize on this process in patients and, complacently ignoring the absence of many proofs, describe it as follows. Governed by a "self-contained system of organizers," the primordial oocyte while attaining full size, effects an investment of several layers of granulosa cells from the primitive epithelium surrounding it. This simple group of ovum and nurse cells causes the adjacent connective tissue to develop the theca interna. This, then, consists of a specially vascularized tissue of enlarged cells, which sooner or later, and again, automatically, by reason of their own intrinsic enzyme system, secrete estrogen.

The estrogen from the theca interna now empowers the granulosa layer to produce a fluid that it holds within a small, newly formed antrum. The appearance of this small vesicle terminates Hisaw's first stage, and ushers in the second stage of follicular development.

Estrogen thus appears as the indispensable self-organizer of the graafian unit. After responding to estrogen the follicle "gains competence" to react to the follicle-stimulating hormone of the hypophysis (FSH). This requirement of preliminary conditioning by estrogen explains why some follicles mature and others do not, for it is FSH that stimulates gross enlargement of the vesicle, but only after estrogen has first primed the granulosa and possibly its source, the theca itself. Estrogen also has other targets. It induces the hypophysis gradually to quit production of FSH and to secrete luteinizing hormone (LH). It is now apparent that both LH and the previously secreted FSH act on the theca to start the luteinizing process.

With the well developed follicle, about 1 cm in diameter, Hisaw's third stage begins. As this progresses, more estrogen, together with gradually increasing amounts of progesterone is secreted by the theca, and the follicle extends its growth toward maturity. It enlarges to a diameter of even 2 cm by the accumulation of fluid, the increasing estrogen reacts on the hypophysis to diminish its production of FSH and to bring forth more LH. As these combined gonadotropins act on the follicle most sensitized by estrogen and previous FSH, this one secretes more progesterone. Furthermore, it

acquires reactivity to what is a variant of LH or is a new pituitary gonadotropin, luteotropin. Hisaw's fourth stage of development, that of the corpus luteum, begins.

Meanwhile the ovum has matured and, in its first mitotic division, has split its chromosomes longitudinally and extruded half their substance in a polar body. The follicle ruptures, floating out the mature ovum on the liquor folliculi (described below). With rupture the luteinization that started the third stage of follicular maturation continues. More progesterone, as well as estrogen, is secreted. As estrogen continues to suppress FSH production by the anterior pituitary body, LH and its successor, the luteotropic hormone, acquire ascendancy and establish the corpus luteum. For about ten days this produces gradually increasing amounts of estrogen and of progesterone. After the first week it starts morphologic regression, for it loses susceptibility to further stimulation by pituitary gonadotropins. Only chorionic hormone, secreted by the trophoblast of the differentiated conceptus, can revive this declining gland.

Meanwhile, what has happened to the several other graafian follicles that by estrogen had been sensitized to FSH and had begun to grow? They reached that degree of maturity at which they were ready to start luteinization — Hisaw's third stage of development. They failed to qualify at this point because of a delicate species quality. In the human subject there seems to be just enough LH in co-operation with FSH to evoke effective amounts of progesterone and increased estrogen in only the most receptive follicle. This most sensitive follicle takes all there is, and its resultant endocrine activity diminishes the hypophyseal product below the reactive threshold of the other follicles or progesterone desensitizes them to the FSH and LH present. It is known that these other thecated follicles regress, leaving only those with well developed antra but without well luteinized thecae internae.

Thus it is in human beings that, typically, only one follicle ruptures, other competing follicles regress. Time is required after the corpus luteum involutes for more follicles, by their own estrogen, to become successively responsive to FSH and to LH that gradually increase when the regressing corpus luteum diminishes its production of estrogen and progesterone, which respectively had inhibited the very hypophyseal activity that evoked each of them.

OVULATION

The accumulation of liquor folliculi within the distended granulosa and theca of the maturing follicle may increase the internal pressure. Were this so, something must give or the granulosa and the ovum would be crushed. Perhaps the pressure is transmitted through the concentric muscled laminations of the thecae interna and externa to the less organized stromal connective tissue, surround-

ing the follicle. This would then recede before the stress of the follicle and its supporting thecae. At all events, unless only superficial follicles mature, the whole growing graafian unit moves toward the surface. It bulges as the cortical germinal layer and the underlying thecal layers as well become thinner. Finally, the continuity of these surface layers is broken, and the fluid escapes. Floating out with it are the disrupted portions of the granulosa and cumulus. In the latter is the ovum within its zona radiata of more cohesive granulosa cells. Recently, Kraus⁷ experimented with rabbit follicles in an attempt to determine the factors of rupture. From these experiments it was deduced that not internal pressure, local enzymatic action, muscular force in the theca or "pull" of the cilia of the fimbria was involved. It was therefore postulated with proper serenity that there occurred a "morphologic change in the stigma" of unknown nature and caused by unknown agents.

Time of Ovulation

As is common, with only rare exceptions, to all species of animals studied, a short individual life is the lot of human germ cells. To serve their function those of the two sexes must unite within a number of hours after being freed, the ovum from the ovary and the sperm from the male genital tract. The chance of conception in human beings is exceedingly slight, indeed perhaps impossible, if the nearest preceding coitus occurs more than forty-eight hours before ovulation, and the first succeeding, more than twelve hours after escape of the egg. Once meiosis, the process of diminution of chromosomes, has begun, as it does usually in the follicle with the first polar division, it progresses steadily. When terminated in the tube, probably at most twenty-four hours later, more chromosomes, to complete the species number, must soon be added or life processes cease. Furthermore, it seems likely, from studies such as that of Blandau and Young⁸ in the guinea pig and those of several others in different species, that if ova approaching deicide do become activated, or if an aged sperm succeeds in fertilizing an ovum, the resultant conceptus is very likely to be defective. It is of great practical importance, therefore, to know just when in the menstrual cycle ovulation takes place.

The number of independent biologic factors involved in the whole process of ovulation from beginning luteinization of the theca interna to the final rupture of the mature follicle makes evident the probability that no sign of the exact moment of ovular release will ever be recognizable. Ovulation is the result of the interplay among hormonal agents such as carefully adjusted proportions of FSH and LH, physical agents such as accumulation of fluid in the follicle and migration of this enlarging cyst to the cortex, and possibly enzymatic agents or even the more obscure internal "cell organizers."

that cause final dissolution of continuity in the wall of the follicle and in its thinned-out cortical cap. It seems unlikely that all of these are trigger mechanisms, which function with exact time relations to each other. It is of great interest in this connection, on the other hand, that Sawyer, Markee and Hollinshead⁹ have shown that the hypophysis in the rabbit responds to the coital stimulus within at most three minutes. It has long been known that, in rabbits, follicles rupture from ten to fourteen hours after coitus. But even in rabbits the exact time of ovulation is not easily detectable without inspection of the ovaries. An indicative change in electropotential was reported by Burr et al.¹⁰ and Reboul, Friedgood and Davis,¹¹ but this is not a useful method even in rabbits, and Snodgrass¹² has shown it to be quite undependable in human beings.

In the monkey and the cow the approximate time of ovulation, within hours, may be determined by repeated palpation of the ovary through the rectum—a method not likely to be practical with patients. Except in rare cases “mittelschmerz” is quite unreliable. The specific cause of the pain is unknown, so that even in the occasional case in which it is so peculiar as to be unmistakable it can do no more than indicate the process of ovulation and not the actual event.

It is now generally admitted that ovulation occurs about two weeks before the manifest onset of normal menstruation. This must be so, for flow is precipitated by withdrawal of corpus luteum hormones, and the corpus luteum may be said to acquire definitive form and function within perhaps a day of ovulation, and to remain active for about two weeks. The duration of luteal dominance is deduced from observation of the effects of its specific product, progesterone, on the endometrium,¹³ by detection in the urine of pregnanediol,¹⁴ an excretion product of progesterone,¹⁵ by proportional changes in urinary estrogens¹⁶ and by cytologic and histochemical study of corpora lutea themselves.¹⁷ Comparison of previllous human conceptuses with those of the macaque, in which the actual ovulation ages are known, because the actual day of ovulation had been determined by Hartman's method of bimanual rectal palpation, gives final confirmation to the deduction that human ovulation occurs *about* fourteen days before the first day of normal menstruation.¹⁸

Consideration of the inexactness of all these data is salutary. In the cytologic studies of the endometrium, in the biochemical assays of excretion products and in the cytologic and histochemical studies of corpora lutea, the results pointing to about fourteen days of function either were averages of findings or were postulated from a theoretical date of ovulation and then found to agree with this date within a statistically significant limit of error. The constancy of the agreement was hence taken to

substantiate the theoretical date. In the case of the actual conceptuses whose ovulation ages could be determined fairly accurately, the time between the day of ovulation and the onset of menstruation had to be estimated, for, of course, in the particular pregnant cycle, there was no subsequent menstruation. The dates when catamenia would have occurred were arrived at by reference to each mother's previous menstrual cycles, which are generally constant within an inclusive range of 5 days.

In 1937 Rubenstein¹⁹ revived interest in the fact that during most menstrual cycles the curve of daily basal temperatures is diphasic, lower in the first part of the cycle than in the second. He correlated the shift in temperature levels with changes in the vaginal smear that had been shown by Shorr and Papanicolaou²⁰ to be attributable to ovarian function. In 1944 Klasten showed,²¹ by experiments with amenorrheic women, that the increase in temperature was a function of progesterone. Thus, it is now generally believed that when the temperature rises to stay it may be assumed that the corpus luteum is functioning and, so, that ovulation has occurred.

To minimize disturbing factors the temperatures recorded are best taken each day promptly on awakening and before any activity beyond placement of the thermometer. For those who are careful, mouth temperatures give informative curves, but for most women rectal or vaginal readings are more dependable. There is no uniformity in the curves of women in general, except that during the ovulatory cycles they are diphasic. Indeed, among succeeding ovulatory cycles in the individual woman, the temperature levels and the gradients may both be noticeably dissimilar. Examination of the completed curves, however, will usually reveal either the sudden or the gradual termination of the lower first phase. The day or days of the last lowest temperature from which, either abruptly or by stages, it rises to stay are generally taken to be the day or days of the ovulation phase. Only very rarely does one see a chart in which this apparent sign of ovulation is beyond the limits of 14 ± 4 days before the onset of flow. In most women this assumed ovulation phase is found to lie usually within the range of 14 ± 2 days before menstruation, but every woman is likely to stray out of range every now and then.

TUBAL FUNCTION

Whence goes the 1, 2 or even 6 cc. of liquor with its indispensable egg when it escapes from the follicle? It must flow into the variable amount of peritoneal fluid that bathes all viscera. Doubtless it is not infrequently dispersed about the pelvis, washing the ovum to distant places beyond the reach of spermatozoa. To prevent this in some mammals there is an ovisac, surrounding the ovary, a delicate serosal receptacle attached to and open-

ing into the tube Human beings have not thriftily acquired this little catchbasin that would prevent loss of eggs, they have a more complicated and defective mechanism

The fimbriae of the tubes vary widely among women Some consist of short and closely approximated growths of ciliated epithelium on a narrow, flat collar of muscled connective tissue surrounding the ostium This collar may have a radius of less than 1 cm Sometimes the flared end of the tube is found to have a long fringe that may extend outward to a radius of 2 cm (especially on the abovarian margin) This fimbriated structure is important, and modification of the ideal wider collar may be very significant to fertility Westman²² has credibly postulated that as ovulation approaches, muscle fibers in the tubo-ovarian ligament contract to approximate the fimbria to the ovary and that, furthermore, other muscle fibers in the thin connective-tissue collar spread out this structure so as to engross the ovary in a curved, fan-shaped envelope, which constitutes a homologue of the ovisac of some so-called more primitive animals Careful exposure of adnexa at laparotomy during the ovulatory phase often discloses both ovaries thus covered

Improving this system of receptivity is the ciliated mucosa that forms the surfaces of this extension of the ostial border adjacent to the ovary In functional position this epithelium faces the ovary, and the beating cilia establish a current from the ovary and the pelvic cavity toward the uterus Physiologically, the liquor folliculi is pulled toward the tube Carried in the liquor, the ovum in its tattered vestment of granulosa doubtless thus floats into the ampulla, when the system works Otherwise, and perhaps more often than has been thought, the liquor is dissipated and the ovum lost in the pelvis

The quality of tubal fluid with regard to the egg may be very important, but at the moment all one knows is that it offers a warm, moist medium in which the ovum may be fertilized and conveyed to the uterus Mouse ova, removed from the tube and placed in the anterior chamber of the eye,²³⁻²⁴ have achieved implantation there Rat ova, similarly obtained and properly placed, have implanted under the capsule of the kidney²⁵ Once fertilized, neither apparently suffered by deprivation of tubal fluid²⁶

Judging by 4 activated human eggs cultured in vitro and 1 human incipient morula found in the uterus, there is little if any increase in protoplasmic bulk up to the 4-cell stage Between this and the 8-cell stage the vitelline mass apparently does grow, but probably in human beings this growth occurs in the uterus (The mouse eggs observed by Lewis and Wright,²⁶ as well as the rat eggs studied by Alden,²⁷ may have increased in size in the tube)

It appears that tubal fluid may be not only a protective covering and vehicle for the egg but also

a substrate delicately adjusted in pH and osmotic pressure for the fertilization process and, too, a nutrient medium for ova The possibility that the ovum makes respiratory demands on this tubal product must be considered, but of this nothing is really known

Sojourn in the tube is fairly short A 4-cell human morula, possibly abnormal, but yet not more than four days old was found by Hertig⁵ in the uterine cavity Two other human conceptuses between seven and eight days of age, both doubtless normal, were found to be so well embedded in the endometrium as to indicate that nidation had been started not later than the sixth postovulatory day There seems good reason to believe, then, that the antrum-containing blastocyst takes shape about the fifth day and that at this time the new organism must be where the rapidly differentiating trophoblast will be offered appropriate nidation How does it get there?

The tube is roughly seven hundred times longer than the diameter of the inert egg (100 μ m versus 0.150 mm) The comparatively long haul to make delivery in the uterus is accomplished by downward propulsion of the fluid carrier with its cargo by the ciliated endosalpinx, doubtless aided by the more effective peristalsis of the myosalpinx During the few days of its journey the single cell, by mitotic division of the vitellus, changes into at least or at most a 4-cell morula Some time after this cleavage the jelly-like pellucida disappears Fawcett²⁴ and Runner²³ have called attention to the fact that even for this process neither the tubal fluid nor the uterine fluid is necessary in the mouse and rat, for this structure is equally well disposed of in such foreign places as the eye, the kidney or the peritoneal cavity

The tubes also serve the spermatozoa as conduits at least How the motile organisms progress through them is considered below Here it is pertinent to note that there is reason to suspect that, in the rabbit, tubal fluid supplies an enzyme system that conditions the sperm for facile entry into the vitellus through the vitelline membrane²⁸ Such a possible biochemical process must be nicely integrated with the probable antigen system effecting conjugation so carefully studied by Loeb,²⁹ Tyler³⁰ and others, mentioned below under "Fertilization"

UTERINE FUNCTION

As segmentation progresses, the conceptus increases in bulk it takes something from the thin layer of fluid separating the anterior and posterior surfaces of the endometrium This must include metabolites as well as water, but of their nature little is known beyond the fact that starting about four days after ovulation, or about the time the ovum reaches the fundus, the uterine glands discharge a secretion containing glycogen During the fifth day progressive cell division of the

blastocyst results in differentiation into two kinds of tissue. One forms the inner cell mass, which projects into the newly formed antrum. This will develop into the embryo proper. The other specialized group of cells is the outer trophoblast, which constitutes the wall of the antrum. The latter tissue apparently secretes some substance that causes vasodilatation and even extravasation of blood in the neighboring maternal tissue, which, normally, is the endometrium.²¹ The outer, or syncytial, trophoblast at the embryonic pole also engorges the surface epithelium as it "forages" its way toward the vessels in the stromal bed underneath.²¹ In the human being it goes farther. In the youngest implanted specimen, barely seven days old, one sees the syncytium phagocytizing stromal cells as well, while the whole organism is gradually enclosed within the endometrium. Judging from the effect of the trophoblast on several different tissues, — the iris,²³ the kidney capsule,²⁵ the peritoneum, the endosalpinx and the endometrium, — access to maternal blood is the ultimate objective. While struggling on to this complete food, the trophoblast must be nourished by contributions from intercellular fluid and from the ingested stroma cells. The biochemicals, necessarily found here, have not been identified except for phosphatases, glycogen and some lipids.²²

There seems little doubt that whatever the food material is, its presence is caused by progesterone and estrogen from the corpus luteum. It was stated above that the corpus luteum of the nonpregnant cycle ceases further growth after about the seventh day following ovulation, for then its ability to respond to pituitary gonadotropins has reached its peak. If conception has occurred, however, the sequence changes. Until the definitive placenta is formed — that is, until there is plenty of maternal blood available to fetal villi capable of utilizing it, — the trophoblast must be sustained partly by maternal blood that enters the lacunae and also by endometrial fluid and cells. On the seventh day the conceptus is barely embedded. Villi are not recognizably started until it is about fourteen days old. During the week intervening, and indeed for several weeks later, while the fetal portion of the placenta is establishing itself, the corpus luteum is maintained, providing increasing amounts of progesterone and estrogen. This perpetuation of the corpus luteum is brought about by a gonadotropin secreted by the trophoblast, the so-called chorionic hormone. The continuance of luteal activity by this fetal hormone substantiates the decidua, which would break down in menstrual disintegration were its supporting hormones, progesterone and estrogen, withdrawn. This must be prevented not only because this tissue with its juices sustains the growing trophoblast but also, perhaps primarily, because it serves as the protecting matrix within which the

ever-increasing vascular bed of the maternal part of the placenta is forming.

The versatile trophoblast eventually assumes an added function. At some time between the first and the eighth week of gestation (the twenty-fifth day in monkeys)²² it takes over the work of the corpus luteum and secretes its own large amounts of progesterone and estrogen throughout the allotted remainder of pregnancy, thus continuing the support of the decidua and the maternal placenta.

Aside from the fact that spermatozoa utilize carbohydrates and produce carbon dioxide, their metabolic processes are almost unknown. Compared to their size they must use a great deal of energy. Do they get their source material from the uterine and tubal fluids? After ovulation the endometrial glands secrete a glycogen-bearing mucus. This comes too late for the fertilizing agents. The food stuffs that are mobilized into and out of the endometrium and the various enzymes and their adjuncts that accomplish this are being studied in several research centers. It will be known in time what are the requirements in their medium for the spermatozoa, and then, doubtless, methods of detecting whether or not essentials are present. In the meantime one can only postulate the necessary presence there of some easily utilizable glucose, and, in the spermatozoa, the enzymes, adapted for its use.

CERVICAL FUNCTION

The cervix, which constitutes the portio or passage way to the uterus from the vagina, ideally enters this muscled sheath for the functioning penis in the rear of its superior wall, about 8 cm from the posterior border of the symphysis. So variable are the length of the vagina and the position of the uterus in the pelvis that the portio may lie anywhere in the superior or posterior wall. It never enters from below. Furthermore it may point forward or downward instead of in its normal direction, backward. As can be observed through a glass obturator of a caliber similar to that of the phallus, about 4.5 cm, stretching of the vaginal walls as occurs during coitus brings the attached cervix into the axis of the vagina, except when the portio lies within about 5 cm of the symphysis. In such cases the penis by-passes it, and ejaculation doubtless hits the posterior wall. Consideration of the following remarks about insemination will suggest that, except when maladaptation is extreme, the position of the cervix is probably of but slight significance. In about any position it can serve its only apparent function, which is to produce a quantity of favorable fluid that, mixing with the ejaculate, still maintains continuity through the canal with the fluid of the fundus.

While estrogen from the growing follicle is causing proliferation of the endometrium, it is also cultivating the endocervical mucosa. Just after

menstruation the mucous excretion from the cervix is scant, very viscous, sometimes even gelatinous and replete with epithelial cells and granular debris. At some time during the week preceding ovulation, when estrogen secretion is mounting, the cervical product increases in amount and decreases in viscosity and cell content. Throughout the phase of ovulation it is normally plentiful, grossly clear as water and of comparatively low viscosity. Careful exposure of the cervix at this time reveals it bathed in this alkaline polysaccharide that before degeneration is easily penetrable to spermatozoa. So copious is the normal production of this fluid that it spreads outward through the vagina and sometimes even rises over the perineal body to bathe the introitus.

SEMEN

Now, what of the man? Spermatozoa are produced continuously through adult life by the germinal epithelium lining the seminiferous tubules. Fully grown, but immature in some one or several metabolic capabilities required for fertilization, they congregate in the tubules until, with their successors, they are moved out into the epididymis. In the almost interminable coils of this organ the fairly solid mass of closely approximated inactive germ cells is propelled onward, again possibly by the pressure behind of newer organisms, and possibly also by peristalsis of the tubular walls. Here in the epididymis some obscure maturing or complementing process takes place. In the vasa the column moves still onward, the cells here also improving, but still more or less inactive, until either those in the vasa gradually spill over into the posterior urethra to be washed out in the urine or a large part of the whole column is ejected through the ejaculatory duct in the first phase of ejaculation.

As Hotchkiss²⁴ properly complains, "the exact physiology of the mechanism of ejaculation has not been ascertained." Apparently, within a split second of their arrival, thus, in the posterior urethra, they are joined by a little secretion from the promptly contracting prostate and perhaps vesicles and almost immediately this mixture, made up largely of spermatozoa, is vigorously propelled, ideally, to the cervical os. The total ejaculate varies in amount from about 3 to about 9 cc. and normally contains about 500,000,000 spermatozoa. Recurrently, contractions of the penile muscle discharge the mixed portions, but with each successive ejaculation the concentration of spermatozoa diminishes while the proportion, not the amount, of prostatic and vesicular increment increases.

Thereafter the prostate and vesicles together with the vasa start to replenish their secretions, and the vasa their supply of sperm. The respective characteristic contents of these accessory organs, both in volume and constituents, however, are not re-

established usually within two days, and, in some men past the primal late teens and twenties, possibly not within four days. A second total ejaculation within hours of the first contains comparatively few spermatozoa and a diminished amount of fluid.

Physiology of the male generative tract is still lamentably obscure. (Every gynecologist dealing with infertility should read carefully Hotchkiss's²⁴ chapters on this subject, for then he can keep both himself and his ethical and conscientious urologic consultant from subjecting distraught and hence credulous couples to plausible but futile, troublesome and expensive procedures and medication.)

The seminal vesicles and prostate function under the influence of the male sex hormone. The former produce a mucoid substance rich in sugars among other chemicals, and sperm have been shown by MacCleod²⁵ to acquire their energy by utilization of the sugar thus provided. Mention must be made of the enzyme, hyaluronidase, that may be a factor in denudation of the granulosa vestment of the ovum. It is possible that this, or a precursor of it, comes from the secretions of either prostate or vesicles, for it is somehow acquired by the spermatozoa. This subject is further discussed below under "Fertilization."

Furthermore, Chang²⁶ has recently noted that the ability of rabbit sperm to activate ova may be dependent on some substance contained in the seminal substrate. Perhaps this also comes from some one or other of the accessory male organs. Munro²⁷ showed that in fowl less than 1 per cent of ova were fertilized by sperm from the testicle, whereas 63 per cent were fertilized by sperm from the efferent ducts. Does the substance postulated by Chang come from the vasa? (As stated above, Finkle²⁸ proposes that tubal fluid may also improve the effectiveness of rabbit sperm.)

COITUS

Human copulation does not lend itself easily to scientific investigation, and what is known of the process in other mammals is not very helpful. The genital anatomy of human beings is quite different in important details from that of even the other primates. I know of no authoritative description of what actually happens in the human vagina during coitus and at ejaculation nor of the behavior and progress of spermatozoa from the time they leave the penis until one penetrates the ovum. I may therefore be permitted to surmise, trying always to restrain my imagination by a few actual observations.

It may be conjectured that during coitus the recurring thrusts and retractions of the penis cause the vaginal walls alternately to approximate and separate from the portio, thus serving, with the intermittent contact of the glans to cervix, to spread much of the cervical mucus on to the vaginal wall. If this is so, the external os is thus partially cleared of

excess and sometimes opaque degraded secretion such as is commonly seen about the portio. The forceful impact of the first ejaculated mass of spermatozoa and a little seminal fluid against the layer of mucus that covers the deeper vagina and the portio joins these two viscous liquids. Movements of the penis mix them, as continued discharge of alkaline semen containing a few more spermatozoa places such a quantity of material in the vagina as will spread over its walls, when these again become contiguous on withdrawal of the penis. Spermatozoa are thus protected from the usual acidity of the vaginal desquamate.

I do not know what constitutes female orgasm. Perhaps contractions of the myometrium are a component, and perhaps subsequent relaxation contributes a pull on material in the cervix and at the external os. Whether or not this is so is not clearly significant, for there is no doubt that, other factors being adequate, conception is easy without female orgasm.

The stratified epithelium of the vagina is highly absorbent. After coitus some of the ejaculate may be taken up, some is slowly extruded through the introitus as the vaginal walls contract. Active spermatozoa produce carbon dioxide. Gradually, the acidity of the vaginal content is re-established, and after four hours all spermatozoa therein cease motility and probably die.

INSEMINATION

When, as is normally the case, some 500,000,000 spermatozoa are originally present in the fluid that, on withdrawal of the penis, is spread over the vaginal walls, several hundred thousand will by chance find their way into the cervical canal before they succumb.

The mixture of semen with mucus from the cervix is continuous with the column of clear secretion in the cervical canal, as this in turn connects with the thin layer of mucoprotein from the endometrium. Until there is evidence, now completely lacking, that some chemotropic, rheotropic or electrotropic force directs their movements, it must be supposed that spermatozoa swim aimlessly in the widespread vaginal pool, the deepest part of which, containing most of the spermatozoa, is that into which the portio projects when this is normally placed at the end of the vagina.

Observation of the post-coital content of the cervix shows clearly that its secretion at ovulation time offers a very favorable substrate for spermatozoa. In the ovulatory phase, even forty-eight hours after ejaculation, normally progressive organisms are not infrequently seen in great profusion in cervical mucus. About sixteen hours after coitus each high-power field of fluid from within the cervical canal may contain from 10 to several hundred organisms.

At other times in the menstrual cycle sperm from a normal ejaculate may or may not penetrate the

cervical product. Occasionally one sees a woman in whom the endocervical mucus almost throughout the cycle secretes a fluid low in viscosity and cellular debris. Penetration by sperm is not as uniform or as extensive as it is normally at ovulation time, nor do those organisms that do enter the cervix apparently find therein a medium that satisfies their needs. They may remain active for twelve or more hours, but usually few are progressively migratory even six hours after coitus.

We may assume that some spermatozoa, highly activated by what they utilize from their ejaculated substrate, still as if aimlessly, find their way from the cervical mucus into the fundus and there deploy. Here is a broad, thin layer of fluid lying between anterior and posterior walls, which connect along the edges in an arc so acute that they would touch one another were it not for the shallow lake of secretion interposed between them. Where the lateral shores of this triangular lake meet the basal fundal border are the two tiny inlets of the tubes. As one watches active spermatozoa in a hanging drop one sees large numbers of the more normal ones gather along the edges, heads out and thrashing tails inward. In this so-called phalanx formation, individual sperm move sideways along the border, sometimes in one direction, sometimes in the other, but in general maintaining their outward orientation. Perhaps by a similar tendency in the uterus sperm may gather along the shore and some of these, perchance, come across the tubal ostia and swim into them.

Progress of sperm in a straight line in cervical mucus has been measured as about 1 mm per minute. A direct line from the external os to the opening of the tube is perhaps about 120 mm—a two-hour trip. Spermatozoa were found in the tube by M. Edward Davis³⁸ about three hours after coitus. If movement is truly random perhaps they move faster in the uterine medium.

In comparison to the size of the spermatozoon, the mass of the cervical and fundal body of fluid together with that in the vagina is so vast as to make it unlikely that a very high proportion of spermatozoa in any single ejaculate ever reaches the tubes. One might guess from the numbers seen in the cervical mucus after coitus that of the several hundred million placed in the vagina, only several hundred thousand reach the cervix. Of these probably some tens of thousands migrate into the fundus, and only a few thousand, at most, eventually enter the tubes.

Here they move upward by swimming against what to their vigor must be a very weak current if it is established only by the cilia of the endosalpinx. The generally downward progress of the tubal fluid—after ovulation, at least—is doubtless accomplished by peristalsis. The waves of this increase in magnitude during the ovulation phase. Just before and perhaps immediately after ovulation, when the necessary spermatozoon, along with

those that accompany it, must find its way to the outer ends of the tube, weaker and more frequent contractions of the myosalpinx might easily form eddies among the irregular rugae of the endosalpinx. In these inconstant but connecting pools the vigorously swimming spermatozoa might, with many slips backward, conceivably be helped onward. Parker⁴⁹ has studied the migration of sperm in several species of terrestrial vertebrates (turtle, pigeon and rabbit), in the rabbit, he attributes to the downward ciliary current along the edges of the endosalpinx a reverse central flow that facilitates upward progress. This may be the case in human beings, but, as demonstrated in the film of Somers Sturgis entitled "Observations on Some Factors Which Influence the Direction of Sperm Motility" (1946), the spermatozoa are so enormous and so strong in comparison to the force of the ciliary current, as, apparently, to disregard it. I should think that, if there is any tropism in action, peristalsis is the effective factor.

Of the few thousand spermatozoa from a single ejaculate that might enter the tubes, how many by these theoretical mechanisms reach the ampulla wherein to meet the ovum? Probably not more than a few hundred, or approximately one-hundredth of 1 per cent of the number in the ejaculate. Hence the handicap of oligospermia.

FERTILIZATION

As the inert ovum, still in its ragged zona radiata of granulosa cells, is gently rolled and pushed here and there along the opposing walls of the somewhat dilated outer end of the tube, more than likely, but not inevitably, it encounters a few of the few hundred spermatozoa thrashing about in the ciliary current.

While the second mitotic division is taking place — that is, while the second polar body is being extruded from the vitellus, after halving of the number of chromosomes — the zona radiata of granulosa cells is dispersed. Denudation of the zona pellucida is accomplished. This may be an important process for fertilization. The multicellular coating of the ovum is desirably removed or else the sperm must have great difficulty reaching the zona pellucida through which one enters the vitellus. The granulosa cells of the zona radiata are held together by a glucoside common to many other cell aggregates or tissues of the body, called hyaluronic acid. This adhesive substance is broken down by the enzyme, hyaluronidase, alluringly found in semen. This very useful agent, possibly also produced by the germinal epithelium,⁴⁴ is taken by spermatozoa and freely relinquished whether or not they manifest life.⁴⁰ I have watched many human ovarian ova become denuded during culture in human blood serum, in which hyaluronidase is doubtless inactivated. But, like several others, I have also seen granulosa cells of ova in Ringer-Locke's solution leave their fellows

while vigorous spermatozoa thrash among them. I had thought that while in culture in vitro, and so possibly in vivo in the tube, granulosa cells died because of separation from the follicular lining and, by resultant proteolysis, lost their cytoplasmic connections, thus dissolving the intercellular matrix by their own degradation products, and so easing their removal by motile sperm. And indeed this may be at least one of the means by which the ovum is stripped. But there is hyaluronidase in or on human sperm,⁴¹ and only a little is needed to dismember hyaluronic acid. This method, then, may be either an essential or merely an adjunctive one. The question is important, for on the answer, as determined by more extensive, controlled experimentation, depends the significance in human fertilization of the presence or of the amount of hyaluronidase in or on the spermatozoa.

Attempts to fertilize mammalian eggs in vitro have been numerous, and successes exceedingly few, and in only two species, the rabbit⁴² and the human being,⁴³ and in only one medium, Ringer-Locke's solution. Is there a substance present in tubal fluid and absent in culture mediums that facilitates fertilization? In some of the invertebrates whose eggs form a fertilization membrane after the entrance of one sperm, the enzyme "fertilizin" is postulated as on, and perhaps in, the egg.³⁰ This reacts as an antigen to the first sperm that makes contact so as to form a substance that makes impossible the entrance of other sperm heads. Is there present in blood serum and some other body fluids, including semen, an antistubstance that makes penetration of the vitelline membrane by even one sperm, or engrossment of the sperm by the vitellus, impossible? Pincus,⁴² working with rabbit ova, and Menkin and Rock,⁴³ working with human ova, were unable to cause recognizable fertilization of even denuded eggs in blood serum.

* * *

It must be concluded from the foregoing discussion that much remains to be learned about how human beings reproduce. This ignorance is not fatal, for fortunately the intricate process does not require carefully executed managerial control — that is, when the delicately adjusted and integrated mechanism functions normally. Furthermore, perfection in each unit is not always required for in many details there is a fortunate leeway of error. On the other hand, when an apparently healthy copulating couple fail to reproduce, knowledge of required physiology is necessary for success. Knowledge is also requisite for faultless and harmless prevention of conception, which human reason clearly manifests is an indispensable factor for the health, wholesomeness and progress of human society. Intensive research will bring rich rewards that will greatly facilitate the elevation of fallen man.

CASE 35201

PRESENTATION OF CASE

First admission A twenty-one-year-old barber was admitted to the hospital complaining of crampy abdominal pain.

Three years before admission the first episode of low abdominal cramps appeared. There was no obstipation or vomiting. He was hospitalized for two days. The second attack occurred twenty-seven months before entry. He was hospitalized, an appendectomy was performed. He was well until four months later, when nausea, vomiting and jaundice appeared without any severe abdominal pain. He was hospitalized for three weeks, at the end of which the jaundice had disappeared. Following discharge he began having episodes of crampy lower abdominal pain, with constipation for two or three days, which then subsided for symptom-free intervals of about a month, to be followed by similar episodes. There was no nausea or vomiting with these attacks. The attacks over the three-year interval had a persistent pattern. The cramps, definitely lower abdominal, were increased by ingestion of food. The symptoms were accentuated as the day progressed. A prodrome of "tightening up" in the lower abdomen preceded cramps. Constipation with the cramps was usually relieved by enemas. Between attacks the appetite was fair, there was no indigestion, the bowels moved daily, and there was no melena or hematemesis. One week before admission an attack recurred with the usual lower abdominal cramps, constipation and the inability to pass flatus. Several enemas helped a little, and mineral oil three days before entry gave him some loose movements. In the two days before admission there were no further bowel movements, nausea and vomiting appeared for the first time and persisted. He vomited solid foods but was able to retain liquids. The abdomen did not become distended.

Physical examination showed a thin, slightly dehydrated man in no distress. The chest was normal. Spasm of both rectus abdominal muscles was present. There was no tenderness or masses and

no distention. Occasional high-pitched peristaltic tinkles were heard. A well healed appendectomy scar was seen. Rectal examination was negative.

The blood pressure was 130 systolic, 70 diastolic. The white-cell count was 16,000. The hemoglobin was 14.8 gm. The urine was normal. The stools were repeatedly guaiac negative. The serum total protein was 7 gm. per 100 cc. The cephalin-flocculation test was ++ in twenty-four and forty-eight hours. The gastric contents were guaiac negative, and free acid was present. The sedimentation rate was 5 mm. in one hour. The blood Hinton test was negative.

A plain film of the abdomen and barium enemas demonstrated no abnormality. A gastrointestinal series, including small-bowel examination, was negative. The Graham test showed good concentration, and contraction after a fatty meal. No stones were seen. Proctoscopy and sigmoidoscopy showed no abnormality.

While in the hospital the patient was afebrile. On a soft diet and cathartics the symptoms decreased in severity. The white-cell count returned to normal. He was discharged on the tenth hospital day. A full diet supplemented by mineral oil and metamucil was prescribed.

Second admission (one week later) He re-entered the hospital with a recurrence of severe lower abdominal cramps and constipation of three days' duration. There was no change in the objective findings since discharge.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD HAMLIN, JR. This case seems unusual for one of these exercises in that there is a complete lack of red herrings or any positive information. I think it would be helpful to see the films.

DR. STANLEY M. WYMAN. There is very little to add to the written description. The plain film of the abdomen reveals no unusual soft-tissue shadows and no evidence of intestinal obstruction. I can see no definite stones. Films after the Graham test show no organic abnormality. The barium enema and the gastrointestinal series show, as far as I can see, a normal large bowel, stomach and duodenum, and on these two films taken at one and two hours, respectively, a normal-appearing jejunum and ileum.

DR. HAMLIN. That is no help either.

We have, then, to explain the cause of lower abdominal cramps that eventually required an operation and, in a young, apparently otherwise healthy person, had occurred intermittently and perhaps increasingly over a period of three years. One examiner, at least, had the opportunity of exploring the abdomen and removing the appendix, but apparently the cause of the present difficulty was not noted even though presumably the difficulty

had been present before. The episode of jaundice, we will do well to discard and call some form of infectious hepatitis because, at that time at least, the symptoms of which he had previously complained and of which he later complained apparently were in abeyance.

Lower abdominal, crampy pain usually means large-bowel involvement, and the causes of lower abdominal crampy pain as applied to large bowel would mean some degree of subacute intestinal obstruction. Volvulus is something that one should think of, but I certainly see nothing in the films that looks like volvulus, nor do I see anything that looks like subacute intestinal obstruction. There are many other possibilities in the large bowel. One can run through a list of them, only to say that the normal barium enema, negative proctoscopy and sigmoidoscopy should effectively rule them out. They are not necessarily ruled out by such procedures, but for our purposes we must assume that they were. Small-bowel difficulties can also cause crampy low abdominal pain. Usually, pain in the small bowel is referred to the region of the umbilicus, disease of the lower end of the ileum, however, may cause, as most of us have seen, pain referred to the lower abdomen. Since the roentgenologist has a far more difficult job to rule out disease in the small bowel than in the large bowel, and since proctoscopy and sigmoidoscopy do not reach that far, it would perhaps be politic to confine our attention to the lower small bowel. It would seem at least unusual to have to examine the intestinal tract any higher than that.

What other possibilities of subacute intestinal obstruction have we to consider? The description is certainly that of a low order of intestinal obstruction. What are the possibilities of such an obstruction existing in the face of no increase in distention noted on several occasions, and no increase of air in the small bowel as seen on x-ray study? The only evidence is the subjective impressions of the patients, and it was mentioned that occasional high-pitched peristaltic sounds were heard. Again, one can run through a long list of possible lesions. We can, however, restrict ourselves to a lesion that had existed for at least three years, which will rule out a good many conditions or make them at least much less likely. For my own sake, I cannot see the point of running through a long list except from a statistical point of view. Certain things can be ruled out or partially ruled out, such as lymphoma, which should have produced blood in the stools on some occasion, although it might have existed for three years. A lipoma or large polyp of the small bowel could produce such symptoms. I expect, however, over this period of time that some bleeding would have been noted at least microscopically. The one best entity that I can think of that would be chronic and that would produce very slowly increasing symptoms would be a constricting lesion

of the small bowel, which produced symptoms only when some intercurrent irritation of the bowel was present, and, of these, the best example that occurs to me is carcinoid.

DR JACOB LERMAN: The results of the barium enema need not rule out volvulus. The bowel could unwind in a few hours.

DR HAMLIN: Yes, but a redundancy of the sigmoidal loop is usually seen. Certainly I do not think one can rule out anything with the data as presented, but I think volvulus is unlikely.

DR ALFRED KRANES: Was the original appendectomy done here?

DR TRACY B. MALLORY: I think not.

DR HAMLIN: I should also mention Meckel's diverticulum as a possibility.

DR MALLORY: Dr Ellis, you saw this man.

DR DANIEL S. ELLIS: Yes, but as Dr Donaldson's patient. I saw him in consultation. He had been followed outside by one or two doctors, who had become desperate because of the recurrent attacks, and they sent him down here for surgery. I saw him and decided that the history was not very definite. I did not see him in an acute attack in the first hospital admission, and I was of the opinion that he probably did not have anything but "gas pains," but that if he did have something, Meckel's diverticulum was the most likely possibility. I was largely responsible for saying that he should not be operated on at the time of the first admission but that he should be sent home with definite rules to follow and that, if he continued to have pain, he should be explored even though we might not know at that time what he had. I thought it important to be absolutely sure in view of recurrent attacks that there was not something that might be cured by surgery if attacks continued. They did, and he was explored.

DR GORDON A. DONALDSON: The family physician was the only one who really knew what should next be done for this patient — and that was to be a diagnostic exploratory laparotomy. However, he had had the chance, as Dr Ellis pointed out, to see him in an acute attack. During the first admission the patient had had no acute pain, so we did a proctoscopy and a sigmoidoscopy because the pattern of his pain pointed to the large bowel, as Dr Hamlin has said, and we had a very good view of the large bowel both from proctoscopy and barium enema. It was low abdominal crampy pain, which we associate only with large-bowel lesions. The other point was that the patient was constipated and had been constipated for some time and had taken a high-carbohydrate diet, it was believed that he might have nothing other than constipation. Sure enough, he was home for only three days, long enough to become constipated again, when he appeared for the second admission. On two consecutive days he again had pain after eating. We

finally did an exploratory laparotomy as a diagnostic procedure

DR HAMLIN The implication is that we are descending the bowel. I cannot descend it with you though

CLINICAL DIAGNOSIS

Meckel's diverticulum?

DR HAMLIN'S DIAGNOSIS

Carcinoid of small bowel

Meckel's diverticulum?

ANATOMICAL DIAGNOSIS

Persistent omphalomesenteric duct, with focal ulceration, probably peptic

PATHOLOGICAL DISCUSSION

DR DONALDSON I would like to draw a diagram of the lesion. It was something I had not seen in an adult, although at the Children's Hospital it is seen occasionally. This is a lateral view of the abdomen, with the navel in the center, and this is a loop of small bowel. About 60 cm from the ileocecal valve (where it should be), there was a patent tube-like structure measuring 25 cm in length and 1 cm in diameter, running from the ileum to the umbilicus. There was a good deal of thickening near the umbilical end, and this was important in view of the symptoms.

DR MALLORY This tube, which was resected, was lined with intestinal mucosa of the small-bowel type. At one spot was an area of ulceration, which looked very characteristic of peptic ulcer, although in several sections we were not able to identify any gastric endothelium. I think probably it was present, and we missed it in picking out blocks for sectioning. The diagnosis, of course, is obvious — a persistent omphalomesenteric duct, which is much less common than the usual Meckel diverticulum. Projecting a short distance from the intestine. The origin of both is similar, of course.

CASE 35202

PRESENTATION OF CASE

A seventy-four-year-old man was admitted to the hospital because of abdominal pain of three days' duration.

The pain began suddenly following the ingestion of a small amount of food. It was severe, was

localized to the right lower quadrant and came in waves. There was associated nausea, and dark-green material was vomited. The pain persisted with slight diminution in severity. He had one stool and passed gas by rectum. The patient had always been constipated and took laxatives frequently. Several times recently he had noted tarry stools. Seven years before entry an acutely inflamed appendix had been removed, and a wound abscess had complicated recovery. Three years later a defect in the appendectomy scar and a right inguinal hernia were repaired. A year and a half before admission the patient had five or six episodes of severe epigastric pain. Following one of these episodes he was admitted to another hospital with vomiting and abdominal distention. A serum amylase of 500 units per 100 cc was found. A cholecystectomy was performed. The gall bladder contained many small stones, and the common duct was large and much thickened but contained no stones. The pancreas appeared to be thickened, but no areas of fat were visible. He recovered uneventfully and was well until four months before entry, when he was again hospitalized with a picture of intestinal obstruction. The serum amylase again was elevated. There was prompt recovery on conservative therapy. Guaiac tests on the stools were 0 to ++++ on several occasions. A barium enema showed no abnormality of the colon. He was readmitted to the hospital two weeks later when he had a sudden onset of pain radiating across the abdomen. There were fever, leukocytosis and an elevated serum amylase. On the sixth hospital day he felt something "give away" in his abdomen, and he was immediately relieved. A gastrointestinal series showed a small hiatus hernia. The stomach and esophagus were normal. The duodenal cap was intrinsically normal, but the bulb, although normal in size, showed an abnormally smooth contour to the inner loop, questionably encircling a mass. Also, a questionable filling defect of the mid-transverse colon, not previously seen, was noted on barium enema.

Four weeks before entry "operation for strangulated umbilical hernia" was performed at another hospital. He remained well until the present episode.

On physical examination the chest was emphysematous. There was a Grade II, precordial systolic blow. The abdomen was distended, more so on the right, and was moderately tympanic.

Tenderness and spasm were present over the entire abdomen, most marked in the right upper quadrant, where a large, smooth, tender mass, 15 to 18 cm in diameter, was felt. The mass seemed to be continuous with the liver. Peristalsis was diminished. Rectal examination was negative except for an enlarged prostate.

The temperature was normal.

The urine specific gravity was 1.017, a trace of sugar was present, and the test for albumin was ++. Many granular casts and 5 pus cells per high-power field were found in the sediment, which gave a ++ test for bacteria. Examination of the blood showed a hemoglobin of 13.8 gm. The white-cell count was 12,000, with 82 per cent neutrophils. The nonprotein nitrogen was 66 mg per 100 cc. The van den Bergh reaction was 0.8 mg per 100 cc direct and 1.4 mg indirect. The stools were guaiac negative. A plain film of the abdomen showed no obstruction.

Auricular fibrillation was noted a few hours after admission. The pain, vomiting and distention persisted. On the second hospital day one observer felt a mass in the right upper quadrant, which was believed to be attached to the liver. On the third hospital day the patient suddenly cried out with pain and vomited, and the abdomen became rigid and silent. Preparations for operation were made. As anesthesia was given, the patient suddenly became pulseless, and respirations soon ceased.

DIFFERENTIAL DIAGNOSIS

DR RICHARD WARREN. It is significant that the pain was in the right lower quadrant. It is important to note that the sequence of events began a year and a half before entry. I believe that the seven-year and three-year episodes can be put down as separate diseases or separate episodes in this man's history.

May we see the x-ray films?

DR STANLEY M. WYMAN. This is the only film available. It is a plain film of the abdomen taken after admission and shows the gas-filled cecum, the transverse colon and the splenic flexure. I cannot see the descending colon or rectum. There are no dilated loops of small bowel and no unusual areas of calcification.

DR WARREN. Is there any evidence of fluid or gas?

DR WYMAN. I cannot be sure that there is free fluid or gas in the abdominal cavity. The film was

taken with the patient in an upright position. I am not much help.

DR WARREN. In discussion of this case I would first like to take up the point of whether or not the patient had something new on this admission or whether what he had was a direct extension of the previous symptomatology. When he entered this hospital the trouble was in the right lower quadrant for the first time. A serum amylase was not done so it raises a little doubt whether the patient had something new or whether it was a continuation of the old symptoms. However, the discussion of the case can best be centered around the question of whether or not he had pancreatitis. I would like to point out the things in favor of pancreatitis and those against it. The pain came on after the ingestion of food. Pancreatitis is supposed to come on after dietary indiscretion, such as overeating of food. This one came on with the eating of food in small quantities. Pain in the epigastrium on the previous admission is in favor of it also. Above all we have the operative findings. The gall bladder was removed, the pancreas was found to be thick, and there was disease of the common duct. They are the most cogent features in the past history. The x-ray films showing extrinsic pressure on the duodenum and transverse colon are in favor of pancreatitis, as is the presence of a tender inflammatory mass in the upper abdomen. The patient did not have much infection and the low white-cell count and normal temperature could be perfectly consistent with pancreatitis. The polymorphonuclear ratio is not recorded, nor is the pulse.

DR BENJAMIN CASTLEMAN. The patient was in for only three days on the last admission. The pulse was 80 on admission, but went up later to 100.

DR WARREN. That does not mean a great deal except that he did not have an overwhelming infection. Finally, the elevated serum amylase, which was determined at the other hospital and repeated here, is overwhelming evidence in favor of pancreatic necrosis.

What do we have against pancreatitis or pancreatic disease? We have a history of tarry stools. We have a ++++ guaiac test on the stool on the previous admission. This might be thought to be some evidence against pancreatitis. However, I believe that it is consistent with it, particularly an inflammatory lesion with presumably enough congestion of the gastrointestinal region to cause bleeding. I have recently seen a patient who had

pancreatitis who was a problem in differential diagnosis because of the fact that he had tarry stools. Because of the blood in the stools many people thought that it was not consistent with pancreatitis. I am sure that it is. I cannot explain right-lower-quadrant pain in pancreatitis. The absence of back pain in pancreatitis of this degree is very unusual. The abstract does not say that it was absent, it merely does not mention it. The mass on the right side of the abdomen is unusual for pancreatitis. An inflammatory mass in pancreatic necrosis is most often in the midline or on the left in my experience. The absence of fat necrosis at the preceding operation throws a little doubt on the diagnosis. How far fat necrosis was looked for, I do not know. Fat necrosis in pancreatitis is classically behind the pancreas in the retroperitoneal area below the transverse colon. We are not told whether or not that area was inspected.

What else do we consider in differential diagnosis besides pancreatitis? The question of intestinal obstruction is brought up often in the history. The patient had previously been operated on for inguinal hernia, which makes me think of intestinal obstruction. I believe the x-ray examination rules out any significant degree of small-bowel obstruction. The fact that he passed gas and had a bowel movement during the three days of his illness is also against it. Peritonitis from perforation of a gastroduodenal lesion cannot be ruled out. He had a gastrointestinal series three months previously. Could some other viscus have perforated? The colon, possibly. In view of the history I do not believe that is likely.

How about the possibility of a vascular accident? Auricular fibrillation was noted. If we are going to assume a vascular accident, we must assume that he had something within the abdomen. He could not possibly have had repeated emboli to this region for a year and a half. Could he have had thrombosis of the celiac axis or the splenic artery? That might explain the final episode, but certainly it could not explain the long-standing history. The mass was always recorded as being contiguous with the liver. What condition in the liver could cause a mass of this nature? Could the patient have had a pylephlebitis coming from pancreatitis and a large abscess perforating from the liver into the right gutter? That is unlikely, I think. Cancer of the pancreas or of the bile duct in the

absence of jaundice is unlikely. As far as I am concerned I can make no other diagnosis than that of acute pancreatitis with abscess. I believe that death was due to rupture of this abscess into the peritoneal cavity. Presumably, the marked degree of collapse was due to the liberation of tryptic ferments from the abscess into the peritoneal cavity.

DR SEDGWICK MEAD Dr Warren, do you have any explanation for the episode when the patient felt "something give way" and then felt better?

DR WARREN I purposely skipped over that because I could not explain it. That is in favor of intestinal obstruction but there are so many other things in favor of pancreatitis here that I really must make that diagnosis.

CLINICAL DIAGNOSES

Metastatic carcinoma

Perforated viscus

DR WARREN'S DIAGNOSIS

Acute pancreatitis, with abscess formation and rupture into peritoneal cavity

ANATOMICAL DIAGNOSES

Pancreatitis, acute and chronic, with pseudocyst formation

Erosion of superior pancreaticoduodenal artery

Hematoperitoneum, severe

Squamous-cell metaplasia of pancreatic ducts

Adenomatous polyp of colon

PATHOLOGICAL DISCUSSION

DR CASTLEMAN When the abdominal cavity was opened the first thing that the prosector found was a large mass of blood clot in the right upper quadrant, going under the liver as well as over it. Most of this blood was old, but there was also a great deal of fresh blood, some of which was not clotted. It was estimated as being over a liter. I think we can assume that that was the immediate cause of death—that is, exsanguination into the abdominal cavity.

Further exploration revealed blood in other parts of the abdominal cavity, fresh rather than old. This blood was coming from a large cyst, which involved the entire head of the pancreas, or at least

involved the region where the head of the pancreas should be. This cyst was about 12 cm. in diameter, and on its superior aspect was a hole from which blood apparently had escaped into the abdominal cavity. When this cyst was opened the lining was found to be shaggy and covered with fibrin and old blood. On the posterior aspect of this cyst there was a small blood clot that blocked the opening of a large artery, which was found to be the main superior pancreaticoduodenal artery. We have, then, erosion of an artery into this cyst and rupture of the cyst superiorly into the right-upper-quadrant region and the abdominal cavity. There was also another smaller cyst just to the left, which involved part of the body of the pancreas. The tail and rest of the body of the pancreas were firm and on sectioning showed the normal lobular architecture. The pancreatic duct was dissected beginning at the tail and found to end abruptly in scar tissue just about where the cyst began, when dissected from the ampulla, it was patent down to the same spot behind the cyst. So there was obliteration of the pancreatic duct in its mid-portion for a distance of 12 cm. Sections of the cyst showed just fibrous tissue without any epithelium. Sections of the body and tail of the pancreas showed a mild inflammatory reaction, mostly monocytes and lymphocytes and a few polymorphonuclears. Most of the pancreas was fairly intact. The ducts, however, showed a very severe degree of squamous-cell meta-

plasia, which according to Rich* may be a factor in the cause of pancreatitis — that is, the heaped-up squamous cells blocked the smaller ducts allowing for seepage of the ferments into the parenchyma to produce pancreatitis. Whether that was the primary disease here or a secondary change due to the block caused by the cyst, I do not know. With long-standing obstruction in any duct, squamous-cell metaplasia may develop. I believe these cysts originated from previous necrosis of the pancreas and were "so-called" pseudocysts of the pancreas rather than true neoplasm. When the pseudocysts appeared, I do not know. Certainly they were not present a year and a half previously, when the patient was operated on by Dr. McKittrick, who examined the pancreas very carefully and found nothing but a thickened pancreas and no fat necrosis. We found fat necrosis all over the abdomen. It is possible that what "gave way" was one of the pseudocysts, which relieved the tension in the pancreas.

DR. WARREN: There was no suppuration in the pancreas itself, just two hemorrhagic pseudocysts?

DR. CASTLEMAN: That is right.

DR. WARREN: Did the pancreatic duct communicate with the cyst?

DR. CASTLEMAN: No. The patient also had an adenomatous polyp in the colon which may account for the positive guaiac test in the stools.

A NEW VIRUS DISEASE

DURING the past few years several new nonbacterial infections apparently transmitted from animals have been described in human beings. Notable among respiratory infections have been psittacosis (ornithosis), which is transmitted from birds, and Q fever, apparently acquired from cattle. Evidence that a new virus disease of fowls, which has recently been recognized as highly prevalent in the United States, may be transmitted to human beings and may be spreading in some parts of this country has recently been presented by workers of the United States Public Health Service*.

In 1926, a highly infectious and fatal disease of fowls was recognized in the Dutch East Indies

and at about the same time at Newcastle-on-Tyne. In England a filter-passing agent, designated as Newcastle disease virus was isolated from infected birds in the following year. Similar outbreaks were soon described from various parts of the world outside the United States, but it was not until 1941 that a disease of chickens was recognized in California under the name of avian pneumoencephalitis. The disease in fowl is usually characterized by neurologic symptoms in immature birds, whereas respiratory manifestations predominate in the adults. This disease was subsequently shown to be caused by a virus similar to the one that causes Newcastle disease. Systematic surveys subsequently demonstrated the presence of the disease in almost all parts of this country. It has therefore become of major importance to poultry men throughout the world.

Many groups of workers have studied the Newcastle disease virus. It has been found possible to propagate the virus in embryonated hens' eggs, and the infection has been transmitted to some laboratory animals by intracerebral inoculation. It is of interest that this virus has the ability to agglutinate chicken red cells just as the influenza and mumps viruses do. Although many workers have handled both the virus and infected fowl tissues, there have been very few reports of human infections. All the previously recorded human infections with this agent seemed to involve the eyes and had resulted from accidental laboratory infections.

Although the Newcastle disease virus was first recognized in California in 1941, it was not reported in the eastern states until 1944-1945, and it was at about this time that certain atypical cases of human infection began to appear in Tennessee. Furthermore, the disease in fowl was not described in Alabama and Tennessee until 1947, although it may have been present earlier, and apparently some human infections also began to appear in Alabama in 1948 or perhaps late in 1947.

Howitt, Bishop and Kissling, working in the virus laboratory of the Communicable Disease Center that the United States Public Health Service operates in Montgomery, Alabama, studied serums received in 1947-1948 from various groups

*Howitt, B. F., Bishop, L. K., and Kissling, R. E. Presence of neutralizing antibodies of Newcastle disease virus in human sera. *Am. J. Pub. Health* 38: 1263-1272, 1948.

of children in Alabama and Tennessee who had suffered from a mild and brief central-nervous-system infection that had left no sequelae. Some of the patients were thought to have some form of encephalitis, and others were considered as having nonparalytic poliomyelitis.

Because of a history of frequent association with chickens and the absence of antibodies for common neurotropic viruses, these workers did neutralization tests with these serums against the virus of pneumoencephalitis or Newcastle disease of fowl. Of 15 serums from children in Tennessee with this new clinical syndrome, 12 showed antibodies for the virus of Newcastle disease. One case of encephalitis and one with a poliomyelitis-like syndrome also had antibodies for this virus. Numerous other serums that had been obtained in previous years from children without this atypical syndrome were negative. Two chickens from the premises of one of the patients showed both the pathological lesions of Newcastle disease and the presence of neutralizing antibodies in the blood. Serums were also obtained from 10 human cases of a mild central-nervous-system syndrome in rural areas of Alabama, and 8 of these showed definite neutralizing antibodies for the virus of Newcastle disease, and chickens with similar antibodies were also found in association with several cases.

After work with the virus was started in the Montgomery laboratory, an acute influenza-like infection developed in 6 of the laboratory personnel. Antibodies in high titers against the virus of Newcastle disease were found in the serums of these 6 persons. In addition, antibodies were found in 4 of 11 serums from laboratory personnel without symptoms. Serums obtained from 19 people before the virus work began showed no such antibodies. However, the blood of 3 persons who had typical symptoms before they came to the laboratory also showed neutralizing antibodies for Newcastle disease, whereas neutralization tests were negative on serums obtained earlier from many children and adults who had not shown these atypical neurologic symptoms.

Although no virus has yet been isolated from any of the human cases in this country, Howitt and her co-workers believe that their evidence in-

dicates that the virus of Newcastle disease of fowls is probably the agent responsible for many of the atypical central-nervous-system infections that have been reported in man during the past few years. They also suggest that, as in fowl, the manifestations are neurologic in young persons and influenza-like in adults. They believe that the virus originating with fowls has probably spread to man, and their evidence suggests that in many cases there is a man-to-man, rather than fowl-to-man, dissemination of the disease.

NO HOLDS BARRED

THE Committee for the Nation's Health, in a characteristic release, continues its campaign of disparagement against the American Medical Association. Since the Association is the accepted agent of a large majority of the practicing physicians of the United States, who are currently expressing their approval of its present policies in a very tangible manner, this campaign has the effect of reflecting on their judgment.

The Committee for the Nation's Health, under the chairmanship of a former president of the Massachusetts Medical Society, scrutinizes in this release the relations between the American Medical Association and the National Physicians Committee, suggesting that the American Medical Association may be blowing both hot and cold. It happens that nothing particularly new has developed in these relations. Since the formation of the National Physicians Committee over ten years ago, it has had the general approval of the American Medical Association, and this general approval has at no time been withheld. Within a matter of months the objectives of the National Physicians Committee have also been approved by the Council of the Massachusetts Medical Society.

The National Physicians Committee, during the course of its activities, has made some palpable mistakes. So have the American Medical Association and the Congress of the United States and so have most, if not all, of the persons comprising our somewhat disturbed society, if given the opportunity. Even the Committee for the Nation's Health, granted a long enough rope and enough time, may some day be in error.

The Committee for the Nation's Health continues its allusions to the "slush fund" of the American Medical Association, employing suggestion as a substitute for evidence, it crows over the news that Whitaker and Baxter, in dutiful compliance with the law of the land, have registered as lobbyists. Congress, it may be hoped, will not be unduly disturbed over the implication that the profession of lobbying, which it has legally recognized, is somehow not respectable.

The physicians, at least, on the Committee for the Nation's Health, are aware that the profession to which they are devoted is under heavy fire. Regardless of whether, in their devotion, they believe that it requires a major operation or can recover through more conservative treatment, they must admit that the argument cannot be fairly settled with six shooters on one side of the table and water pistols on the other.

CORN FOR INSTANCE

NEWSPAPER headlines and magazine digest articles that keep the public informed concerning scientific progress make it hard for the family medical adviser to remain a jump ahead of his patients. For example, what is monosodium gluconate, is a diet of rice and pineapple juice "good for you", what about salt substitutes, does the television tube emit enough gamma rays to warrant concern over its possible harmful effects on the family, can oranges be bought to better advantage by the pound or the dozen, is painless childbirth possible without anesthesia, and, perennially, should canned foods always be immediately emptied into a dish when the tin is opened?

One might suppose that housewifely concern over the supposed dangers of canned foods had been completely quieted, now that perhaps three fourths of the food comes from tins and the younger generation has almost universally learned to prefer canned peas to the violently green fresh variety that seems to please their elders. But enough vague fear of what may happen to food left in the opened tin persists to impel the manufacturers of tin cans to publish accurately documented scientific information about the healthfulness of the products sold in their containers. These products are steri-

lized in the tin, which may or may not be lined with a coating of enamel, in any case no harmful interaction occurs between food and container, and the food is more apt to stay sterile and harmless if left in the clean open tin (provided it is kept cool and covered) than if placed in a dish of questionable sterility and left exposed. Eye appeal may be enhanced if the food is placed in an attractive bowl, but hygiene does not require the transfer.

HEALTH ACCESSORIES

BRITAIN'S bald heads of both sexes, according to a recent statement in *Newsweek*, will soon be demanding Government-financed wigs at the rate of 100,000 a year. The estimate has been made by the two dozen busy wigmakers currently engaged in supplying utility wigs, at \$40, and non-utility wigs, at \$50, for the Ministry of Health.

Two styles of wigs are furnished for men, full wigs or "sculpettes," and five for women. Each applicant is allowed two wigs at \$40, creating a possible demand that may cost the Government \$8,000,000 annually, in addition, cleaning and dressing the spare wig every two months (another Government obligation) will add \$400,000 to the bill.

Under other provisions of the National Health Act false teeth, hearing aids, trusses, electric wheel chairs and spectacles are supplied to a grateful public. November estimate of the Ministry of Health was that 1,700,000 pairs of glasses had already been issued. An applicant was unsuccessful, however, in procuring a free bottle of hair shampoo.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

HEFFERNAN — David A. Heffernan, M.D., of Brighton, died on April 13. He was in his sixty-ninth year.

Dr. Heffernan received his degree from Harvard Medical School in 1902. He was a member of the New England Otological and Laryngological Society and a fellow of the American Medical Association.

His widow survives.

SMITH — Lillian R. Smith, M.D., of Harwich, died on April 15. She was in her sixty-fourth year.

Dr. Smith received her degree from Tufts College Medical School in 1917. She was formerly director of Maternal Health and Child Hygiene in Michigan and was in charge of the Emergency Maternal and Infant Care Program in that state during World War II. She was a fellow of the American Academy of Pediatrics and the American Medical Association.

A sister survives.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

RHEUMATIC-FEVER FELLOWSHIPS

The United States Children's Bureau has made available through the Massachusetts Department of Public Health and the Harvard Medical School one fellowship in rheumatic fever at the House of the Good Samaritan of the Children's Medical Center, Boston, for the year beginning July 1, 1949.

Applicants should be interested in working eventually in the field of rheumatic fever in public health or in teaching, rather than in private practice.

Work under this fellowship will probably be acceptable for credit by the American Board of Internal Medicine or the American Board of Pediatrics.

Application should be made as soon as possible to Dr. Benedict F. Massell at the House of the Good Samaritan, 25 Binney Street, Boston 15 (telephone, BEacon 2-3002).

REPORTS OF RESEARCH PROJECTS IN PROGRESS

Division of Biologic Laboratories

In this division, field studies in medical students and Army personnel in collaboration with the staffs of various medical schools, hospitals and other groups in Greater Boston regarding diphtheria immunity in adults are continuing with the support of a Government contract, studies of immunity in diphtheria patients in collaboration with the staff of Boston City Hospital are still in progress, in the chemical and immunologic studies on purification of diphtheria toxoid, begun in 1944 and continuing to date, various methods have been employed, and recent results have produced a toxoid almost 100 per cent pure and considerably more potent than the starting material (studies are also under way on methods for more exact measurement of the potency of diphtheria toxoid), for the past five years a long-term study on the stability of biologic products has been in progress, directed toward elimination of unstable lots and discovery of stabilizing substances, studies of newly reported methods of rapid diagnosis of smallpox have been undertaken, for possible use in an emergency, in conjunction with the development of pertussis vaccine, studies have been instituted on the blood-cell clumping factor in pertussis cultures, on the toxic factor in culture supernatants and on other significant properties of pertussis preparations, about 1600 liters of outdated plasma have been fractionated, laboratory and clinical tests on albumin and gamma globulin prepared from this source having shown both fractions to be fully as effective as the products made from fresh plasma (this finding opens the way to a major and hitherto undeveloped field of blood fractions), under grants from Research Corporation totaling \$41,940 (July, 1945, to June, 1949, inclusive) a program for testing blood fractions made under license from the Cohn patents has been conducted and has included tests on numerous major and minor products, and assistance to miscellaneous studies.

Division of Cancer and Other Chronic Diseases

In this division, an effort is being made to evaluate detection-center activities, to measure screening by means of the seven danger signals and to ascertain the incidence of cancer among persons with and without any of the seven danger signals, a six-year evaluation of the cytology test for cancer, which is more than half completed, will answer many questions regarding procedures and will determine the value of the test itself, a study is underway showing environmental factors in relation to the length of life of patients after visiting a cancer clinic, in a long-term study on environmental factors in relation to the etiology of cancer one report is in the process of being published, and others are nearly ready (cancer of the breast, cervix and skin are being studied at present, a continuation project on familial aspects of cancer that has been in progress for several years embraces the possible etiologic effects of heredity, conjugal state, number of children and so forth, the accuracy of the death record in respect to certain chronic diseases is constantly under study and will continue until maximum results have been obtained (work has been done on heart disease, cancer, diabetes, nephritis, arteriosclerosis and rheumatism), since at present certain sites of cancer show an upward trend in death rate and others a downward trend, and still others are trendless, twenty sites are being watched, and future changes in their trends will be reported, the best mediums and the various channels for propaganda purposes, for creating awareness and for stimulating patients to action if symptoms of cancer appear are being evaluated.

Division of Communicable Diseases

In this division, a bacteriologist assigned to the Virus Laboratory at Harvard Medical School is working on the laboratory aspects of the diagnosis and epidemiology of poliomyelitis, a study to determine the feasibility of giving booster doses of diphtheria toxoid to high-school students is underway, records of all cases of typhoid fever reported since 1940 are being thoroughly analyzed, the titers of naturally occurring anti-A and anti-B isohemagglutinating bodies in the serum of persons donating blood to the mobile blood bank are being studied, the presence, type and titer of Rh antibodies in the sera of Rh- persons who have received transfusions of blood not typed for the Rh factor are being investigated, studies directed toward improving the mediums and methods of culturing of tubercle and diphtheria bacilli and enteric pathogens are underway, and the laboratory, in co-operation with the Influenza Information Center, National Institute of Health, is performing serologic tests on blood specimens from persons suspected of having infections with either influenza A or B viruses.

Dental Division

Observations on the clinical effect of the use of a fluorinated dentifrice on the incidence of dental caries in 3000 school children are in their second year in two separate locations, fluorination of the water supply of two state schools is now in its third year of operation, and a yearly check on the incidence of dental caries is being kept by investigation of the rates of decayed, missing and filled teeth (nutritional studies are being included)

Food and Drug Division

The effects of the addition of water upon food value and keeping qualities of shucked clams by the various methods of washing, as practiced in clam-shucking plants, are being studied, new, sensitive, qualitative test for the detection of glycogen in horse meat is being investigated, the stearin derived from beef fat, horse fat and pork fat, or mixtures of these fats, is being identified microscopically, and the specific volumes of the hemi-cellulose content of soy flour in frankfurters is being determined, the analytical constants to determine genuine qualities of cider and other vinegar are being evaluated, the possibilities of a rapid sorting test for the initial separation of samples of enriched flour from those of unenriched flour are under investigation, the methods of identification of the newer synthetic narcotic drugs are being studied, a new, sensitive method for the detection of urea-formaldehyde sizing in garnetted clippings or shredded cloth is being developed, and analytical procedures for differentiation of new and second-hand bedding filling materials are being evaluated

Division of Maternal and Child Health

The activities of this division include performance of the Massachusetts hearing test (a successful and inexpensive adaptation of pure-tone-testing methods to large groups of children), a study of the relation of stereopsis to muscular co-ordination and educational adjustment of children, the Harvard pediatric study of the incidence of illness and the types and costs of pediatric care and the maternal-mortality study conducted by the Committee on Maternal Welfare of the Massachusetts Medical Society

Division of Sanitary Engineering

In this division the following matters are being investigated: trickling filters, with emphasis on rates of B O D removal, effects of recirculation, size of filter medium, oxygen requirements and physical design, disposal of trickling-filter effluents on intermittent sand filters, design and operation of septic tanks for small installations, subsurface disposal of septic-tank effluents, with emphasis on rates of application to particle size of soil, anaerobic digestion of sludge from sewage receiving phenol and formaldehyde wastes, aerobic biologic treatment

of aldehyde-bearing wastes resulting from the manufacture of synthetic resins, aerobic biologic treatment of the effluent from the primary treatment of wool scouring wastes with calcium chloride, with special reference to B O D and color removal, methods of treatment of waste dye liquors to remove color and B O D, methods of treatment of shellfish to reduce pollution load, investigation of new methods of analysis, preparation of samples, new mediums and use of enterococci as an indicator of pollution, methods of removal of iron and manganese from the public water supplies of Lowell, Billerica and Somerset, effect of long storage on color, chemical changes and reduction of bacterial load of water, effect of particle-size gradation of filtering mediums versus effective size for the filtration of water and sewage, use of cumene hydroperoxide for reduction of B O D in sewage and industrial wastes, in co-operation with the Federation of Sewage Works and United States Public Health Service, the effect of chrome salts on B O D and an improved method for grease determination, method of analysis of gases produced by the anaerobic digestion of sludge, method of determination of phenols, effects of storage and inhibitors on determinations of phenols in water, effectiveness of precoat type of diatomaceous earth filters for removal of bacteria and reduction of chlorine demand in swimming pools, effect of sodium hexametaphosphate on yellow brass pipe, quantitative determination of odors in the atmosphere, a rapid method for the determination of fluorides in water, use of sodium fluoride in water for the prevention of dental caries, and investigation of various commercial weed killers

Division of Tuberculosis

The Division is at present carrying three research programs in co-operation with the Children's Hospital, Massachusetts General Hospital and the Boston Floating Hospital, under a grant from the National Institute of Health, streptomycin treatment of children suffering from acute forms of tuberculosis, including particularly the use of streptomycin in tuberculous meningitis and miliary tuberculosis, a five-year co-operative study of BCG vaccination in student nurses and medical students by the Massachusetts Department of Public Health and the United States Public Health Service to determine the desirable preinoculation test with purified protein derivative and the optimum dosage of BCG vaccine, method of inoculation, duration of immunity and degree of protection conferred, and the study of hormonal changes in patients with carcinoma, both during and after therapy with sex hormones and related compounds, under a grant to the President and Fellows of Harvard College and Harvard School of Public Health for study from September 1, 1948, to August 31, 1949 (this work is being carried on in the laboratory of the

Department through the Pondville Cancer Hospital, where, in January, 1949, a new research laboratory for cancer, under the direction of a half-time director, was opened

Division of Venereal Diseases

This division is evaluating the penicillin treatment of gonorrhea and syphilis, the streptomycin treatment of granuloma inguinale in varying doses to determine the most effective dose and schedules, aureomycin treatment of lymphogranuloma venereum in selected cases, and a research project to find the most effective transport mediums for gonococcus cultures

MISCELLANY

PLASTIC SURGERY

Plastic surgery as a specialty has become well recognized. During the two world wars surgeons accumulated a wealth of experience in this field, and consequently the specialty has been greatly enlarged to the point where it is represented in organizations and publications. The newest periodical to be welcomed into the ranks of medical journalism is the *British Journal of Plastic Surgery*, inaugurated in 1948, under the editorship of A. M. Wallace, M.Sc., of the Department of Surgery of the University of Edinburgh. It is the official organ of the British Association of Plastic Surgeons. In 1946 the American group began the publication of *Plastic and Reconstructive Surgery* as the organ of the American Society of Plastic and Reconstructive Surgery, Incorporated. The typography and illustrative work of both journals are excellent.

CORRESPONDENCE

CARBON TETRACHLORIDE AND AZOTEMIA

To the Editor In the April 7 issue of the *Journal* appears a comment by Dr. Jacob J. Silverman, of Staten Island, New York. Replying to this comment, I should give the following facts:

The patient concerned in the article on extrarenal azotemia, which appeared in the January 20 issue of the *Journal*, did indeed work in a rubber factory, and the question of any exposure to noxious agents at work was carefully considered. Not only was there communication with the factory physician about whether the patient had been exposed to noxious agents, but also one of the consultants who saw this patient was an authority on industrial diseases, and was asked to see the patient with this point particularly in mind. We were not able to obtain any evidence that he had used carbon tetrachloride or other noxious agents, and we believed that this possibility was excluded as far as possible.

JAMES H. TOWNSEND, M.D.

Mount Auburn Hospital
Cambridge, Massachusetts

SKIN THERMOMETERS AVAILABLE

To the Editor In the April 7 issue of the *Journal* (on Page 587) Dr. John B. Sears, in speaking of mercurial-type skin thermometers, states "I have found none like it manufactured in this country."

A little less than two years ago I purchased a mercurial-type skin thermometer manufactured by, "RASCHER AND BETZOLD, INCORPORATED," Chicago, Illinois. This thermometer is most satisfactory, and the price is very reasonable. I believe that any surgical supply house could order it for physicians desiring one.

ROBERT J. FERGUSON, M.D.

Ashland, Ohio

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The Metabolic Brain Diseases and Their Treatment in Military and Civilian Practice By G. Tayleur Stockings, M.B., D.P.M. 8°, cloth, 262 pp. Baltimore: Williams and Wilkins Company, 1947. \$4.50.

Peripheral Vascular Diseases: Diagnosis and treatment By David W. Kramer, M.D., associate professor of medicine, Jefferson Medical College, assistant physician, Jefferson Hospital, chief clinical assistant, Vascular Clinic, Jefferson Hospital, visiting physician, Medical Division, and consultant on peripheral vascular disorders, Philadelphia General Hospital, attending physician, Metabolic Division, and chief of Diabetic Clinic, Jewish Hospital, attending physician and physician-in-charge, Department of Metabolic and Peripheral Vascular Disorders, St. Luke's and Children's Medical Center, and metabolist to Eagleville Sanatorium. With a foreword by Edward L. Bortz, M.D. 8°, cloth, 620 pp., with 157 illustrations. Philadelphia: F. A. Davis Company, 1948. \$8.00.

NOTICES

NEW ENGLAND DIABETES ASSOCIATION

The annual meeting of the New England Diabetes Association will be held in Thayer Hall, City Hospital, Worcester, Massachusetts, on Monday, May 23, at 4 p.m.

CLINICAL PROGRAM

Neuropsychiatric Aspects of Diabetes Dr. Foster L. Vibber
Potential Diabetes Dr. Joseph A. Lundy
Necrotizing Papillitis in Diabetes Dr. Edward F. Ramsdell
Pathology of Necrotizing Papillitis Dr. Raymond H. Goodale
Experience with Diabetic Coma at Worcester City Hospital Dr. Albert E. Hall
Optimism and Diabetes Dr. George Ballantyne

The clinical program will be preceded by the annual business meeting including the election of officers and four directors. This meeting is planned in conjunction with the annual meeting of the Massachusetts Medical Society, May 23 to 26. The meeting will be completed in time so that councilors of the Massachusetts Medical Society can attend the Cotting supper at 6:00 p.m.

AMERICAN SOCIETY OF ELECTROENCEPHALOGRAPHY

The annual meeting of the American Society of Electroencephalography will be held at Chalfonte-Haddon Hall Hotel, Atlantic City, on Saturday, June 11 and Sunday, June 12. The meeting will begin at 10 a.m. on Saturday, and there will be a dinner for members and their guests which ladies may attend, on Saturday night at the Chalfonte-Haddon Hall Hotel. On Sunday morning there will be a joint meeting with the American League Against Epilepsy consisting of a symposium on corticothalamic circuits. On Sunday afternoon the American League Against Epilepsy will hold the remainder of their meeting, to which members of the American Electroencephalographic Society are invited.

The business meeting of the Society, open only to members, will be held on Monday, June 13.

AMERICAN NEUROLOGICAL ASSOCIATION

The annual meeting of the American Neurological Association will be held in Atlantic City, New Jersey, on June 13, 14 and 15, with headquarters at Chalfonte-Haddon Hall.

THE SHATTUCK LECTURE*

La Médecine du Coeur

PAUL D. WHITE, M.D.†

BOSTON

IN 1806 there was published at Lyon in France by Mark Anthony Petit an essay entitled "La Médecine du Coeur," literally translated medicine of the heart but actually signifying not cardiology but medicine *from* the heart — that is, benevolence in the practice of medicine. It was composed of four parts written as poetry and presented as such before the Academy of Lyon, the first in 1800 on the difficulties and disappointments connected with the profession of medicine, the second in 1801 on trust in the physician, the third in 1802 on gratitude toward physicians, and the fourth in 1805 on pain. Petit was surgeon-in-chief of the Hôtel Dieu in Lyon, professor in the university and member of the Academy, there and of the society of professors of the medical schools of Paris, Brussels, Antwerp, Bordeaux, Nîmes, Marseille, Avignon, Grenoble and of Montpellier, where he had himself studied medicine. Nearly one hundred and fifty years have elapsed since these notable writings, but their truth and appeal endure and I have selected them as a text for the Shattuck Lecture of which I am sure Dr Shattuck would have approved. It is of interest that George Cheyne Shattuck was himself a student at Dartmouth Medical School during the early years of the nineteenth century at the very time that Petit was delivering his essays. In fact, Shattuck received his M.B. at Dartmouth in 1806. He was president of the Massachusetts Medical Society from 1836 to 1840 and delivered the annual discourse in 1828. He established the Shattuck Professorship of Pathological Anatomy at Harvard Medical School in 1853. At the time of his death in 1854 his will established this lectureship, which was called by his name.

I shall discuss the subject of *médecine du coeur* from four viewpoints, which at first sight may seem quite unrelated but which actually are closely interwoven and together present the picture of the

physician's position as a whole in the world of our day. All four subdivisions have been topics for addresses and lectures concerning the medical profession in the past, including Shattuck lectures themselves, but they have not, so far as I know, been correlated to give the complete picture. These four parts of the whole are in sequence: first, the individual doctor-patient relationship, secondly, the position of the physician in his community, thirdly, the national problem, and fourthly, the international or worldwide scope of medicine. Some would have it that in all these relationships a simple detached so-called "scientific" attitude should prevail, as from an "ivory tower," devoid of *médecine du coeur*, but those of us who have observed the actions of mankind during a generation are aware of the actual failure to apply science in such an attitude. So long as man is an emotional animal with a "heart," one must act truly scientifically — that is, with knowledge and wisdom — in recognizing that fact and in dealing with medical problems accordingly. I have long been impatient with the distinction so commonly raised separating the science from the art of medicine, they are both essential parts of one whole so far as the actual practice of medicine is concerned, embodying the know-how to deal with man himself as well as with his fellows of a lower order such as the bacteria that prey on him or help him. After all, science literally means knowledge based on accurate observation, and art is simply the skillful and scientific application of such knowledge, they are inseparable and should be taught as such.

It is so obvious to those of us who have been practicing medicine privately that our patients should be our friends that we do not often stop to ask the question, "Why?" The statement may seem trite to some, but to the beginner and to the skeptic it is well to pause a moment to present some of the answers. The first of all is in establishing more easily an accurate diagnosis. In my own field and in most other fields of medicine the diagnosis is in large part dependent on an adequate history

*Presented at the annual meeting of the Massachusetts Medical Society, Worcester, May 25, 1949.

†Clinical professor of medicine, Harvard Medical School; consultant in medicine, Massachusetts General Hospital; executive director, National Advisory Heart Council.

of the present illness, past troubles, family history, and social and business relationships. The sooner one establishes a sympathetic and friendly relationship with one's patient the sooner will one obtain the necessary information from all the story that can be told, any minor portion of the patient's account, sometimes in the form of a confession, may be vastly more important than all the laboratory tests in the world and may save not only time and money, but even misery and death themselves. A few years ago I gave an address to the McGill medical students entitled "The Patient Advises the Doctor," and to obtain such advice I asked some of my own private patients and also patients in the hospital wards to write to me what they thought would be worth telling young men and women who would soon be doctors themselves. I received many interesting and helpful replies, one of which was from Miss Mary Ellen Chase, professor of English literature at Smith College, whose essay inspired us to invite her to give the address at the annual banquet before this society a year ago. A letter to me from one of the ward patients at the Massachusetts General Hospital stated that she had so much friendship for her doctor that she would tell him even more than she would tell her priest. Such telling can contain invaluable information of strictly medical importance.

A second reason for establishing a friendship with one's patient is to ensure better treatment. Not infrequently necessary therapy is difficult, time consuming or expensive, and therefore likely to be neglected or postponed if impersonally prescribed by the physician. One might say "All very well, if the patient does not carry out the doctor's advice, whose fault is it? The patient's, of course." I deny that, except in rare instances in which one is dealing with persons of the lowest order of intelligence or who are mentally unsound, and even then the doctor should have recourse to some arrangement, public or private, which may more adequately deal with such persons than can the doctor himself with the limited time and resources at his disposal. In general, then, it is the doctor's fault if he cannot induce the patient or his family to carry out the necessary treatment, often the importance of establishing an initial friendship here becomes obvious.

The value of a clear and friendly explanation of one's diagnosis to the patient himself was well and forcefully stated by Petit more than a hundred years before it was appreciated by the medical profession in general, in fact, it is still frequently neglected even in these advanced and enlightened days. Petit wrote

When a patient asks us about the nature of his illness, we should not, like an oracle, reply in obscure terms and proclaim the ridiculous pretention of science in speaking only its language. The art of rendering oneself intelligible applies to all, and since it is one of the best means of persua-

sion, it should be one of the very first studies of the physician and medical student.

A third scientific reason for *la médecine du cœur* as it affects the private or individual patient is in the accretion of new knowledge. The co-operation of the patient in special investigations of symptoms, signs, mechanisms of disease that involve physiologic and biochemical procedures, prognosis, and therapy may be of inestimable value in the advance of medicine. Such co-operation is much more likely to come from a friend. For example, one of our recent studies has involved the follow-up records of 173 private patients of my own who consulted me over twenty years ago for neurocirculatory asthenia — all but 2 have been traced and one of these lost persons should be discovered before long, since she was a one-time volunteer in the Social Service Department of the Massachusetts General Hospital. Such a high percentage of success in follow-up study is less likely when one is dealing with case numbers and not with one's own friends. Also, post-mortem examinations are still of much value in adding to our medical knowledge, the families of patients of ours who have also been our friends are much more likely than the families of "cases" to permit such autopsies if we but take the trouble to ask for them.

A fourth reason for establishing a good doctor-patient relationship is for teaching purposes. Some of the most important lessons that I have been able to present in my teaching to both undergraduates and graduates of medicine have been made possible because some of my most articulate patients, who have taken an active part in the teaching of my students individually, in small groups, or even in large amphitheater clinics, have been warm friends of mine.

And, finally, there is a great personal satisfaction and joy in the establishment of human friendships, not wholly definable, both for the doctor and, I am sure, for his patients. This human relationship is doubtless a potent reason for attracting many to the profession of medicine as to religious ministries. There is something here that we doctors prize and for which we should be grateful, something that is sacrificed by those who deal largely with inanimate nature, or even with growing things in the vegetable and animal kingdoms that lack the intelligence and soul of man himself.

With this introduction of the role played by *la médecine du cœur* in the doctor-patient relationship that makes up the vast majority of the functions of the physician in the world, let me go on now to the place of the doctor in his community. Actually he holds his honored place locally because he is medical adviser and friend of many of his neighbors and of other citizens of his community and their families. Often he is himself the leading citizen of his village or town, and I have prized among my own friends physicians, mostly family doc-

tors, whose help was sought not only to diagnose and to treat disease among their patients but also to decide about the daily problems of the community, whether they concerned the public health or the schools, the church or even the roads. My own father, a family physician, was such a person, a deacon in his church, a teacher and an active man in the good works of his environment, great compensations, to be sure, for his hard and exacting life. At one time when he was ill and I was a hospital intern off duty for a few days I made rounds for him and quickly discovered that strictly medical advice played only a partial role in what was expected of him.

Many doctors have served on boards of health, school boards, lay councils of the church, and even governing boards of institutions and civic bodies, but as a rule they are too busy and must burn the midnight oil even to do their ordinary doctoring. It is at considerable sacrifice that they can do more, and not a few physicians have fallen victim to the demands that have been made upon them. They have practiced a benevolence (*médecine du cœur*) far beyond their strength, and I would here and now put in a plea not only to the doctors themselves but also to their communities to help to spare them for longer and greater usefulness than has been the lot of the majority of the doctors in the past.

Since the days of Hippocrates it has apparently been the tradition in medicine for the doctor to overwork and to be himself a sacrifice. It is expected of him, somehow, whether he be general practitioner, specialist, teacher, administrator or research worker. It may quite possibly have been a noble tradition, but often it has been too noble and unreasonable. There are some signs of improvement in progress in this respect. For example, nowadays, it is common for the young doctor or indeed even for the medical student to marry and to begin to raise a family, doubtless fostered in part by World War II but also by a saner public opinion, which in my day frowned on such doings until we were well established medically after completing our hospital residencies. Perhaps likewise it will be possible more and more by the establishment of group practice and convenient substitutions to give doctors adequate vacations and time off at night so that they will not be constantly on the job. The communities as well as the doctors themselves should see that this is done and that the doctor be treated as a human being and not as a machine. The opposite evil of the establishment of an eight-hour day for all physicians is equally to be avoided. Medicine is not a trade so to be arranged, but there should be a happy mean between these two extremes.

And last but not least the doctor's family must be treated with more respect than customarily in the past. Too often wife and children are disappointed in their plans because of the exigencies

of medical practice or research — some of this cannot be helped, but much of it can by better organization and by sharing of work, not in the form of socialized medicine with its threat to the all-important doctor-patient relationship but by simpler plans developed by the doctors themselves with the help of their respective communities.

There is another point of importance with respect to the doctor in his community, and that concerns his relationship with his medical colleagues. Great variations exist in such relationships from the friendliest co-operation to the bitterest hostility, fortunately the former situation holds most often. In Massachusetts we have been fortunate in inheriting and in maintaining a tradition of a friendly medical atmosphere. I would herewith pay tribute to the many physicians in Boston and throughout the State for their kindness and help to me, both personally, in my practice, and in my clinical research. My colleagues working in other hospitals in my field have invariably contributed data about cases, even from their private practice, to aid me in some study or other and have also given me their helpful advice and encouragement. Thus I would acknowledge my own debt and at the same time plead for more *médecine du cœur* from the doctor to his colleagues and from the community to its doctors.

The third phase of my subject deals with *médecine du cœur* for the nation. Here the public health is the main problem to be dealt with by both public and private enterprise. It is here too that I would plead for more understanding and co-operation between our Government administration on the one hand and the American Medical Association and its component parts in every state on the other. With a benevolent (*la médecine du cœur*) attitude to public-health problems of the nation, which is characteristic of each of these bodies, there should be no real conflict between them. Ample and friendly discussions should solve the difficulties that do exist. There is no need to enter into acrimonious dispute, which in the past has sometimes been based on personal prejudices and false pride.

It is obvious to us all that in the field of our own public health certain facts exist. In the first place, tremendous strides in medical knowledge by research have been made in this country during the past generation, more than in all the centuries of the past, and this has been in largest part under the stimulus, guidance and support of private enterprise in medical schools, hospitals and foundations throughout the nation. But it is now equally true that we are but at the beginning of our knowledge of the pathogenesis and mechanism of disease processes and of their adequate treatment and prevention. There remains much more still to be done than has been done in the past. Private resources, important though they still be, are inadequate for the job. Public aid, largely through

the new developments in the United States Public Health Service, can very wisely supplement the private resources for medical research. Not only is this necessary financially but the public wants and is now demanding a stake in medical research, and with increased interest and appreciation of the need and prospects for the future, they too wish to help. The greater number of trained research workers that can be put on the job with adequate facilities, the sooner we shall have answers to vital and important problems of public health such as cancer, or rheumatic fever, high blood pressure and coronary atherosclerosis, in which I happen to be personally interested and to help solve which the National Heart Institute was set up by an act of Congress last June. It was my conviction that public and private enterprise should join to fill this vital need, and that was why I enlisted part time in the work of the National Heart Institute and National Advisory Heart Council while continuing my private practice in cardiovascular disease. My experience to date, I might add, has been most encouraging—I have found my colleagues of the Public Health Service engaged in this work and my fellow private citizens on the Council most able, honorable, diligent and co-operative. *Médecine du cœur* has been constantly in evidence in all our deliberations and practice. I might add that it is these public officials themselves, medical and non-medical, who have constantly expressed and practiced a jealous protection for private enterprise and a liberal attitude toward private medical endeavor in research and teaching.

A second obvious fact that indicates the need of a liberal national support of medical endeavor in this country is the plight of the medical schools themselves. Both private and state schools require a large share of the resources of the universities throughout the country, so much so that the presidents themselves have been worried. Medical teaching is vital to the national health. Not only must we continue the high standards of the present day but also we must add appreciably to the output of new medical graduates. There are not enough doctors in the whole country as yet to meet all the demands. Since that is so I would plead for the admission to this country and for their distribution where most needed of several hundred able physicians still classed in Europe as displaced persons. Dr Burgess, of Providence, has well spoken in their behalf and incidentally thereby in behalf of many thousands of citizens of our own country who need their help.

A third obvious fact is the lack that still exists in the United States, among many people, of adequate medical attention both for diagnosis and for treatment. The costs of medical care have risen so high that many of our citizens cannot afford them. Some are insured, but many are not. In some way or other, which must be decided by care-

ful, conscientious and friendly discussion, such people must be protected and not left merely as a casual burden and charge for the medical profession or public purse, or both. The private practice of medicine should continue without interference, and the adequate care of the health of those unable themselves to pay for it should certainly necessitate neither the general socialization of medicine with its disadvantages as we see it elsewhere in the world today, nor the pauperization of our improvident people or of those unable financially to meet all the costs of medical care. This problem will take years still to solve. To my mind it is, however, less urgent than that of medical research, whose function it is eventually to make hospitals unnecessary.

Finally, we come to the most important of all the applications of *la médecine du cœur*—namely, the international. Fewer doctors are involved in this, but those that are realize its tremendous significance and power for good in these troubled times. It is a challenging but rewarding privilege to have a share in this work, which can be as potent a factor for peace as any in existence today. Without peace during the next generation all mankind will suffer, and attempts to advance in medical research, teaching and practice will be nullified. In fact if further and more devastating wars take place our civilization, including the present advanced state of medicine, can be set back a thousand years. With peace we can make great strides in the advancement of health for all the people of the world. Nothing else is so likely to maintain peace as the solicitous regard for the health and happiness of every inhabitant on this old planet of ours. We doctors are actually in a better position to accomplish this through the establishment of friendly and co-operative relations with the medical professions of other countries than are any other groups—in business, law, government or military circles. We have no ax to grind. We doctors are close to the hearts of all the world's citizens, and so by our own international medical friendships we surely can advance the peace of the world.

Medical congresses, visiting lecturers and medical traveling fellows can all play a role, but the most useful function of all, in my experience and in that of a good many others, as noted by neutral observers in many lands, has been played by the medical missions that have gone out to foreign lands, especially to those that have been ravaged by war, under the aegis of the Unitarian Service Committee. It is of these, as an example of what can be done, that I would like to speak briefly now, and for which I would ask your vigorous support.

Medical missionaries have traveled abroad for generations to do good, and they have done good, often but little known, but nevertheless of much significance in our international friendships, as in the case of my old acquaintance, Paul Harrison,

who has just completed thirty years of the ablest surgery and of setting a Christian example in Arabia Relief missions have gone to every corner of the globe to succour people in need at times of epidemic disease, famine or disaster. I myself was privileged to spend a few months in Northern Greece in 1919 to help in the control of exanthematic typhus, a serious disease, which, like malaria, has now been largely wiped out in that part of the world.

The special teaching missions of which I speak are, however, something new and more important than other missions in the past. They have gone out during three consecutive years to establish or renew medical associations between the medical profession of our own country and those of other lands, many of which had been crushed down by the iron heel of the invader with abolition or reduction to a minimum of medical education, research and practice. We went throughout the countries in central and southern Europe to share our good luck and to repay a little of the debt that the doctors of the new world owe to the old.

I myself was privileged to serve on two of these missions, the first to Czechoslovakia in 1946 and the one to Greece and Italy in 1948. Other missions of similar nature went to Poland in 1946 and again more effectively in 1948, to Austria in 1947, to Finland and to Germany in 1948, to Colombia in South America in the fall of 1948, and most recently to the Philippines. Still another smaller group went to teach at the medical school for displaced persons in Bavaria last summer. New missions will be needed for other parts of the world, — for example, India, — but we must not forget to follow up especially those already carried out.

Each of these teaching missions has been composed of a group of professors, numbering from 6 to 16, from several different medical schools in this country and even from Canada or from countries abroad, presenting in lectures, demonstrations, and conferences (with the help of interpreters and student guides) various special fields in medicine, surgery, the preclinical subjects (such as physiology) and dentistry. Thus each group has acted as a peripatetic medical school carrying good will and friendship as well as medical knowledge throughout these foreign lands. The invitations came to us from the foreign universities themselves, but the purpose and success of the missions quickly appealed to UNRRA, to WHO, to the peoples themselves, and to the governments of the countries involved, and resulted in warm support and the most cordial reception everywhere. An excellent press publicity followed the course of each mission as it traveled through the countryside.

The enduring effects of such missions are still seen in Czechoslovakia, where, despite the Communist regime and the serious hardships suffered therefrom, our friends, medical and nonmedical, made by the mission in 1946, have continued to

be our friends as was clearly evident during my return visit there a year ago and by correspondence ever since. In the other countries too we have made and have held many friends. In these difficult days all this is bound to count in the long run. What we would have liked most of all to do would have been, and would still be, to re-establish a friendly medical contact with the USSR. We offered our services, but they were not accepted by the dictatorial group in power at the moment, I am sure that the doctors and the Russian people themselves would have welcomed us from their hearts and will do so one day. Meanwhile at the present time all indications seem to point to the political control of science in general and of medicine in particular in the USSR, resembling a good deal the Nazification of German medicine under Hitler, which not only blocked advances in medicine in Germany but actually resulted in a deterioration.

We hope that we may have the chance to share our medical experiences with our colleagues on the other side of the iron curtain when that curtain eventually is swept aside. This could be the beginning of a real friendship throughout the world. Meanwhile we should, with everlasting patience, constantly demonstrate to all parts of the world with which we can get in touch by personal contact, or by writing or radio, including the peoples immediately adjacent to the USSR as well as whatever inhabitants or citizens of the USSR we can reach, that we desire not to impose, but simply to share with all the world our way of life. It is very clear to those of us who have been privileged to make adequate comparisons that this way of life of ours, imperfect as it yet is, has advanced to a higher level than any other, standing as it does for freedom and happiness of all humanity, a precious heritage that we must forever defend from ruthless aggression. I personally believe that we should do more than pay lip service to this idea. We should by our own example and effort become active crusaders. In this small world today we are our brothers' keepers.

Let me emphasize once more the fact that these particular medical missions of ours were not simply "cold-blooded scientific groups." We did, of course, dispense and exchange by word and deed much scientific knowledge, but we did much more than that. We were the bearers of *la médecine du cœur* from this fortunate land of ours to our less lucky colleagues overseas. I have spoken of this particular activity in medicine internationally because it is a good example of what can be done and because I am myself familiar with it. There are, of course, other ways for the medical profession to help out in world affairs.

And so, my friends and colleagues, members and future members of the Massachusetts Medical Society, what a privilege and challenge is ours in the practice of *la médecine du cœur* for our patients,

toward each other, to our communities, for the national public health, and last but not least in our international relationships for the peace and happiness of all mankind!

In closing, let me quote again from our friend Petit

Voula, mon cher Forlis, ce qu'il fallait te dire,
Pour guider, en ami, cette ardeur qui t'inspire
Loin de te détourner par d'effrayans tableaux,
J'ai même en les peignant retenu mes pinceaux,

Mais, sans t'épouvanter d'un récit trop fidèle,
Suis courageusement le penchant qui t'appelle
Au bonheur des humains consacre ton repos
Et que l'art de guérir compte aussi ses héros

And that, my dear Forlis, is what I had to tell thee,
In order to direct, as a friend, the ardor which inspires thee
Far from turning thee away by frightening tableaux,
I have, in painting them, restrained my brushes
But, without the distraction of too exact a recital,
Follow courageously the leaning that calls thee
To human happiness consecrate thy repose,
And let the healing art also count its heroes

TREATMENT AND PROPHYLAXIS OF PULMONARY EMBOLISM BY VEIN INTERRUPTION*

COMMANDER MARION LEE CONNERLEY (MC), U S N,† AND
CAPTAIN JOHN H L HEINTZELMAN (MC), U S N‡

CHELSEA, MASSACHUSETTS

FOR the years 1944 and 1945, an average of 1 to 3 patients died each month at the United States Naval Hospital, Chelsea, Massachusetts, as a result of pulmonary embolism. The diagnosis in 17 of these patients was substantiated by autopsy. It therefore became apparent that some form of treatment must be instituted in an attempt to reduce the toll claimed by this scourge of surgical procedure in New England. In an effort to obtain some useful data that might be a contribution to this problem in general, a regime consisting of interruption of femoral, iliac or inferior-vena-cava venous pathways was adopted. A consistent, single form of treatment seemed more logical, if one desired to obtain data, than the treatment of some patients with heparin, some patients with dicumarol and some by ligation, or a mixture of the three. This report analyzes thirty-six months' experience with these surgical approaches to the treatment and prophylaxis of pulmonary embolism from December, 1945, to November, 1948.

DEFINITION

Thrombophlebitis (phlebothrombosis) is a pathologic process characterized by the occlusion of venous channels, partial or complete, static or progressive, by blood clot, portions of which are liable to fracture and dissemination through venous pathways to the lungs producing infarction of variable degree.

ETIOLOGY

Thrombophlebitis and phlebothrombosis are treated jointly in this discussion, since we now believe both procedures give rise to pulmonary em-

bolism, should a patient succumb to a pulmonary embolism, it matters little whether his original blood clot was bland or inflammatory. It does make a difference in diagnosis, the bland type being much more difficult to detect.

Etiologically no explanation can be given as valid, there are perhaps four groups of conditions that are thought to be contributory.

Venous Pressure

In some diseases there is a definite lowering of venous blood pressure. In some positions there is a lowering of venous blood pressure. With less "urge" to maintain the velocity of venous blood through its channels, there may be some inducement to blood clotting, organization and thrombosis.

Infection

The inflammatory picture and the consequent syndrome of thrombophlebitis are too well known to require elaboration. It should be said, however, that infection, likewise, may give rise to thrombosis.

Mechanical Stagnation

If some of the impetus for blood to return to the right side of the heart is due to muscular activity, alternate contraction and relaxation and so-called "milking," aided by the action of vein valves, anything that may act to counter this influence may considerably affect thrombosis of the vessel. Intra-abdominal disease, cardiac decompensation, prolonged bed rest and so forth may contribute.

Abnormality of Prothrombin Metabolism

This process is little understood actually, and it is only suggested here that a constitutional

*The opinions or assertions contained herein are the private ones of the authors and are not to be construed as official and reflecting the views of the Navy Department or the naval service at large.

†Chief of surgery United States Naval Hospital.

‡Chief of medicine United States Naval Hospital.

factor may predispose to ante-mortem, intraluminal venous thrombosis under certain circumstances

SYMPTOMS

Symptoms are really few and given so little credence by the patient, and often by the doctor, that they are frequently overlooked. Except for the diagnostic symptomatology of pulmonary embolism familiar to all, there are actually only two pre-embolic symptoms: minimal cramps in the calf of the leg, and, if the patient is ambulatory, a slight lump.

That even these minimal pains may not be overlooked, patients are questioned daily on the presence of pain in the calf and pain upon walking. Often the patient remarks that there is some tenderness in the back of his leg upon moving his foot, but he is sure it is due either to the weather or to muscular rheumatism, which he has had before.

PHYSICAL SIGNS

Physical signs, fortunately, are more numerous. Early in our experience we reviewed our patients and our theories with Dr. John Homans, the pioneer in this particular field. He was of the opinion that most of the physical signs we stressed occurred in the relatively late stages of thrombophlebitis and rarely, if ever, in phlebothrombosis. However, owing either to the age group of patients with which we deal or to the fact that patients are carefully and routinely examined with definite signs in mind, we have yet to see a patient with pulmonary embolism who did not exhibit one or more of the following physical signs before the incident. Each patient in bed must be inspected carefully for the presence of these signs each day, often the slight calf-compression discomfort is fleeting, and in the next day the patient may be the victim of embolism.

Changes of Skin Temperature

These can be determined readily if the examiner places the palm of his hand upon the surface of the leg being examined. Often, the skin of the affected leg is cooler to the touch than that of the unaffected side. Gross temperature changes detected in this manner are usually accompanied by cyanosis or skin blanching, sometimes a definite sense of clamminess is discerned. More frequently, however, some objective form of skin-temperature determination must be made. We use the comparatively simple method of determining skin temperature with the McKesson thermocouple operating on a Wheatstone-bridge principle. These readings do not need to be corrected for room temperature and humidity; for all we seek is the relative temperatures of the two legs.

If the underlying process is inflammatory the temperatures will be elevated on the affected

side over that of the opposite side. This, of course, may be attended by redness and other signs of inflammatory reaction.

We believe the common finding is decreased temperatures and think that it is caused by a concomitant spasm of the arterioles stimulated by the presence of a blood clot in the deep venous system. The close physical relation of the femoral vein and artery and the periphlebitis extending toward the arterial adventitia would provide adequate stimuli for such a sympathetic response.

Decreased Arterial Pulsations

Decrease in the strength of pulsation of the dorsalis pedis and posterior tibial arteries of the affected side is also a manifestation of an accompanying periarterial sympathetic stimulation.

Positive Homans's Sign

This should be more properly termed the dorsiflexion sign according to Dr. Homans, but it was he who called attention to its significance and we regard it as specific for thrombophlebitis and phlebothrombosis. Acute dorsiflexion of the foot will produce pain not only in the calf muscles of the affected side but also, in some cases, over the femoral canal. This is probably due to the tension placed on the diseased vein.

Calf Pain on Compression

Gentle to moderate compression of the calf of the affected leg is frequently most disturbing to the patient should a blood clot be present in the femoral system.

Swelling of the Affected Leg

Whether owing to associated lymph stasis, venous stasis or periarterial sympathetic action, the affected leg is increased in diameter when compared to the unaffected leg. The superior extent of the increase in diameter usually lags behind the level of the thrombus. When the calf is enlarged, we believe that the thrombus is at least in the common femoral vein and, when the thigh is enlarged, in the iliac vein. The diameter of each leg should be measured at exactly the same level, and our routine practice is to strike a level midway between the anterior superior iliac spine and the medial condyle of the femur in measuring the diameter of the thigh. The diameter of the calf is measured at a point midway between the level determined as above and the medial malleolus of the tibia.

Tenderness over the Course of the Vein

A vein harboring a comparatively active thrombotic process usually gives rise to some tenderness on pressure. Here again tenderness over the popliteal vein suggests thrombosis extending into the femoral vein, and, by the same token,

tenderness over the femoral vein at the groin suggests involvement of the iliac vein. In a relatively thin, co-operative patient one can occasionally elicit tenderness upon pressure over the iliac vein. This indicates involvement at least as high as the lower portion of the inferior vena cava. It must be remembered that the drastic palpation required to reach the region of the iliac vein will produce tenderness in a normal person, therefore, it is the comparative tenderness that becomes important.

Temperature, Pulse, Respiration and Blood-Pressure Elevation

Thrombophlebitis and phlebothrombosis, particularly as the process advances, will give rise to a slow, gradual elevation of temperature, pulse, respiration and blood pressure. Even in a patient who is doing well postoperatively, and in whom there is elevation in any or all of these factors, thrombophlebitis should be suspected, unless some other adequate etiologic agent can be definitely established for his reaction.

TREATMENT

Immediately upon the discovery of the presence of any one or more of the symptoms and signs of thrombophlebitis pointed out above, the chiefs of medicine and surgery are notified. These medical officers go over the patient again, and upon confirmation of the diagnosis, the patient is sent to the operating room without further ado.

The finite location of vein division depends upon the level at which the thrombus is assumed to be. If the thrombus is assumed to be in the popliteal vein or lower, bilateral common-femoral-vein interruption is performed. If the thrombus is assumed to be present in the common femoral vein on the right side, right-common-iliac and left-common-femoral interruptions follow. If the thrombus is assumed to be in the left femoral vein, owing to the technical difficulty of ligation of the left common iliac vein, an inferior-vena-cava ligation and division is performed.

After operation the patient is returned to the ward with his legs moderately elevated, usually only by means of the elevator of a Simmons bed, and with the pain controlled by sedation as necessary.

All patients whose femoral, iliac or inferior-vena-cava pathways are interrupted show some degree of swelling of the extremity after operation. To diminish the swelling and to prevent it from becoming chronic the following regime is used.

Before arising from his bed the patient is instructed to lie on his back and perform "bicycle" exercises for ten minutes.

With the legs still elevated, elastic bandages

are applied, including the foot, from the ankle to the groin in figure-of-eight fashion.

The patient then gets out of bed and leans over the side of the bed in such a way that his hips are at the edge of the mattress and the body weight is supported by the abdomen, chest and arms.

In this position the patient "walks" for ten minutes without bearing weight.

The patient may then be ambulatory.

After whatever exercise or ambulation the patient elects, he returns to bed, elevates his legs and removes the elastic bandages.

This regime is maintained for two weeks every time the patient arises from bed.

Usually, no swelling is noted upon ambulation after this two-week period of graded exercise. Should any swelling develop, however, the entire procedure is repeated for a second session of two weeks.

SEQUELAE

During the period 1945 to 1948, vein interruptions have been performed in 67 cases. Of these, 51 were bilateral femoral-vein divisions, 6 were a combination of right-common-iliac and left-common-femoral divisions, and 10 were divisions of the inferior vena cava.

In all these patients some amount, either minimal or maximal, of lower-extremity swelling occurred postoperatively. The swelling was most severe after interruption of the common femoral vein. It was moderate after right-common-iliac and left-femoral procedures, and it was minimal after vena-cava operations. The edema was transitory, never over four weeks' duration, except in 2 patients, both of whom had superficial femoral-vein interruptions. One of these patients, who was about sixty years of age, had had persistent swelling of both lower legs for well over eight months. This persistent edema was relieved by lumbar sympathetic novocain block, by 0.3 gm of etamon chloride solution intravenously administered. A bilateral lumbar sympathetic neurectomy was performed on this patient, with dramatic relief. It remains to be seen whether this is a permanent result. The other patient was an eighteen-year-old sailor who had an acute inflammatory thrombophlebitis following a basketball injury. After six months of unrelieved lower-extremity swelling following a superficial femoral-vein division, a bilateral lumbar sympathetic neurectomy was done. Complete remission of all swelling and disability resulted.

In our experience, which is limited not only in numbers but also in age group and which is further restricted by therapeutic ligation rather than prophylactic ligation, so far as the thrombophlebitic process is concerned, we have not seen the persistent chronic edema described by other clinics after

common-femoral-vein interruption above the saphenofemoral junction or after common-iliac and vena-cava interruptions

The second sequela, which we have noted in all patients, was the cyclic recurrence of an acute thrombophlebitis picture in the portion of the venous system peripheral to the level of venous interruption. This was often severe enough to require considerable morphine and, again as suggested by Dr Homans, it is to be expected in ligated veins that contain thrombi. These cycles of thrombophlebitis were usually limited to two or three episodes of three to five days each. In all cases they completely disappeared after three weeks.

In a patient whose collateral venous circulation is not yet completely established as a result of intravenous disease, a rather alarming amount of cyanosis of the extremity involved will be noted immediately after operation. However, just as the collateral venous pathways are established in thrombophlebitis, so are they established after interruption. In the course of twenty-four to forty-eight hours, the cyanosis will disappear, and the leg regain its normal preoperative color. We have noted this phenomenon in 2 patients: an elderly man with cardiac decompensation, who complained of severe cramping in his legs and constricting sensations of his chest, and a forty-year-old man, whose femoral veins were divided after celiotomy at which inoperable Hodgkin's disease of the adrenal glands, mesenteric lymph nodes and jejunum was found. In both cases at the end of forty-eight hours a discoloration was not apparent. Fractional spinal anesthesia of procaine solution to destroy only autonomic nervous activity is used as immediate treatment when this phenomenon occurs.

RESULTS

Among these 67 cases 2 patients died.

The first was a twenty-one-year-old Marine who had had three previous pulmonary emboli following avulsion of his left arm by an airplane propeller. He had received two courses of heparin and one course of dicumarol. On the day the regime described above was instituted, he had a fourth pulmonary embolus. The inferior vena cava was operated on, and a solid thrombus was found extending above the right renal vein and so organized that it could not be detached from the vein wall. This patient died on the operating table. Autopsy revealed a solid thrombus completely occluding the left renal vein, extending up into the right side of the heart and, in addition, propagating into the superior vena cava.

The second patient was a fifty-year-old lieutenant colonel in the Marine Corps, on whom an orthopedic procedure had been performed ten days previously. He was seen immediately after a pulmonary embolism. In obvious distress, he was taken to the operating room immediately, and the right common

iliac and left common femoral veins were interrupted. He did well after operation and was returned to the ward about 8 o'clock in the evening. Between that time and 6 o'clock the next morning he received four whole-blood transfusions of 500 cc each, two plasma transfusions of 500 cc each and two liters of physiologic saline solution intravenously. Although permission for autopsy was refused, it seemed apparent to all concerned that this man had died in severe pulmonary edema that was due to the uncontrolled administration of a large amount of fluid.

These cases must be considered as operative deaths and accredited to vein interruption. It is not believed that they, in any way, disprove the efficacy of this form of treatment and prophylaxis of pulmonary embolism.

Since January, 1946, there has been only 1 death from pulmonary embolism in the United States Naval Hospital, Chelsea, Massachusetts. This occurred in a sixty-five-year-old retired captain in the Navy, in whom the diagnosis of thrombophlebitis was made, but operation not performed.

The previous mortality in cases of pulmonary embolism was 0.5 per cent of all admissions. The average age was forty-one and six-tenths years, with a range of seventeen to eighty-four years. The vein-interruption rate, at present, is 0.5 per cent of all admissions. The average age is thirty-nine and two-tenths years, and the range eighteen to ninety-two years of age.

The coincidence is striking.

TECHNIC

A considerable amount of literature is available describing the various methods of performing vein interruption. Briefly, the femoral-vein interruptions are performed under local anesthesia through a longitudinal incision above the level of the saphenofemoral junction. At least 2.5 cm of vein is removed to prevent recanalization. The dictates of the Halsted school of surgery are followed rigidly, interrupted sutures and ligatures of No. 00 cotton being used.

The right common iliac vein is divided preferably under spinal anesthesia, but occasionally under pentothal and curare, or cyclopropane and curare, inhalation anesthesia. A right pararectus incision is used and carried down through the anterior rectus sheath. Sliding laterally to the right rectus muscle an extraperitoneal approach is made to expose the right common iliac vein. Should clot be encountered in the common iliac vein, conversion to the following operative field is quite feasible when this approach is used.

The inferior vena cava is approached through a similar type of skin incision, after which the right rectus muscle is retracted laterally and the peritoneum entered. The cecum is drawn laterally

and superiorly to the right, and an incision made into the posterior peritoneum medial to the right ureter. This incision is carried as high as necessary to demonstrate the right renal vein. A transperitoneal approach is used to the inferior vena cava, because we believe that such an exposure allows considerably more control of the situation should an untoward event occur. Any of the extraperitoneal approaches to this vital structure give adequate exposure for division, but little control should the distal stump of inferior vena cava slip away.

We do not believe in retrograde aspiration of a blood clot from a vein owing to the risk involved in removal of the clot intact. If the preoperative diagnosis of thrombus level is in error and an intraluminal blood clot in the common femoral vein demonstrated, the wound should be closed without disturbance of the vein, and an immediate attack made on the common iliac vein. Owing to the negative pressure in the inferior vena cava established by the heart beat and diaphragmatic action in respiration, we believe that placing the patient in Fowler's position actually affords little protection against the liability of an embolism.

SUMMARY AND CONCLUSIONS

Thrombophlebitis and phlebothrombosis can be treated by interruption of the common femoral vein, common iliac vein or inferior vena cava to provide prophylaxis against pulmonary embolism.

If careful, daily examination of patients after operation and those with cardiac disease is performed, signs and symptoms of thrombophlebitis and phlebothrombosis usually present themselves prior to pulmonary embolism.

Recurrent thrombophlebitis appears postoperatively but can be reduced to a minimum by graded exercises without postphlebotic syndromes in most patients.

The postphlebotic swelling syndrome may be effectively treated by bilateral lumbar sympathetic neurectomy, if further observations confirm the results of the 2 patients discussed above. These were the only patients in whom edema lasted over four weeks from the date of interruption.

Protection of the patient from pulmonary embolism by surgical interruption of selected veins can be accomplished with an insignificant mortality without the danger of massive delayed hemorrhage and the numerous critical laboratory observations required when anticoagulants are administered.

SPLENIC-VEIN THROMBOSIS FOLLOWING TRANSTHORACIC GASTRECTOMY AND INCIDENTAL SPLENECTOMY*

STUART QUAN, M.D.,† AND BENJAMIN CASTLEMAN, M.D.‡

BOSTON

ALTHOUGH thrombosis of the splenic vein is infrequently reported in the literature,^{1, 2} it is common knowledge among surgeons that this condition may follow splenectomy. In fact, local thrombosis at the site of ligation of the splenic artery and vein with extension back to the first branching vessel is to be expected. This degree of involvement of the splenic vein, however, should be symptomless, but it is potentially important because of possible extension into the portal venous system and as a source of emboli to the liver. Since splenectomy is usually performed for definite diseases of the spleen such as trauma, focal parasitic infection and tumors, or for diseases of the hematopoietic system favorably influenced by splenectomy such as hemolytic jaundice, thrombocytopenic purpura and Banti's syndrome, the risk of extensive splenic-vein thrombosis postoperatively has to be taken. With the introduction of the transthoracic approach to gastric surgery and the associated incidental splenectomy, the possibility of postoperative splenic-vein thrombosis assumes more importance.

Up to 1946 such normal spleens were removed in 70 cases at the Massachusetts General Hospital

TABLE 1 Lesions Resected with Which Incidental Splenectomies Were Performed*

LESION	NO. OF CASES
Carcinoma of stomach (S transabdominally)	48
Carcinoma of esophagus	11
Miscellaneous gastric lesions (S transabdominally)	7
Miscellaneous abdominal lesions (transabdominally)	7
Total	70

*Unless otherwise stated operations were through the transthoracic approach.

The majority of these spleens were removed incidental to transthoracic resections of a carcinoma close to the cardia, in either the upper stomach or the lower esophagus (Table 1).

The reasons for removing the spleen are presented in Table 2. Facilitating the operation by providing more adequate exposure for complete removal of the tumor was by far the most frequent reason. On other occasions the surgeon believed that it would be wise to remove the spleen so that it would not drag on the site of bowel anastomosis. The opera-

tor's note in 12 cases contained no specific statement why the spleen was also removed, but one may assume that it was also to facilitate the operation. Involvement of the spleen or pancreas by tumor represented another frequent cause for splenectomy. Thus, in 19 cases the tumor either was adherent to the capsule of the spleen or had actually invaded the splenic pedicle or hilus. An additional 6 cases

TABLE 2 Reasons for Splenectomy

REASON	NO. OF CASES
To facilitate operation	20
Not stated but probably to facilitate operation	12
Operative trauma	15
Tumor adherent to spleen, splenic pedicle or splenic artery	19
Tumor adherent to or involving pancreas	6
Total	70

showed tumor involvement of the tail of the pancreas as well as the spleen. Surgically induced trauma to the spleen, such as inadvertent injury to the organ's blood supply or persistent capsular oozing after prolonged retraction of the organ, accounted for 12 splenectomies.

Eighteen patients died within forty-five days of operation, and all but 1 were submitted to post-mortem examination. As was to be expected, most of these cases showed local thrombosis of the splenic vein for short distances from the site of ligation. There were 5 cases, however, that showed thrombosis of the splenic vein and more extensive involvement of the portal system. Table 3 describes the extent of the thrombosis and the sequelae in each case. In 4 of these cases the thrombosis had extended into the portal vein and its intrahepatic branches to produce infarcts of the liver. Jaundice was present in Cases 1 and 3.

Case 1§ represents the only case in which the development and progression of the postoperative splenic-vein thrombosis turned out to be the main cause of death, and it was this case that stimulated the present study. It is presented in detail.

A forty-two-year-old wardman was operated on for the removal of an extensive scirrhous carcinoma of the stomach. In an attempt to remove all the disease, a total gastrectomy, transverse colectomy, splenectomy, esophagojejunostomy, jejunojunostomy and complementary cecostomy were performed. The immediate postoperative course was uneventful except for a three-day spike of temperature to 102° F, and he was discharged on the 20th postoperative day. He did well for 1 week on a six-meal bland diet, with only occasional transient abdominal pains, but then, 26 days after

§This case has already been published.

and superiorly to the right, and an incision made into the posterior peritoneum medial to the right ureter. This incision is carried as high as necessary to demonstrate the right renal vein. A transperitoneal approach is used to the inferior vena cava, because we believe that such an exposure allows considerably more control of the situation should an untoward event occur. Any of the extraperitoneal approaches to this vital structure give adequate exposure for division, but little control should the distal stump of inferior vena cava slip away.

We do not believe in retrograde aspiration of a blood clot from a vein owing to the risk involved in removal of the clot intact. If the preoperative diagnosis of thrombus level is in error and an intraluminal blood clot in the common femoral vein demonstrated, the wound should be closed without disturbance of the vein, and an immediate attack made on the common iliac vein. Owing to the negative pressure in the inferior vena cava established by the heart beat and diaphragmatic action in respiration, we believe that placing the patient in Fowler's position actually affords little protection against the liability of an embolism.

SUMMARY AND CONCLUSIONS

Thrombophlebitis and phlebothrombosis can be treated by interruption of the common femoral vein, common iliac vein or inferior vena cava to provide prophylaxis against pulmonary embolism.

If careful, daily examination of patients after operation and those with cardiac disease is performed, signs and symptoms of thrombophlebitis and phlebothrombosis usually present themselves prior to pulmonary embolism.

Recurrent thrombophlebitis appears postoperatively but can be reduced to a minimum by graded exercises without postphlebotic syndromes in most patients.

The postphlebotic swelling syndrome may be effectively treated by bilateral lumbar sympathetic neurectomy, if further observations confirm the results of the 2 patients discussed above. These were the only patients in whom edema lasted over four weeks from the date of interruption.

Protection of the patient from pulmonary embolism by surgical interruption of selected veins can be accomplished with an insignificant mortality without the danger of massive delayed hemorrhage and the numerous critical laboratory observations required when anticoagulants are administered.

produce marked congestion, atrophy and necrosis of the central parts of the lobule — a lesion that is often called “incomplete infarction” or “atrophic red infarct”^{6, 7} (Fig 1). When an interlobar branch of the portal vein is occluded, however, the systemic collateral circulation is usually insufficient to prevent a true infarct. Multiple incomplete infarcts were found in Cases 2, 3 and 5. That these infarcts are not necessarily produced by extension of the thrombus into the intrahepatic portal-vein radicles, but by emboli from the splenic-vein thrombosis was demonstrated in Case 5, in which there was no thrombus in the main portal vein.

Mention must be made of the 52 patients who survived and of the 1 who died postoperatively but was not examined at autopsy. Careful review of their postoperative course revealed little or no clinical evidence that a splenic-vein thrombosis was present. Twenty-six of these patients had temperatures of 100 to 104°F up to fourteen days postoperatively. These elevations of temperature were not accompanied or explained by any clinical development, and after such an extensive operation, it would be foolhardy to attribute them to a splenic-vein thrombosis. In only 1 patient were there complaints of unexplained left-upper-quadrant pain, slight jaundice and a temperature of 102°F, all of which occurred on the fourth postoperative day and lasted several days. This clinical triad is probably attributable to splenic-vein or portal-vein thrombosis.

SUMMARY AND CONCLUSIONS

Seventy cases of splenectomies performed incidental to some other operation (predominantly transthoracic gastrectomies and esophagectomies for carcinoma) are reviewed.

Five of the 17 patients studied at autopsy showed extensive thrombosis of the splenic and portal veins, and in 1 with superior-mesenteric-vein thrombosis the death was directly attributable to the initial splenic-vein thrombosis. The others showed multiple incomplete infarcts of the liver, which, had death not occurred because of peritonitis or massive pulmonary embolism, might have produced symptoms of liver failure.

Of 52 patients who did not die postoperatively, only 1 had suggestive clinical evidence of an underlying splenic-vein thrombosis.

Although it is recognized that incidental splenectomy is often necessary in the course of gastrectomy and esophagectomy, the surgeon should be aware of

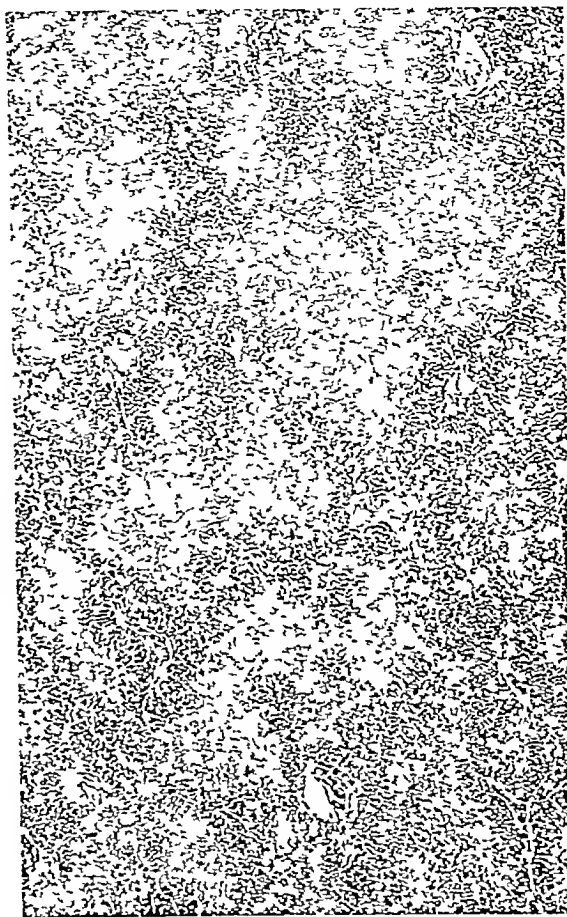

FIGURE 1 Photomicrograph, Showing Marked Central Necrosis of the Liver Lobules in an Area of Incomplete Infarction

the occasional complication of thrombosis of the splenic and portal veins and hepatic infarction.

the operation, he began to complain of increasingly severe lower abdominal pain, which spread to the upper abdomen and down the left side. Pain became almost unbearable after a light supper. He had not vomited and had felt only slightly nauseated. His bowels had moved daily, although on the day of and on the day previous to this admission his stools had been hard and small in amount. Physical examination revealed a slightly distended abdomen, with generalized voluntary spasm throughout, maximal in the left upper quadrant. No masses were made out. Peristalsis was active and normal in pitch when first heard. Two hours later it was diminished to absent. A small amount of feces in the rectal ampulla was found to be guaiac negative. An x-ray film of the abdomen showed only an air-filled loop of small bowel in the left upper quadrant that was somewhat dilated and had a fluid level on standing. The white-cell count was 12,500. A Miller-Abbott tube was passed. Exploratory laparotomy under spinal anesthesia showed a moderate amount of dusky fluid and many white carcinomatous nodules in the small-bowel mesentery. There were no dilated loops of bowel, no evidence of obstruction and no leakage around the anastomoses. Postoperatively the temperature ranged between

Microscopical examination of the portal and splenic veins demonstrated definite organization of the thrombi, whereas those in the mesenteric vein and its tributaries were quite recent. The liver showed central congestion, but no definite foci of infarction were seen. There was also a pulmonary infarct.

DISCUSSION

Although only 1 patient (Case 1) had specific clinical signs and symptoms attributable to the thrombosis of the splenic and portal veins, which eventually spread to major branches of the superior mesenteric vein to cause gangrene of the small bowel and death, there were pathologic changes in the other cases that may have been contributing factors to the major postoperative complications—peritonitis and pulmonary embolism—to which these patients succumbed. For example, it is pos-

TABLE 3 *Complications of Splenic-Vein Thrombosis*

99.6 and 100.5°F. The abdominal distention increased. There was no audible peristalsis. The patient complained of pain in the testes and penis. There was considerable vomiting and occasional hiccoughs. On the 3rd postoperative day jaundice developed. On the evening of the 5th postoperative day he suddenly went into shock, with profuse sweating and dyspnea. The blood pressure was unobtainable. The abdomen was quite distended, and peristalsis could not be heard. He died 10 hours later.

At post-mortem examination the peritoneal cavity contained about 1500 cc. of turbid, straw-colored fluid. Many pale-white carcinomatous seedlings were present over the peritoneum and mesentery. Scars of the operative procedure described above were found, and their various lines of anastomoses were intact. Beginning at a point 100 cm from the origin of the jejunum and extending for about 100 cm, the small intestine was dark red, purple, fibrin coated, markedly edematous and gangrenous. In the mesentery all the veins to this loop were filled with ante-mortem, dark reddish, gelatinous thrombi, which extended into the superior mesenteric vein. The entire portal vein, its ramifications in the liver and the entire splenic vein were filled with reddish-brown, firm, adherent thrombi much older than those seen in the superior mesenteric vein and its tributaries.

sible that if the patients with multiple hepatic infarcts had not succumbed to postoperative complications, symptoms referable to the liver might have developed.

It is generally agreed that true infarction of the liver—that is, actual necrosis—occurs primarily as a result of occlusion of the hepatic artery or its branches. For example, accidental ligation of an anomalous hepatic artery in the course of surgery in the gall-bladder region produces total infarction, whereas emboli to the intrahepatic arteries in subacute bacterial endocarditis or secondary thrombosis of the intrahepatic arteries involved with arteritis nodosa are causes of multiple small infarcts.^{4,5}

Occlusion of the portal vein and its main branches does not result in a true hepatic infarct. It may

liveries, and abortions are considered separately. Comparable figures are given in Table 3.

From 1928 to 1937 there were 271 abortions, with 3 deaths — a death rate of 1.1 per cent. Two were due to sepsis, and 1 to ruptured aorta. From 1938 to 1947 there were 315 cases of abortion, with no deaths. These are not included in the above figures on maternal mortality.

The following are brief reports of the fatal cases during the last ten years.

CASE 1 Labor was induced in a 38-year-old para II. She was 12 days overdue and had had a superficial phlebitis. Labor was very rapid and severe. She had an easy, normal delivery. The baby was stillborn. Immediately after delivery the maternal pulse became very rapid, and soon imperceptible. Respirations were very rapid. The maternal heart could not be heard. Oxygen, caffeine, coramine and epinephrine were given, to no avail, and respiration soon ceased. Permission for autopsy was refused. The presumptive diagnosis was pulmonary embolism. When Steiner and Lushbaugh¹ reported on amniotic embolism,

CASE 4 A 37-year-old para III, 8 months pregnant, was admitted to the hospital with abdominal pain and bleeding. There was marked edema. The blood pressure was 150/100. The patient had a mild convulsion and became comatose, her color was ashy purple, and the respirations were stertorous. The uterus was boardlike. A stillborn baby delivered spontaneously. Rather profuse bleeding followed. Intravenous administration of 25 per cent glucose and plasma was started, but the patient died. The diagnosis was premature separation of the placenta and eclampsia, confirmed by autopsy. It seems that the only chance to save this patient had been lost before she entered the hospital.

CASE 5 A 41-year-old primipara entered the hospital in mild labor with a blood pressure of 150/90. Two days before, the blood pressure had been 130/90. There was no albumin in the urine. Delivinal, 0.28 gm., and 100 mg. of demerol were given at 5:30 p.m. Labor progressed normally. At 8:00 p.m. the patient complained of headache, at 8:30 she became semicomatose and died in less than 1 hour. Autopsy showed eclampsia to be the cause of death. There does not seem to have been any chance to prevent this death.

CASE 6 This patient was a 39-year-old para III who had a rapid, severe labor. Shortly before delivery she had a

*1 proved, 1 presumptive.

the marked similarity with their proved cases led to the opinion that this death was really due to embolism with amniotic fluid. If labor had not been induced, or if it had been slowed down, this tragedy might have been avoided.

CASE 2 A 43-year-old para III was delivered of a 9 lb., 9 oz., baby by midforceps. After delivery the patient seemed in good condition. Over the course of several days vomiting and marked distention developed. Four days after delivery the temperature began to rise, and chest pain developed, and on the 5th day the patient died. Autopsy revealed a rupture of the lower uterine segment, peritonitis, bronchopneumonia and an embolus in the inferior vena cava. Diagnosis of the difficulty or recognition of the gravity of the patient's condition might have saved her life.

CASE 3 This 39-year-old para II, with essential hypertension, was 6½ months pregnant. She had had a severe toxemia with her first baby. She was being checked daily in an effort to attain viability. The blood pressure varied from 160/100 to 224/120. An occasional + test for albumin was found. At noon on May 30, the blood pressure was 210/120 and a voided specimen showed a + test for albumin. The fluid output was equal to the intake. There was no pain, headache, scotoma or edema. At midnight she told her husband that she felt fine. Two hours later she had severe epigastric pain, vomiting and difficulty in breathing. The blood pressure was 290/140, and the pulse 60. Despite treatment, the patient became steadily worse and died. Autopsy showed a massive cerebral hemorrhage and the typical findings of eclampsia. It developed afterward that, unknown to the patient, both her mother and her mother's mother had died of convulsions in childbirth, and several aunts were known to have hypertension. This patient could have been saved if pregnancy had been interrupted early. It was a calculated risk in which it was believed that there would be time to intervene if the patient was watched carefully. The development of eclampsia was too sudden to permit this. More attention should have been paid to the minor warnings, and knowledge of the family history would have helped.

mild convulsion. The respiration became stertorous. After delivery the pulse was unobtainable, and respiration was labored and noisy. Oxygen was given constantly. Intravenous injections of glucose and plasma were given without benefit. The respirations gradually ceased, and the patient died. Autopsy revealed that death was due to embolism with amniotic fluid. Perhaps slowing of the labor would have prevented this death. This is another proved case of amniotic embolism added to the 12 reported by Watkins.²

It is perhaps not significant, but all these deaths occurred in older patients. A comparison of the causes of death for the two ten-year periods is presented in Table 4.

Eclampsia seems to be the major bugbear. In most cases the difficulty has been a failure to recognize and treat the disease in time. This is, in some cases, the fault of the physician, whereas in several the patient has been guilty of at least contributory negligence by failing to keep appointments or to seek medical advice until too late. It is not believed that any doctor has been negligent or culpable in the above cases. The results are good but can be better, and criticism is directed entirely to that end.

Morbidity rates have been figured yearly since 1939 in accordance with the standards of the American Committee for Maternal Welfare. The rate dropped from 7 per cent in 1939 to 4.6 per cent in 1940 and 3.4 per cent in 1941, and since then it has averaged about 2 per cent. Sulfonamides and penicillin must be awarded the credit for this reduction,

OBSTETRICS IN THE WINCHESTER HOSPITAL (1928-1947)

SANFORD H. MOSES, M.D.*

WINCHESTER, MASSACHUSETTS

IN 1938, a report on maternal mortality in the Winchester Hospital for the years 1928-1937 was published,¹ with the intention of demonstrating that good obstetrics could be practiced in a small hospital. This report covers the twenty-year period 1928-1947 and includes fetal-mortality statistics for the last ten years. It is believed that the publication of statistics from this hospital and discussion of the problems and results will be of value to those who practice in similar institutions. Most of the available statistics come either from large maternity hospitals or from city, state or national areas. The figures presented below show the results obtained in a small general hospital, which is where the bulk of obstetrics is done. Comparison between similar hospitals should lead to general all-round improvement.

For the last ten years, a yearly analysis of the obstetric work has been made and presented to the

ing them home early that it has been possible to deliver so many patients. The members of the staff have given perfect co-operation. When the hospital is overcrowded, the patients most able to do so are sent home. So far, all those really needing hospitalization have been kept as long as was really necessary. Table 1 gives the number of deliveries per year and the percentage of deliveries accomplished by cesarean section.

The indications for cesarean section have been reviewed prior to operation by the chief of service

staff. For the last year, monthly section meetings have been held. Both these points have, I think, been helpful in improving the quality of the work.

The number of deliveries has increased to a spectacular degree. The hospital has had to utilize every bit of available space and to encroach to a limited degree upon adjacent rooms. By this means the number of obstetric beds has been increased from 19 to 31, the Department of Obstetrics has still been maintained as an independent, isolated unit in the hospital. The doctors' room has been converted into a 3-bed labor room, giving 5 labor-room beds. In spite of the additional beds, it is only by getting patients out of bed early and send-

The main indications have been repeat section, cephalopelvic disproportion, placenta previa, premature separation of the placenta, toxemia and fetal distress, with a scattering for obstructing tumors, abnormal presentations, previous pelvic repair operations and the like. This system has served to eliminate the cesarean section for convenience. No reasonable indication has been refused, and the plan has worked well. Since 1933 no deaths have followed cesarean section, and in that

	1947	0.15

time 212 patients have been so delivered. However, it is still believed that cesarean section is much more dangerous to the mother than delivery from below.

The maternal mortality, as reckoned by five-year periods, is presented in Table 2.

In the previous report¹ (1928-1937) 3 deaths, which were due to miscarriage, were included. These have now been deleted. The maternal mortality is figured on the basis of the number of de-

*Vice-chairman of staff, Winchester Hospital.

smallest percentage of autopsies was in the premature babies. Undoubtedly, some of the cases classed as prematurity alone would have shown additional causes of death if autopsy had been done. Moreover, the number of cases is not sufficient to give much statistical validity. However, in view of the agreement with other series of fetal deaths, some comment is justified. The most striking thing is that prematurity occurring in 3 to 4 per cent of all cases was a cause in 56 per cent of all deaths and in 65 per cent of all neonatal deaths. In many cases the cause of the prematurity was unknown but in about 35 per cent the situation was due to maternal conditions, such as maternal toxemia, premature rupture of the membranes, placenta previa and premature separation of the placenta, which were all about equally culpable. Better care of premature babies and the exertion of every effort to prevent premature delivery should offer the best chance of reducing the total mortality. Perhaps stilbestrol will be valuable here. Birth injuries occurred much more frequently in the full-term group, though more injuries in premature babies might have been revealed by more autopsies. Prevention of very rapid deliveries and improved obstetric judgment and skill offer hope of reducing this group. Deaths from erythroblastosis and congenital malformations should occur less often in future, owing to recent advances in

knowledge. In general, however, hope of improvement lies not in any one group but in painstaking vigilance and constant alertness to the possibilities of saving one baby here and another there.

Evaluation of these results has been helpful, and it is hoped that publication of them will be interesting and helpful to others. Publication of similar studies from other hospitals, so that various methods and technics may be compared by their results in actual "grassroots" practice, should be very fruitful in raising the general level of obstetric care.

MEDICAL PROGRESS

ABDOMINAL SURGERY

ARTHUR W. ALLEN, M.D.,* AND CLAUDE E. WELCH, M.D.†

BOSTON

A REVIEW of the literature for the past year resulted in the abstracting of over 200 articles on surgical conditions of the abdomen that were considered of value. Since space is limited, all references except those given below are omitted. It is obvious that our selection of the contributions regarded as most pertinent to progress will, in the minds of some, fall short of a complete survey. We have tried, however, to present a fair estimate of the past year's work on new and controversial subjects.

SURGERY IN THE AGED

Cutler¹ reports the results obtained in a group of 204 aged patients operated upon for acute lesions. These were all inmates of a charitable institution

maintained for the care of the indigent in a metropolitan district. The over-all mortality was 44 per cent. The chief cause of failure was postoperative pneumonia, which accounted for 34 per cent of the deaths. One is bound to wonder whether some of these fatal pulmonary complications were embolic in origin since the group includes thigh amputation, intestinal obstruction and acute infections of various abdominal organs, all of which are known to be followed by phlebothrombosis and pulmonary embolism in a high percentage of older patients. It must be borne in mind that institutions for the sole care of the indigent do not have the facilities for early diagnosis and adequate preoperative and postoperative care found in large general teaching hospitals.

A correlation to the above statement is afforded by an excellent presentation by C. Stuart Welch,² who gives the data on 609 operations performed on

*Consultant in surgery, Massachusetts General Hospital.

but it is considered a creditable showing. The principal causes of morbidity were retention of lochia, upper respiratory infection, urinary infection and mastitis.

Figures on fetal mortality are the other side of the picture and of equal importance in an evaluation

deaths. This includes, however, only the first ten days and excludes babies under 1000 gm. No figures are given for the number of deaths after ten days. If the babies weighing under 1000 gm are included, as they are in this series, the total mortality is 3.2 per cent, again equally divided be-

†Hospitals reporting 500 to 999 births.

of the quality of obstetric performance. Only the figures for the last ten years are available. All deaths before discharge from the hospital are reported, though some infants lived many weeks. Any baby that lived even for a short time and all stillborn infants over twenty weeks of menstrual age or over 14 inches in length were considered viable. Any baby weighing under 5 pounds was considered premature. One or two babies each year have been sent to an infants' hospital for special treatment, and some have died there. Inasmuch as these deaths occurred outside this hospital, they have not been included in this report though actually they should be charged against the mortality figures. If these cases are included there is an increase of about 1 or 2 per thousand in the figures. Two of these babies who died elsewhere had diarrhea of the newborn. In 1946 there were 7 sporadic cases, with these 2 deaths. That no real epidemic occurred is, I think, a tribute to the efficacy of the nursing technic. Table 5 presents the fetal-mortality record for the two five-year periods, along with comparable statistics from other hospitals for the same periods.

Standards of viability and prematurity vary in different clinics. Various inclusions and exclusions make it difficult to obtain comparable figures. The figures given by Potter and Dieckmann⁷ for fetal mortality in the Chicago Lying-In Hospital (1941-1946) offer an interesting example of this difficulty. They report a total mortality of 2.5 per cent, with 1.25 per cent stillbirths and 1.24 per cent neonatal

deaths between stillbirths and neonatal deaths—1.6 and 1.59 per cent respectively. These figures are almost identical with those in the Winchester Hospital series.

The causes of fetal mortality have followed the usually reported pattern.^{9,11} The percentages of

TABLE 6 Causes of Fetal Death

CAUSE	PER CENTAGE OF ALL DEATHS	PER CENTAGE OF STILL BIRTHS	PER CENTAGE OF PRE-MATURE DEATHS	PER CENTAGE OF NEONATAL DEATHS

death from various causes have been calculated and are shown in Table 6. They illustrate the relative importance of various causes of death in various situations. They do not total 100 per cent because rare causes were not included.

These percentages are not to be taken too seriously. Autopsies were done in about 35 per cent of all fetal deaths and in 60 per cent of the neonatal deaths among full-term infants. The

thors stress the need of careful preservation of the splenic vein in this procedure since the venous channels are thus left intact as anastomotic vessels.

A more radical attempt to eliminate the hazard of varices in Banti's syndrome is reported by Phemister and Humphreys¹⁴. Total gastrectomy was done in a case in which there were subsequently two episodes of bleeding. Transthoracic resection of the lower esophagus and stomach was carried out in another patient. In the discussion of this paper, Wangenstein¹⁵ stressed the acid-peptic digestive factor in bleeding from esophageal varices. In dogs with a simultaneously produced portal hypertension, a 90 per cent resection of the stomach will not regularly prevent ulcer provoked by histamine in beeswax. Without portal hypertension a 75 per cent gastric resection with short-loop retrocolic anastomosis will prevent this type of ulcer. Wangenstein described 3 patients subjected to extensive gastric resection for esophageal varices in 1945, 2 of whom were alive and well two years later. Pemberton¹⁶ advised early splenectomy in Banti's disease to prevent esophageal varices. Blalock¹⁷ reported a successful outcome after splenorenal anastomosis.

THE PANCREAS

Waugh¹⁸ presents the data from the Mayo Clinic on pancreatectomy up to January 1, 1947. Of 49 patients in this group, 6 had total pancreatectomy with a lower mortality than that in those who had partial pancreatectomy, owing he believes, to the leakage of the closed pancreatic stump in some of the earlier cases. The over-all mortality was 26 per cent. Of 11 patients operated upon for benign lesions there was a fatal outcome in 45 per cent, owing to the technical difficulties associated with inflammation. Thirty-eight patients had carcinoma, 21 per cent of whom failed to survive the operation. One-stage procedures carried a slightly lower mortality than the two-stage operations. The survival rate following pancreatoduodenectomy for carcinoma of the pancreas was discouraging, and the author questions whether or not a cholecysto-enterostomy in these patients would not produce an over-all better outcome when the operative mortality for the radical procedure was taken into consideration. The survival period for carcinoma of the ampulla of Vater was more encouraging, as pointed out by several other observers.

The technic of pancreatoduodenal resection has been described by Cattell,¹⁹ and a further appraisal of the procedure made by him more recently.²⁰ He believes that patients with long-standing jaundice have a better chance for survival by a two-stage procedure. Fifty-two pancreatoduodenal resections have been done at the Lahey Clinic since 1942, with 9 deaths (17.3 per cent). Five of these were for benign lesions. Cattell²¹ believes that one can tell whether or not the obstruction is due to cancer

by the simple expedient of finding a dilated pancreatic or common bile duct. In nonresectable cases he believes that worthwhile palliation can be obtained by anastomosis of the dilated pancreatic duct to the jejunum.

Bartlett²² has reviewed the experience with pancreatic carcinoma at the Massachusetts General Hospital from 1941 to 1947. Seventy-eight patients were seen, and 83 per cent were operated upon. Thirty-two per cent of the entire group had a radical resection. The operative mortality was lower with the two-stage procedures. At the time of his report one patient was living five years and another eight months after operation. The average duration of life of the remainder was seven months.

Owens²³ calls attention to the danger of peptic ulceration following pancreatoduodenectomy if the hookup is such that the acid secretions of the stomach enter the jejunum proximal to the bile and pancreatic juices. He reports 3 cases with this complication. It is generally understood and practiced now that the bile duct and pancreatic duct be implanted into the jejunum proximal to the stomach segment.

Thompson²⁴ has recorded a patient living and well seven years after pancreatoduodenectomy for carcinoma of the ampulla of Vater.

THE GALL BLADDER AND BILE DUCTS

Sainburg and Garlock²⁵ report 75 cases of carcinoma of the gall bladder from the Mt. Sinai Hospital (New York City) between 1933 and 1946. Sixty-five patients were operated upon, and 64 of these were dead within thirty-five months. One patient was alive over thirteen years after operation. Abdominal pain in 77 per cent, jaundice in 38 per cent and a palpable mass in 64 per cent were the predominant symptoms and signs. Seven patients had unsuspected carcinoma revealed after cholecystectomy. Stones were found in all but 1 patient. Graham²⁶ pointed out that stones were found in only 8 per cent of metastatic carcinomas of the gall bladder. These studies further confirm our opinion that stones are a causative factor in carcinoma of the gall bladder. Fortunately, the percentage of cancer in all cases of gall-bladder disease is low. Therefore, this argument should not be used too freely in advising cholecystectomy for quiescent gallstones, since there are much better reasons for so doing. It should, however, be kept in mind.

Strictures of the common bile duct still occur too frequently. They represent such a serious complication that at times we have believed that the patients were unfortunate in surviving their original operation. It behooves every surgeon to consider the possibility of an anomaly of the vascular and ductal region. There cannot be too much caution used in the accurate visualization of all structures during cholecystectomy.

542 patients in the Carney Hospital (Boston) In this group of patients of seventy years or older, there was a mortality of only 11 1/4 per cent The author states that 5 per cent of the population of Massachusetts are over seventy years of age It is pointed out that these persons tolerate abdominal surgery poorly, with a mortality of 22 1/2 per cent in his series Furthermore, in biliary-tract lesions over half the patients had complicated problems, such as common-duct stones, acute cholecystitis and cancer of the gall bladder

TALCUM-POWDER GRANULOMA

Thirty-seven cases of postoperative complications due to talcum-powder granuloma are reported by Eiseman, Seelig and Womack² from the Barnes Hospital (St Louis) The range was from simple wound abscesses to fecal fistula and intestinal obstruction The lesions are most frequently confused with tuberculosis The chronicity of the disease is stressed, and it is compared with pulmonary silicosis There is a full review of the literature on the subject and the methods used for making the diagnosis microscopically

Swingle⁴ cites a patient who was operated upon fifteen times for talcum-powder granuloma with, finally, a fatal outcome Repeated attacks of intestinal obstruction were the reason for the large number of operations He states that the highest number of operations in any case previously reported was five The diagnosis was established by microscopical examination

The importance of this lesion cannot be overstressed It is almost certain that many operations for postoperative adhesions with obstruction have been done without any thought that talcum-powder granuloma is the underlying pathologic process Safe and suitable glove powder can now be obtained It is expensive at present, but serious consideration should be given to its general use Surgeons still using talcum powder should be conscious of the danger Sparing use of this substance on the hands and within the gloves, which must be carefully washed after they are put on, should help in reducing this hazard

HERNIA

Gross⁵ has presented a new and simple method of treatment for large omphaloceles The skin is underrmined on either side and sutured over the large sac, which has been carefully left intact The child is left with the large mass, which gradually recedes into the abdominal cavity during the first ten months of life At this time it is easy to resect the collapsed sac and repair the abdominal wall in an anatomic manner Three cases are cited, in all of which the patients recovered

Harkins and Schug⁶ report the follow-up results on 131 hernias repaired by the McVay technic (conjoined tendon sutured to Cooper's ligament) Three

recurrences were found two or more years after operation The authors have used the method on 367 hernias and point out its value because it is applicable to all types of inguinal hernia The article is well illustrated

There are certain defects due either to repeated operations or to trauma that are not easy to repair even with fascia lata Koontz⁷ gives a preliminary report on the use of tantalum-wire mesh in the closure of such defects He made a further report before the Southern Surgical Association, White Sulphur Springs, West Virginia, December 7-9, 1948⁸ The material is well tolerated in the tissues and causes no foreign-body reaction Although it apparently can be used next to the intestine (without immediate harm) if there is no peritoneal structure available, it is believed that a peritoneal protection should be obtained when possible It is further stated that skin with attached subcutaneous tissue of considerable thickness is preferable to skin alone The mesh is held in place by fine tantalum-wire sutures

Throckmorton⁹ reports the use of tantalum-wire mesh in 16 patients He has observed no wound complications or other evidence that this material was not well tolerated by the host There have been no recurrences in a follow-up study of three to twenty-six months

PORTAL HYPERTENSION

Blakemore¹⁰ reviews the subject and reports 40 cases in which portacaval anastomosis was completed There were 5 postoperative deaths He divides the types of liver disease that may be benefited by this operation into five groups as follows schistosomiasis, Banti's syndrome, cirrhosis of the liver, ascites and posthepatitis cirrhosis The operation is indicated if there has been massive gastrointestinal hemorrhage from esophageal varices or if the varices can be demonstrated by x-ray examination

Linton, Hardy and Volwiler¹¹ divide the patients suitable for portacaval shunts into three groups intrahepatic portal-bed block due to portal cirrhosis or thrombosis of the hepatic veins, extrahepatic portal-bed block due to congenital or acquired obliteration of the portal vein, and a combination of the first two types Of 7 patients with the intrahepatic type operated upon, only 2 survived Deaths in this group were due to liver failure In 8 patients with extrahepatic block, all survived operation, and only 1 has bled since the procedure was done Linton prefers the splenorenal anastomosis with preservation of the kidney, through the thoracoabdominal approach

Welch¹² reports a successful suture technic with the aid of the Thomas-Smith intestinal clamp in an anastomosis between the portal vein and vena cava

Everson and Cole¹³ have ligated the splenic artery in 3 poor-risk patients with portal hypertension The immediate results were satisfactory The au-

between 1939 and 1948. He stresses the importance of the transthoracic approach, the use of antibiotics, including both penicillin and streptomycin locally and parenterally, the use of oxygen post-operatively, continuous gastric suction during operation and drainage of the pleural cavity for forty-eight hours after operation. There were 16 patients who had nonfatal complications, and there was an over-all operative mortality of 11.6 per cent.

An improved method of cytologic examination of gastric secretions is presented by Ulfelder, Graham and Meigs⁴³. After careful lavage of the stomach the patient is left with an inhaling gastric-suction tube overnight. The next morning washings are obtained and centrifuged. Smears are then studied by the Papanicolaou technic. Forty-five out of 48 patients studied had satisfactory smears. The 3 failures were in patients with almost complete obstruction. In 12 of 14 patients with cancer the diagnosis was correctly made by this method. One patient with lymphoma of the stomach showed no abnormal cells in the stomach secretions.

MacDonald, Ingelfinger and Belding⁴² studied the motor function, intestinal absorption, pancreatic function and blood picture in 3 patients surviving total gastrectomy for three, five and ten years respectively. Two patients developed a macrocytic, hyperchromic anemia. The third had been receiving prophylactic liver treatment and had a normal blood picture. The pancreatic function and intestinal absorption were not particularly abnormal. The authors collected from the literature other cases of long survival following total gastrectomy. Apparently, ten and a half years for malignant and twenty years for benign lesions represented the longest survivals reported at the time of their investigation.

THE DUODENUM

Friesen et al⁴⁰ found gastroduodenal lesions or erosions, or both, complicating fractures of the long bones in 27 out of 1432 autopsies. Experimental work was carried out in animals and it was observed that similar lesions could be produced by operative fractures, curettage of the bone marrow and intravenous injection of small amounts of fat. The fractures did not increase gastric secretions or acidity. The authors believe that the ulcerations were produced by fat emboli which could be demonstrated microscopically in the mucosal and submucosal vessels of the stomach and duodenum. The emboli produced anemic areas in the mucosa, which became susceptible to the acid-peptic digestive activity of the normal gastric juice.

Meulengracht⁴⁴ presents his experience of fifteen years with the management of acute bleeding in gastric and duodenal ulcer. He stresses the importance of a full puree diet in all cases. Of 1031 patients treated, 26 (2.5 per cent) died. Unfortunately, the patients are not subdivided into age groups

and the severity of the hemorrhage. He believes these patients should not be operated upon during or just after a hemorrhage and that operation may be considered if the patient is over forty years old, has persistent or repeated bleeding and has a definite ulcer by x-ray examination and if a competent surgeon is available.

Jones⁴⁵ advocates early gastroscopy between the third and tenth days in hematemesis and melena when x-ray films fail to reveal the cause of bleeding. In 60 per cent of cases he found superficial acute ulcers. He states that persistence of pain associated with an ulcer that has bled is a serious omen, and that all his fatal cases came in this group. According to him it requires from 100 to 150 cc of blood to produce a tarry stool, and that 2000 cc of blood introduced into the upper gastrointestinal tract will produce bloody but never tarry stools. He recommends a semisolid puree diet similar to Meulengracht's. The mortality in Jones's series was 8 per cent.

Stewart et al⁴⁶ have recommended immediate operation on all patients with massive hematemesis and melena when there is good evidence that ulcer of the stomach or duodenum exists. Of 54 patients observed, 33 were operated upon and the remainder used as controls since they or their physicians refused to consider surgery. Fifteen per cent of those operated upon died, whereas 29 per cent of those refusing operation succumbed. These patients were not given x-ray examinations prior to operation, and 4 of the 33 proved to be bleeding from other causes than ulcer and all these patients survived the exploration. The stomach was emptied of the blood clot by gastrotomy, and a radical subtotal gastrectomy was done, even if no definite ulcer was found. In 5 of these cases shallow ulcers with bleeding vessels were demonstrated. An average of 3600 cc of blood was used in the surgical group and 2040 cc in patients not having operation.

Warren and Lanman⁴⁷ have presented their experience with massive hemorrhage from gastric and duodenal ulcer in the West Roxbury Veterans Administration Hospital. They advocate urgent operation in patients over forty-five years of age who continue to bleed massively for more than twenty-four hours and in those who have bled massively and stopped bleeding but have shortly thereafter bled again. In patients with difficult duodenal ulcer, they have had good luck in a small number of resections with exclusion of the ulcer and with two-stage procedures.

Dunphy and Hoerr⁴⁸ discuss the problem of massively bleeding ulcers at the Peter Bent Brigham Hospital (Boston). They have limited their operations to patients who appeared to be actually bleeding to death. From 1940 to 1945 there were 117 patients with massive bleeding admitted, with a mortality of 7.6 per cent. In 1946 and 1947 there were 45 cases with 1 death. Of 6 patients operated

Lahey²⁷ has presented the experience in his clinic with stricture of the common bile duct. He stresses the importance of end-to-end anastomosis with preservation of the sphincter of Oddi. In many cases sufficient distal duct can be developed by mobilization of the duodenum and splitting of the head of the pancreas. A T tube is placed through a new longitudinal opening distal to the suture line and is left in situ for one year.

Cole et al²⁸ agree that end-to-end suture of remaining segments of duct gives the highest percentage of good results. When the distal segment was fibrosed and useless, as it often is, their best results followed a Roux Y hookup. A recent development they have made consists in constructing a new duct segment from jejunal mucosa. This may have possibilities, particularly if the newly constructed duct can be supported from within for a long time.

Longmire and Sanford²⁹ have utilized a new method of restoring continuity between the bile ducts and the gastrointestinal tract in 3 patients. In cases in which there is only scar tissue in the hilus of the liver and no available duct structure left that can be found, their operation may be applicable. The edge of the left lobe of the liver is resected. A bile duct is isolated, and this is transplanted into a loop of jejunum, which is further used to provide a cover for the raw surface of the liver. An enteroenterostomy is made between the two limbs of the jejunum.

Wilson and Gillespie³⁰ have reported the successful outcome on a patient with completely destroyed common bile ducts by the Longmire and Sanford method. A modification using the Roux Y anastomosis was considered preferable to the original technic.

Grindlay³¹ has made a significant contribution to this subject. Tubes of a certain type of polyethylene film are constructed to bridge defects in the common bile duct as well as other hollow viscera. Experimentally it appears that this substance is inert in the human tissues. Bile salts do not seem to adhere to the inner surface of these tubes, and it is believed that they may not become plugged as easily as vitallium or rubber. It is important to point out that the polyethylene film must be a certain variety, which will soon be available for surgical use. Many of the polyethylene films employed so extensively in industry have a chemical substance incorporated that will actually cause tissue reaction and scar formation. The shape and size of polyethylene tubes made for a specific purpose offer a great advantage. In 4 patients in whom we have used these tubes in our Roux Y procedure the results have so far been better than those by other methods. If the tube is 1 cm in diameter and can be held in place for many months, there is an excellent chance that scar-tissue constriction will not recur. There are naturally some

difficulties in keeping these tubes from leaving the hilus of the liver too soon. Loops of wire may be incorporated in the outer layers of the tube so that they may be held in place by nonabsorbable sutures.

Best³² again calls attention to the benefits derived from the use of dehydrocholic acid in preventing the deposit of bile salts in tubes that have been used for bile-duct reconstruction. He uses his so-called "biliary flush" of decholin, magnesium sulfate, cream or olive oil, nitroglycerin and atropine in all his cholecystectomies and common-duct explorations as well. Although this is a very useful method in postoperative common-duct stricture, it is a nuisance to the patient and is expensive and hardly seems justifiable as a routine after adequate gall-bladder and common-duct surgery.

THE STOMACH

Hamilton³³ calls attention to the development of gastric ulcer after deep x-ray therapy of the abdomen. In a group of 256 patients receiving more than 5000 r in the upper abdominal region as a part of the treatment for metastatic cancer of the testis, epigastric distress in two or three months developed in half the cases. In 35 of these patients gastric ulcer developed in a previously normal stomach.

This is confirmed by Bowers and Brick,³⁴ who have observed 6 patients with post-radiation gastric ulcer requiring surgical intervention. Three of these were operated upon for perforation, and 3 for massive hemorrhage, with recovery in all cases.

Marshall and Welch³⁵ have reviewed the Lahey Clinic experience with gastric ulcer for the period between 1936 and 1945. One hundred and thirty-one, or 16.4 per cent of 800 patients, were treated surgically. In this group there were 26 malignant ulcers (19.8 per cent). From this evidence the authors believe a more radical attitude should be accepted regarding the treatment of gastric ulcer. The results following resection for benign gastric ulcer were satisfactory, and no recurrent or anastomotic ulcers occurred in their cases. The operative mortality was 2.85 per cent.

An excellent article on the incidence of gastric cancer has been presented by Pack and McNeer.³⁶ Since this is not a reportable disease, it is not possible to obtain accurate figures for the United States. This lesion accounted for over 26,000 deaths in 1940, in this country. The reported incidence throughout the world varies directly with the economic status, the educational and medical facilities and the life expectancy of the community or country. Deaths reach the highest level in the age group between sixty-five and seventy. A most striking rise in the death rate from gastric cancer was noted among the Negro race. It appears to be slightly less prevalent among the Jewish race than it is in the non-Jewish population in European cities.

Sweet³⁷ reviews 86 patients with carcinoma invading the cardia and lower esophagus observed

Spackman⁵⁶ reports 5 additional cases of bowel obstruction following irradiation for pelvic carcinoma. He calls attention to the early hyperemia and edema of the ileum and sigmoid that are often seen, and believes that the late obstruction is due to resulting scar tissue.

THE COLON AND RECTUM

Swenson and Bill⁵⁷ have deduced from the study of 20 children with congenital Hirschsprung's disease that this lesion is due to an area of localized spasm in the low sigmoid. Careful x-ray examination will reveal the area of spasm accurately. After an operative procedure had been developed in animals, thought best adapted to resection of the spastic area and preservation of the sphincter in such cases, 3 children were successfully operated upon. The follow-up period is short, but the method promises to revolutionize the management of this troublesome malady.

Kiefer⁵⁸ tried all the "specific" methods of medical treatment known to him in ulcerative colitis. Sulfaguanidine benefited the greatest number of patients, but penicillin and sulfasuxidine were of most value in the preoperative and postoperative periods and for control of abscesses or peritonitis. In 527 cases followed for two or more years the results were satisfactory in 46 per cent. Medical management was successful in two thirds of the milder cases and in a third of the severe forms of the disease. Ninety-nine of 400 patients under observation for a long period were eventually operated on.

Vagotomy has been performed by Dennis⁵⁹ on 28 patients with ulcerative colitis or regional enteritis. Response to this indirect attack was successful in a high percentage of the patients so treated. The method is more adaptable to patients whose disease has not already produced extensive fibrosis and lack of distensibility of the bowel wall. The mechanism of this effect is in doubt, but the reduction in mucosal vascular response to intense emotional disturbances and relief of enteric spasm seem to be relevant. Vascular response to strong emotion can be observed through the sigmoidoscope in these patients, and it appears that such responses are no longer present after vagus-nerve interruption.

Cattell and Sachs⁶⁰ report that 26 per cent of 630 patients under treatment at the Lahey Clinic for ulcerative colitis were operated on. Ileostomy was performed in 145 cases, partial colectomy in 46, and total colectomy in 75. The operative mortality was 18, 15 and 4 per cent respectively in these procedures, with a total patient mortality of 22.3 per cent. Patients recently operated upon show a reduction in operative mortality to 4 per cent. The authors believe that when surgical intervention is necessary in ulcerative colitis, ileostomy will be required, and in most cases this procedure must be followed by removal of the colon.

On the basis of a recent study of 71 consecutive cases of ulcerative colitis, Best⁶¹ believes that approximately 90 per cent of these cases can be managed medically. In his opinion there is little evidence to support early ileostomy in the hope of arresting the disease so that restoration of continuity may eventually be carried out. Furthermore, he considers it better to have a few patients arrive too late for successful operation than to subject too many to permanent ileostomy.

Crohn, Garlock and Yarnis⁶² state that 8 per cent of their patients with idiopathic ulcerative colitis have right-sided lesions. There is a tendency to spread to the left side of the colon, and even when the rectum and sigmoid appear to be normal, fistulas and abscesses in the perirectal area develop. The authors have apparently had greater success with subtotal colectomy and ileostomy, with final re-establishment of ileosigmoidostomy, than other observers.

McKittrick⁶³ has presented an excellent treatise on carcinoma of the colon. The historical background is given, as well as a modern set of basic principles regarding the problem, as follows: the proper preparation of the patient for operation, optimum exposure of the segment of bowel to be excised, adequate mobilization of the bowel, adequate operation for cancer, free blood supply of both segments to be anastomosed, avoidance of tension on the suture line, and proximal complete temporary colostomy if adequacy of suture line or blood supply is in doubt. The surgical mortality in 90 patients operated upon between 1932 and 1941 was 11 per cent in comparison to 3.6 per cent in 110 with primary anastomosis operated upon between 1942 and 1947.

Jones, Robinson and Meads⁶⁴ report 137 consecutive combined abdominoperineal resections for carcinoma of the rectum and lower sigmoid without mortality. They attribute their lack of fatal complications largely to the use of alloy steel wire in abdominal-wound closure. The usual amount of urinary retention and bladder infections was obtained. Mild obstruction relieved by passage of a Miller-Abbott tube occurred in 9 per cent. There were only 2 cases of pulmonary infarction, and 4 of atelectasis. Wound infection occurred in 2 per cent of the cases.

Dixon⁶⁵ presents the results obtained in 426 cases in which anterior resections of the rectosigmoid and upper rectum, with primary anastomosis, were performed. A routine defunctioning transverse colostomy is done, and drainage is established to the sacral area through the lower end of the abdominal wound. Since chemotherapy was made available the operative mortality has been reduced from 5.9 to 2.6 per cent. In 272 patients the five-year survival was 67.7 per cent.

Wangensteen and Toon⁶⁶ review the results of low anastomosis after anterior resection. They

on in the first series 3 died, whereas in the last group 7 were operated upon, with no deaths

Baker⁴⁶ made a clinical study of 576 patients admitted to the Selly Oak Hospital (Birmingham, England) in the six-year period 1940-1945, with bleeding from gastric and duodenal ulcer. In this series the mortality was 14 per cent, whereas in a similar group admitted from 1934 to 1939 it was 7 per cent. The effect of the war on the psychic and economic situation is offered as an explanation of this discrepancy. The author believes that x-ray examination should be withheld during the acute phase, since recurrence of bleeding that resulted fatally was noted in 6 patients shortly after fluoroscopy.

A comparative study has been made by Allen⁴⁷ on two series of patients with uncomplicated duodenal ulcer. One group was treated by the standard partial gastrectomy, and the other by vagus-nerve resection. The results are considered on the immediate and interim basis, since many of the cases, particularly in the vagus-resection group, have not been followed sufficiently long to be classified as end results. The good results in both groups were approximately the same: 85 per cent in the gastric resections and 87 per cent in the vagus resections. The operative mortality was 2 per cent in the former as opposed to 0 in the latter. A similar study has been carried out by Warren and Meadows⁴⁸ on a smaller group of patients with almost identical findings.

Moore⁴⁹ gives a detailed analysis of 84 patients subjected to vagus resection. A strict grading revealed 75 per cent good results, 18 per cent fair results and 7 per cent poor results. Actually, the surgeon and the patient were reasonably well satisfied in 90 per cent of the cases. Sixty-two per cent of patients had diarrhea, which was of major importance in 14 per cent. Sixty-seven per cent had some sensation of fullness, which was major or continuing in 13 per cent. Incisional pain was serious in 3 per cent, and subsequent gastroenterostomy was necessary in 2 patients. The highest percentage of satisfactory results was found in patients subjected to vagus-nerve resection for anastomotic ulcer.

Colp et al.⁵⁰ made a comparative study on two groups of patients with duodenal ulcer. In one group 38 patients were subjected to partial gastrectomy only, and another group of 34 had vagotomy in addition. The added vagus resection did not increase the operative mortality (no deaths in the group), but definitely increased the morbidity. A higher incidence of achlorhydria was noted after the combined procedure.

Walters and his associates⁵¹ state that vagus-nerve section gave results that were inconstant, variable and in most cases unpredictable. The relief of pain after vagotomy was considered to be due to a release of gastric spasm and a reduction

in gastric acidity. Since one incident of unsuspected perforation of a duodenal ulcer occurred after vagus-nerve section, the authors deduced that the freedom from pain was unrelated to the healing of the ulcer.

It appears that the majority of surgeons dealing with a large number of patients believe that vagus-nerve resection should be used for the treatment of stomal ulcer if none of the antrum had been left behind at the initial resection. Also, the procedure should be evaluated when operation for uncomplicated, intractable ulcer is considered in patients under thirty years of age. It is definitely contraindicated for gastric ulcer, because it is never possible to be certain that the ulcer is benign. It is generally believed that vagus resection and gastroenterostomy are illogical since, as Faxon⁵² has suggested, gastrojejunal ulcers with gastrojejuno-colic fistula might again become a common problem under such a regimen.

The clinical features and late results in 244 patients with gastrojejunal ulcer entering the Mayo Clinic between 1937 and 1948 are discussed by Priestly and Gibson.⁵³ The surgical mortality was 4 per cent. Subtotal gastrectomy with excision of the stomal ulcer gave satisfactory results in 87 per cent of the patients over a period of five to ten years. If a previous partial gastrectomy had been done the results with a higher resection were less satisfactory. The immediate results following vagotomy were good in 19 of 24 patients who had had previous partial gastrectomy and in 19 of 20 patients whose previous operation had been gastroenterostomy only.

THE SMALL INTESTINE

Ravitch⁵⁴ suggests the implantation of the ileum into the anus after total colectomy for benign lesions such as polyposis and ulcerative colitis. In 2 patients so treated after colectomy for ulcerative colitis, there was good sphincter control, and excoriation of the skin was not a problem.

Endometriosis as a cause of small-bowel obstruction is discussed by McGuff et al.⁵⁵ Obstruction occurred in 16 of 48 cases of endometriosis of the bowel observed at the Mayo Clinic between 1920 and 1946. The patients varied in age from thirty-one to fifty-four years, with an average of thirty-nine and a half. Although 15 of the 16 patients were treated by bowel resection the authors believe that ovarian ablation, preferably by operation with proximal decompression of the bowel, will result in complete resorption of the obstructive process. Although their premise may be sound, one doubts the advisability of such an indirect attack for localized obstructive lesions since the morbidity is greatly increased. Furthermore, it is well known that scar tissue resulting from endometriosis may produce obstruction of the bowel after ovarian function has ceased.

CASE 35211

PRESENTATION OF CASE

A sixty-five-year-old machinist was well until three months before admission, when he consulted his physician because of progressive weakness and a persistent upper respiratory infection. He had a "mild cough" productive of a small amount of mucoid sputum. There was no hemoptysis, no pain and no exertional dyspnea. Since the onset of his illness he noted difficulty in breathing during bad weather. For the two months preceding admission he was confined to bed. During this time his weakness progressed, and just prior to admission his sputum increased in amount. There was no history of fever, night sweats or wheezing. There was a 17-pound weight loss in these three months. In the month prior to admission he developed hoarseness and diminished hearing.

Physical examination on admission showed a dehydrated, cachectic and slightly cyanotic man. There was a cataract on the right, and posterior superior synechia with fixation of the right pupil. There was no gross loss of hearing. There was a palpable lymph node in the left supraclavicular fossa, and the trachea was markedly deviated to the left. There were hard movable lymph nodes, measuring 1 cm diameter or more, in both axillae. There was dullness to percussion posteriorly on the left below the level of the eighth rib, and bronchophony and absent breath sounds over the same area. The heart was normal in size, with a regular rate, and free of murmurs.

The temperature was 100° F, the pulse 90, and the respirations 30. The blood pressure was 88 systolic 64 diastolic.

Examination of the blood disclosed a hemoglobin of 12 gm and a white-cell count of 25,800, with

91 per cent neutrophils. Urinalysis was negative. A stool was guaiac negative. Blood culture was negative. Repeated sputums and gastric washings were negative for acid-fast organisms. The prothrombin time was 17 seconds (normal, 15 seconds). The nonprotein nitrogen was 19 mg, and the total protein 5.8 gm per 100 cc.

A chest film was reported as follows:

There is collapse of the left upper lobe and partial collapse of the left lower lobe. The mediastinum is shifted to the left. Within the collapsed segment, there are several fleecy densities and a suggestion of small punctate calcifications. The left costophrenic sinus is blunted, and the left leaf of the diaphragm is not visualized. There is also partial collapse of the right upper lobe, with irregular increase in density and punctate calcifications, also there is some thickening of the overlying pleura. The right lower and right middle lobes are overexpanded, and they herniate into the left side of the chest anteriorly. The right leaf of the diaphragm moves freely and is elevated somewhat anteriorly. The patient was given a swallow of barium, and the esophagus showed no obstruction, although it was deviated to the left by the collapse on that side.

The patient's course in the hospital was febrile, the temperature varying between 99 and 104° F. At times he was disoriented and incoherent. An electroencephalogram was reported as a borderline record. A lumbar puncture showed normal pressure, and the spinal fluid was normal. Penicillin was given, with no effect on the febrile course. A chest film taken sixteen days following the first film was reported as follows:

The left chest is now entirely dense. A few air-containing areas shine through in the central portion that look like small abscessed cavities. How much of the density in the left side is due to consolidation atelectasis, or drowned infiltration, or how much to fluid in the pleural sinus is not determinable. There are areas of infiltration in the right apex and first and second interspaces, with small areas of cavitation interspersed.

The patient's course remained febrile, and terminally respirations became rapid, and he died of respiratory failure on the thirty-eighth hospital day.

DIFFERENTIAL DIAGNOSIS

DR ARTHUR PIER. In summary, we have a sixty-five-year-old man who was perfectly well until recently, when he developed a cough, fatigue, weakness, weight loss and x-ray evidence of bronchial obstruction and pulmonary infiltration and then went rapidly downhill to die, with fever, leukocytosis and a low-grade anemia accompanying his hospital course. We do not get much information from the physical examination of the chest except to learn that there was disease present. I wonder

found 7 local recurrences in 51 cases (14 per cent) and state that these were outside the anastomotic area. Their patients had no difficulty with sphincter control and had normal sexual function.

Preparation and aftercare of patients on whom operations on the lower bowel have been performed is discussed by Bacon and Rowe.⁸⁷ A clean, tranquil bowel is desired, and this state may take several days of preparation. Sulfathiazole and streptomycin are advocated for only forty-eight to seventy-two hours preoperatively, because it is believed that the early effect can be depended upon but that reversion of action frequently occurs. A recent series of 142 cases without mortality is reported.

The urge for sphincter preservation may be on the wane. The number of local recurrences has been too great in the hands of most surgeons. Implantation of cancer cells into the suture line must be considered as a possible cause for recurrence. One is justified in preserving the sphincter in patients who have liver metastases and in those with very early lesions that can be adequately removed by any local procedure. Judgment based on experience plays a greater role in this situation than in many others.

CASE 35211

PRESENTATION OF CASE

A sixty-five-year-old machinist was well until three months before admission, when he consulted his physician because of progressive weakness and a persistent upper respiratory infection. He had a "mild cough" productive of a small amount of mucoid sputum. There was no hemoptysis, no pain and no exertional dyspnea. Since the onset of his illness he noted difficulty in breathing during bad weather. For the two months preceding admission he was confined to bed. During this time his weakness progressed, and just prior to admission his sputum increased in amount. There was no history of fever, night sweats or wheezing. There was a 17-pound weight loss in these three months. In the month prior to admission he developed hoarseness and diminished hearing.

Physical examination on admission showed a dehydrated, cachectic and slightly cyanotic man. There was a cataract on the right, and posterior superior synechia with fixation of the right pupil. There was no gross loss of hearing. There was a palpable lymph node in the left supraclavicular fossa, and the trachea was markedly deviated to the left. There were hard movable lymph nodes, measuring 1 cm. diameter or more, in both axillae. There was dullness to percussion posteriorly on the left below the level of the eighth rib, and bronchophony and absent breath sounds over the same area. The heart was normal in size, with a regular rate, and free of murmurs.

The temperature was 100° F., the pulse 90, and the respirations 30. The blood pressure was 88 systolic 64 diastolic.

Examination of the blood disclosed a hemoglobin of 12 gm. and a white-cell count of 25,800, with

91 per cent neutrophils. Urinalysis was negative. A stool was guaiac negative. Blood culture was negative. Repeated sputums and gastric washings were negative for acid-fast organisms. The prothrombin time was 17 seconds (normal, 15 seconds). The nonprotein nitrogen was 19 mg., and the total protein 5.8 gm. per 100 cc.

A chest film was reported as follows:

There is collapse of the left upper lobe and partial collapse of the left lower lobe. The mediastinum is shifted to the left. Within the collapsed segment, there are several fleecy densities and a suggestion of small punctate calcifications. The left costophrenic sinus is blunted, and the left leaf of the diaphragm is not visualized. There is also partial collapse of the right upper lobe, with irregular increase in density and punctate calcifications; also, there is some thickening of the overlying pleura. The right lower and right middle lobes are overexpanded, and they herniate into the left side of the chest anteriorly. The right leaf of the diaphragm moves freely and is elevated somewhat anteriorly. The patient was given a swallow of barium, and the esophagus showed no obstruction, although it was deviated to the left by the collapse on that side.

The patient's course in the hospital was febrile, the temperature varying between 99 and 104° F. At times he was disoriented and incoherent. An electroencephalogram was reported as a borderline record. A lumbar puncture showed normal pressure, and the spinal fluid was normal. Penicillin was given, with no effect on the febrile course. A chest film taken sixteen days following the first film was reported as follows:

The left chest is now entirely dense. A few air-containing areas shine through in the central portion that look like small abscessed cavities. How much of the density in the left side is due to consolidation, atelectasis, or drowned infiltration, or how much to fluid in the pleural sinus is not determinable. There are areas of infiltration in the right apex and first and second interspaces, with small areas of cavitation interspersed.

The patient's course remained febrile, and terminally respirations became rapid, and he died of respiratory failure on the thirty-eighth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. ARTHUR PIER. In summary, we have a sixty-five-year-old man who was perfectly well until recently, when he developed a cough, fatigue, weakness, weight loss and x-ray evidence of bronchial obstruction and pulmonary infiltration and then went rapidly downhill to die, with fever, leukocytosis and a low-grade anemia accompanying his hospital course. We do not get much information from the physical examination of the chest except to learn that there was disease present. I wonder

if we can look at the x-ray films I believe they were taken two weeks apart

DR STANLEY M WYMAN They show the mediastinum and heart to be displaced toward the left, with rather mottled density occupying the distribution of the left upper lobe and to a lesser extent in the left lower lobe. Unfortunately, the films are not penetrated sufficiently to outline the bronchi well, but on the second examination, one can trace the left main bronchus down to the region of the upper and lower lobe branches, at which point it is impossible to trace the bronchi farther. The multiple areas of infiltration in the collapsed right upper lobe are well seen, and there is definite calcification within them. I am not able to be certain of calcification in the left-lung field.

DR PIER Do you see any involvement of the mediastinum, or can you tell?

DR WYMAN It is impossible to see it adequately.

DR PIER Has there been any change in the right apex between the first and second films?

DR WYMAN There is a suggestion that there had been some added density in the lower portion of the diseased area. It does suggest a progression of some infiltrative or consolidating process.

DR PIER I must say that I am a little nonplussed by these films and a little less certain about the diagnosis than I was on reading the protocol because these calcified flecks in the right apex represent old, healed, burned-out tuberculosis. I cannot attach to them any further significance. I do not believe that tuberculosis was an active participant in the patient's very rapid decline.

Could he have had some bizarre infiltrative process in the lung such as a mycotic infection—for example, actinomycosis? It is my impression that actinomycosis, although often involving both lungs, usually involves the lower portions of the lungs rather than the upper. It is an invasive disease, which causes necrosis and small abscess formation and spreads relentlessly, without regard to any barrier through lung tissue, pleura and chest wall, creating on its way fistulas and sinus tracts. A patient with actinomycosis frequently raises large amounts of yellow sputum in which can be found the characteristic sulfur granules. I do not see any evidence here on which to base a diagnosis of actinomycosis or of any other mycotic infection.

Nor do I believe he had a necrotizing pneumonia. The onset was too insidious and the course was too long.

The history in a sixty-five-year-old man of cough, weight loss, bronchial obstruction and pulmonary collapse, with rapid deterioration leading to death, spells bronchiogenic carcinoma to me, and very little else. I am going to cling to that diagnosis although I am somewhat disturbed by the bilateral nature of this man's disease. I do not see why it could not have been bilateral if it had gone far enough. His symptoms and his course are more

consistent with bronchiogenic carcinoma than with anything else. His mucoid sputum, even though not bloody at any time, is characteristic of bronchial irritation and is often seen, in the early stages at least, in cases of bronchiogenic carcinoma. His fever, pronounced leukocytosis and low-grade anemia are also entirely compatible with a diagnosis of bronchiogenic carcinoma and are probably indicative of pulmonary infection peripheral to the obstruction. The early course of bronchiogenic carcinoma is often insidious and deceptive. Frequently, there are no noteworthy symptoms or signs until it is far advanced. Certainly, if that is what this man had, and I am sure it is, it was way out of possible therapeutic bounds by the time he developed outstanding symptoms.

It is perhaps a little academic for me to try to determine what type of cell his cancer arose from. The three types generally classified are the small-cell, or oat-cell carcinoma, the adenocarcinoma, and the epidermoid, or squamous-cell carcinoma.

The oat-cell, or small-cell type, is a very malignant variety that usually arises in or near the hilus and tends to invade the mediastinum, often getting tangled up with the aorta and great veins and often causing symptoms of mediastinal compression. It infiltrates lung tissue and metastasizes widely via the lymphatics to distant parts of the body—to the liver, lymph nodes, bone, adrenal glands, brain and other organs. It usually occurs in a somewhat younger age group than this man falls into. It is impossible to tell by looking at this patient's films whether the mediastinum was extensively involved or not. He developed hoarseness, however, and hoarseness implies involvement of the recurrent laryngeal nerve.

The adenocarcinomas usually arise somewhat more peripherally in the bronchial tree and form round masses and invade the lung tissue extensively and metastasize widely via the blood stream to the liver, opposite lung and brain.

The epidermoid, or squamous-cell, variety grows more slowly than the others, metastasizes less widely and is the most amenable to surgical resection. Like the other types it invades the lung tissue and spreads to the hilar lymph nodes.

Finally, there is a cell type that is so undifferentiated that it cannot be well classified.

All these carcinomas cause bronchial obstruction with atelectasis, damming-up of bronchial secretions and often pneumonitis, frank suppuration, and all the evidence of infection.

I think this patient had a very rapidly growing bronchiogenic carcinoma, probably of an undifferentiated variety and probably arising in the left-upper-lobe bronchus. I would guess that it also involved the left-lower-lobe bronchus and spread across the trachea to involve the right-upper-lobe bronchus. I think the left lung will be found to be extensively invaded by tumor, and I think there

was abscess formation secondary to this tumor invasion, partly from obstruction and partly, perhaps, from necrosis of the cancer itself. I rather think that a good deal of what we see in the right apex is tumor. A massive, left pleural effusion seems to have developed terminally and probably contributed to his death.

The only diagnosis I can make is bronchiogenic carcinoma, probably of an undifferentiated sort. I do not see any very good evidence for distant metastases except the lymph nodes in the axilla and supraclavicular region, which were undoubtedly involved. I do not think that we need to postulate adrenal or cerebral involvement to account for his relatively low blood pressure on the one hand and for his disorientation on the other. I think there could be nonspecific findings that might occur in any very sick, dehydrated, cachectic man.

DR JOSEPH C AUB: Dr Pier did better than we did on the ward.

DR TRACY B MALLORY: Do you want to discuss it?

DR AUB: No.

DR MALLORY: Does anyone want to take up the cudgels for tuberculosis?

DR HELEN PITTMAN: I took them up when Dr Aub showed me the films on the ward the other day.

DR LAMAR SOUTTER: It is worth commenting from the tuberculosis standpoint that one occasionally sees older people who have considerable tuberculosis without positive sputum. We had one such patient a few years ago with progressive collapse of one lung from whom several sputum specimens were examined but were never positive until the day before operation.

DR EDWARD B BENEDECT: I recall doing a bronchoscopy on an elderly man eight years ago. The gross appearance of the bronchi was consistent with cancer. The pathology report was tuberculosis, and I think we had seriously considered tuberculosis. But I must admit that we see both cancer and tuberculosis in the same patient.

DR J GORDON SCANNELL: Is it fair to ask if he was bronchoscoped?

DR BENEDECT: He was probably too sick.

CLINICAL DIAGNOSIS

Pulmonary tuberculosis

DR PIER'S DIAGNOSIS

Bronchiogenic carcinoma, undifferentiated, left upper-lobe bronchus, with involvement of entire left lung and apex of right lung

ANATOMICAL DIAGNOSES

Oat-cell carcinoma of left main bronchus, with metastases to brain, liver, adrenal gland and lymph nodes

Atelectasis, severe, left lung

Organizing pneumonia, slight focal, left lung

Pulmonary tuberculosis, chronic, active, right lung

PATHOLOGICAL DISCUSSION

DR MALLORY: Autopsy showed extensive carcinoma in the left main bronchus, which had spread extensively into the lung. The tumor was adherent to and narrowed by compression, both the aorta and the esophagus but did not invade either organ. The remainder of the left lung showed some foci of old organizing pneumonia and almost complete atelectasis. There was no fluid in the pleural cavity, and the apparent consolidation was due to complete absence of air in the pulmonary parenchyma. There was extensive old tuberculosis at the right apex, and other foci in the right lung, which were not entirely inactive. Some fresh tubercle formation was found, and it is quite conceivable that he might have shown positive sputum, from time to time. The tumor had metastasized very widely. The bronchial lymph nodes and nearly all the retroperitoneal peripheral nodes were involved. There were metastases in the liver and one in the adrenal gland, but the most notable metastases were in the brain, where some forty or fifty small separate tumor nodules were found widely scattered through all parts of the brain cortex, white matter and the cerebellum, but were not of sufficient size to have produced localizing symptoms.

DR AUB: What kind of tumor was it?

DR MALLORY: An oat-cell carcinoma.

DR PITTMAN: Was the disease on the right all tuberculosis?

DR MALLORY: Yes, there was no tumor there.

CASE 35212

PRESENTATION OF CASE

First admission. A fifty-six-year-old Russian physician was admitted for diagnosis and treatment of a lung tumor.

Twenty-seven years before this admission he was treated with bed rest for six months because of tuberculosis in the left upper lung. Nine years before this admission while he was being routinely fluoroscoped, a lesion the size of a dime was detected in the same location as the previous tuberculous infection. At this time he was practicing medicine and was symptom free. Six years before this admission, while he was having a gastric series, during the investigation of a possible duodenal ulcer, the chest lesion was seen again now the size of a quarter. Many x-ray films were taken until three years before admission, when the patient decided to forget the whole matter. These films were all available for examination when he was admitted to this hospital. Some of them taken about four or five years before

admission showed definite regression in size of the lesion until it was about the same size or even smaller than when found originally nine years previously. The decrease in size was a shrinkage of the shadow, rather than a central destruction. The lesion then (three or four years before entry) returned to the same size or larger than it had been six years before entry.

Two months before admission he had a short illness accompanied by chills, fever and blood-streaked sputum for one day only. An x-ray examination showed still further enlargement of the lung lesion. There was no chest pain, dyspnea, joint symptoms, weight loss or loss of appetite. He did have occasional bouts of productive coughing.

The temperature, pulse and respirations were normal. The blood pressure was 130 systolic, 90 diastolic. Physical examination was negative. The hemoglobin was 14.6 gm, and the white-cell count 6800, and urinalysis was negative. Sputum examination was negative for acid-fast bacilli.

A chest x-ray examination was reported as follows:

Lying in the left mid-lung field in the anterior segment of the left upper lobe is a lobulated homogeneous mass approximately 5.0 by 4.8 by 6.0 cm, in which no calcification is recognized. The superior portion of this mass shows an

show a suggestion of a division of the mass into possibly three component parts, the strongest suggestion being in the upper portion. A review of previous films shows the superior and lateral portions of the mass to be of more recent origin than the medial lower portion.

Exploratory thoracotomy was proposed but the patient left the hospital to settle his affairs.

Second admission (two and a half months later). The patient continued to have a cough with sputum and occasional blood streaking. On a repeat chest x-ray examination it was reported that "the superior lobulation of the mass appears to be slightly larger than at the last examination, otherwise there is little if any change." The sputum was again negative for acid-fast bacilli. On the seventh hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. RICHARD SCHATZKI. The record mentions a series of films dating back nine years prior to admission. These films are not available now. I would like to see the films and not take someone else's word for them. I will have to do so, and for the sake of this exercise I will assume that the interpretation was correct and did not show any more than is given in the record.

I will start with the x-ray films. There is very little I can add to the description as given in the record. There are two striking features about this mass. One is the marked lobulation. It is really segmentation, as if the mass had originated from more than one place, possibly, it arose from more than one focus. Another interesting feature is the fact that the point of attachment of the mass, at this anomalous fissure between the left middle and upper lobes, shows surprisingly little if any bulging. The second striking thing about this mass is its duration, if we can assume that what we see now has been present for at least nine years. The mass is reported to have markedly decreased in size at one time, and to have increased again. It is also a mass that had in no way handicapped the general well-being of the person who had it. That is a rather unusual story. If one did not have the history and just looked at the films, things would be much easier. I should like to ask one or two questions, which are not in the record, in order to exclude certain things, which I think can be excluded fairly rapidly. There is no differential count mentioned. How many eosinophils were there?

DR. TRACY B. MALLORY. None.

DR. SCHATZKI. No blood Hinton test is mentioned.

DR. MALLORY. I can find no record of that. Do you remember, Dr. Scannell?

DR. J. GORDON SCANNELL. I do not, but I assume it was negative.

DR. SCHATZKI. That is enough.

There are numerous lesions that might occasionally produce a shadow in the lung, as this one did. I am not going to enumerate all of them. I will mention a few likelier ones rather than other

FIGURE 1

unusual degree of lobulation. The lesion lies in intimate contact with the minor fissure, separating the left-upper from an anomalous left-middle lobe (Fig. 1). There is no apparent extension through the fissure, and the lung fields appear clear, except for a few calcified scars in the upper-lung fields. Definite hilar or mediastinal lymph nodes are not recognized, although there is a suggestion of an ill-defined similar density just above the left main bronchus. Spot films of the lesion

rarer ones. There are four conditions, if we exclude echinococcal cyst and the very rare gumma of the lung, which conceivably could produce such a picture and such a history. A bronchiogenic cyst would explain the fluctuation in size, which occurred during observation. It is very difficult to explain the appearance of the lesion on that because of the marked lobulation. I do not remember having seen or heard of a segmented bronchiogenic cyst. It is conceivable but so unlikely that I will exclude the possibility. The second is benign adenoma in the periphery of the lung. Benign adenoma occurs practically always in the large bronchi. It rarely occurs in the periphery, but we have seen in these exercises at least 2 cases in which benign adenoma did occur in the periphery of the lung. In favor of it would be the marked lobulation. The shape would be consistent. The absence of any appreciable amount of atelectasis — in the last film a small amount is visible — and the rather recent clinical history make me believe that it is not so very probable. I put particular stress on the definite decrease in the size of the lesion, which we are going to take for granted. If we exclude these possibilities, there are two left that are uppermost in our minds: primary malignant tumor of the lung and tuberculoma. The history, of course, points very strongly toward the latter possibility. Could this have been a tuberculoma? The present x-ray appearance is consistent with a diagnosis of tuberculoma, although it is a little different from the tuberculomas that I remember having seen. It is unusual for tuberculoma to have such a sharp edge. Usually there is some scarring or small area of atelectasis, which produces the appearance seen in the corona of the sun. But I can conceive that this does not always have to be so, and it may be tuberculoma. How about the history? I have seen a case in which a tuberculoma grew under observation and was proved by operation. It would be a little more difficult to see how a tuberculoma could shrink and then start to grow again. As a matter of fact that statement is unusual for anything I can think of.

The last possibility I am going to discuss is that of malignant tumor of the lung. Could this have been a bronchiogenic carcinoma of the lung? If we had x-ray films alone and no history this would be our first bet. It is a little difficult to reconcile the history with this diagnosis. Can someone have bronchiogenic carcinoma for nine years, and have no more symptoms than this man had? Certainly I have never seen one, although I can conceive that it might be possible. Bronchiogenic carcinoma is a more slowly growing carcinoma than we usually assume. However, it is difficult to see how bronchiogenic carcinoma could decrease in size without evidence of ulceration, and one would be forced to make two diagnoses. I would say that my choice is between tuberculoma and malignant tumor in the lung. If the two lesions are the same it will have to be tuberculoma. If it just happens to be in the

area where the patient had had old tuberculosis, I would make bronchiogenic carcinoma my first bet. For the record's sake I have to choose one of the two, and I shall therefore take bronchiogenic carcinoma as my first choice, and tuberculoma as my second.

DR JOSEPH C. AUB: I am surprised at that diagnosis. The record states that this lesion was situated between two lobes and from here it looks like a cyst. The patient came from Russia even though he did not have a high eosinophil count. Why could it not have been a hydatid cyst, since it lay between the two lobes?

DR SCHATZKI: When I read the record without seeing the films, I made a diagnosis of echinococcal cyst. When I saw the films, I still thought it could be an echinococcal cyst. If I had been the clinician I would have done all that was necessary to rule that possibility out, I could not do that here. The only thing I could ask for here was the eosinophil count because I realized I would not get an answer if I asked for the result of a complement-fixation test for echinococcus. For that reason I had to exclude it from my differential diagnosis. I agree, from the history, that it could be, however.

DR AUB: Does the mass lie between the two lobes?

DR SCHATZKI: No, I would say it lies in the lobe.

DR ALFRED KRAVES: Is it possible that the repeated chest x-ray examinations that he had would affect a sensitive tumor?

DR SCHATZKI: Not the amount he apparently had.

DR EDWARD B. BENEDICT: Was a bronchoscopy done?

DR SCANNELL: No.

DR BENEDICT: Was there any reason for not doing one?

DR SCANNELL: Yes, because of the peripheral nature of the lesion. Opinion was divided into two camps. We joined the camp that thought he ought to be operated on.

DR BENEDICT: I agree that he certainly had to be treated as a cancer patient, but I would have bronchoscoped him on the chance of finding a finger-like process in the left-upper-lobe bronchus with a right-angle bronchoscope and obtaining washings for a cytologic study. Even if it were negative, I would still explore.

DR SCANNELL: That was our viewpoint. We did not see how it would change the therapy.

DR LOWREY F. DAVENPORT: I would like to ask a general question. The statement has been made that on a percentage basis peripheral tumors are more apt to be adenocarcinoma. Dr Siegfried J. Thannhauser called my attention to the fact that he was certain that the ones that shelled out forming abscesses were more apt to be epidermoid than adenocarcinoma. What would you say to that as a differential point in the case of a solitary tumor in the periphery of the lung?

DR MALLORY Most of our abscesses have been either with epidermoid or with oat-cell tumors, rather than adenocarcinomas

DR STANLEY M WYMAN It is worth stating, as the record says, that careful review of the old films convinced us, at least, that the nodule had been in the same location from the first examination, and represented a part of the mass that we now see

DR SCANNELL My impression is that a complement-fixation test was done before he came here and was negative He was Russian born, but had lived in South Africa for twenty years He had had the whole gamut of studies done by all his medical friends every place he went Our opinion as we stood at the operating table was similar to Dr Schatzki's Before we operated Dr Edward D Churchill, at least, said that he thought it was a tuberculoma, and we were prepared to give streptomycin On opening the chest we found a complete left middle lobe, and in the anterior segment of the left upper lobe was a puckered area with an underlying mass, no overlying pleural adhesions and very little injection of the surrounding lung or pleura A left upper lobectomy was done A biopsy was also taken since we believed at that point that it was probably tumor rather than tuberculoma There were no involved lymph nodes, and the hilar areas were clear There were minimal adhesions at the left apex

CLINICAL DIAGNOSIS

Tuberculoma?

DR SCHATZKI'S DIAGNOSIS

Bronchiogenic carcinoma?
Tuberculoma?

ANATOMICAL DIAGNOSIS

Adenocarcinoma, left-upper-lobe bronchus

PATHOLOGICAL DISCUSSION

DR MALLORY The specimen we received showed a lobular, very sharply circumscribed but nonencapsulated tumor, which, on microscopical examination, proved to be a very well differentiated adenocarcinoma Portions of the tumor were, in my opinion, better differentiated than any cancer of the lung that we have ever seen, and yet there can be no doubt about its malignancy It appeared to be still relatively slowly growing, and I believe the tumor could have been present for a large part of the recorded history We did not find any other lesion that would explain the previous shrinkage of the shadow

DR SCHATZKI Do you have any explanation how that might occur?

DR MALLORY No, I have not This was an extremely solid tumor, rather scirrhous, in fact, which is unusual in a pulmonary tumor, and it is very hard for me to see how it could have shrunk

DR BENJAMIN CASTLEMAN The scirrhous character might mean that there had been previous necrosis of the tumor, which had caused it to shrink

DR MALLORY It is possible, but there are so many sclerosing tumors in which one has no such evidence of episodes of necrosis that I do not think we can draw such a conclusion safely

DR SOUTTER What is the possibility of a metastatic adenocarcinoma?

DR MALLORY I cannot rule out that possibility

DR SCANNELL That was probably ruled out clinically from previous studies The tests were not done here, but barium studies and pyelograms carried out elsewhere were all negative

DR MALLORY The tumor involved the entire bronchial segment and was growing into the lumen of the bronchus in a fashion characteristic of primary tumor Of course we do know that metastatic tumors occasionally grow intraluminally

DR SCHATZKI What caused the extreme segmentation—just the shape of the tumor?

DR MALLORY Yes

AMERICAN ACADEMY OF GENERAL PRACTICE

THE first annual clinical meeting of the Massachusetts Chapter of the American Academy of General Practice, which was held in Boston on April 15, not only represents the growing extension of chapters of the Academy (which have been formed in almost all the states) but also recalls the principles and goals of the organization. The purposes of the Academy, as stated in its constitution, are as follows: to promote and maintain high standards of general practice of medicine and surgery, to encourage and assist young physicians in preparing, qualifying and establishing themselves in general practice, to protect the right of the general practitioner to engage in medical and surgical procedures for which he is qualified by training and ex-

perience, to assist in providing postgraduate study for general practitioners and to encourage and assist physicians and surgeons to participate in this training and to advance medical science and private and public health. The Academy at present has a membership of more than 10,000, and the potential membership includes more than 100,000 general practitioners.*

The officers of the Massachusetts Chapter include Dr. John R. Fowler, of Spencer, as president, Dr. Lewis S. Karp, of Worcester, as vice-president, and Dr. James G. Simmons, of Fitchburg, as secretary-treasurer. The directors are Dr. Nathaniel N. Bennett, of Springfield, Dr. Harold F. Brown, of Brookline, and Dr. Fred L. Campbell, of Brighton. The activities of the first annual meeting comprised ward rounds, clinics and lectures on such varied subjects as psychosomatic illness, premarital counseling, the Rh factor, hypertension and virus diseases, all presented with particular attention to the interests of the general practitioners.

At the first scientific assembly of the Academy, held in Cincinnati early in March, the attendance was more than twice the number that had been anticipated. Meetings of the various chapters have evoked a similar interest.

The Academy, which represents at once the oldest of the medical arts and the newest of the specialties, is the result of a conviction among groups of general practitioners in several states that progress in medicine and surgery is basic to the welfare of the people and, incidentally, of the medical profession. As he takes his place among his fellows in more dramatic (and often more remunerative) specialties, the general practitioner epitomizes the best and most familiar aspects of medical practice. His role of healer, counselor and friend in time of need is a bulwark against interference with the free practice of medicine.

*First scientific assembly is outstanding success. *Gen. Practice News* 21 April 1949.

"FETUS AND NEWBORN"

THE strength of a nation may be said to depend primarily on the care and training of its young. Such a statement, no doubt true, can nevertheless be variously interpreted. In the city-state of Sparta

artificial means were added to the method of natural selection the weak infants were exposed upon the hillsides, and only the strong survived to be subjected to the rigid discipline of the nation. Under conditions imposed at the highest levels of modern civilization, total survival is sought, for better or for worse, with quality to be attained through environmental influences rather than by the processes of natural selection.

In this country, still devoted to humanitarianism, every effort, come what may, is bent toward both the preservation and the betterment of life.

The American Academy of Pediatrics, in a relatively short existence, has already made two important contributions to child care. The second of these, the recently completed Study of Child Health Services, is already notable as the most exhaustive inquiry that has yet been made into the pediatric resources of the country, the earlier and continuing study, the work of the Academy's Committee on Fetus and Newborn, less ambitious in scope and less widely publicized, is nevertheless hardly of less importance.

In 1943 the Committee on Fetus and Newborn, working with the Children's Bureau, assisted in developing "Publication 292" of the Bureau — its manual, *Standards and Recommendations for the Hospital Care of Newborn Infants — Full-Term and Premature*. Continuing its program of developing and improving facilities for the hospital care of newborn infants and aided by state groups covering the entire country, the Committee, under the chairmanship of Dr. Stewart H. Clifford, of Boston, last fall presented its completed manual.

This manual, as its title implies, embodies a most acceptable and inclusive set of standards for the hospital care of newborn infants. It is particularly timely at a period during which deficiencies in hospital personnel have combined with an increased popularity of hospital lying-in to make the risks of neonatal infection a very real hazard.

No hospital that offers obstetric facilities can afford to operate its nursery along lines other than those established by the committee. In this instance the benefits of uniform procedure far outweigh its disadvantages.

MENE MENE

THE New York County Medical Society, which last winter "disapproved" the assessment and twelve-point program of the American Medical Association, has seen new writing on the wall. Repenting of the stand taken by a militant minority of the membership at the earlier session, a "huge attendance" at a later meeting on March 28 reversed the previous vote and recorded overwhelming approval of the present policies of the national association.

The general trend on the part of physicians is in the direction of adoption of the principles and acceptance of the program of the American Medical Association. Distrustful of the Association's conservatism, which has at times amounted to reaction, a number of its fellows at first hesitated to subscribe to its rejuvenated policies. These physicians, convinced of its integrity, are now joining the ranks in increasing numbers. A few, doubters to the last or devoted to the principles of paternalism in government, will never join. In general it may be said that the profession is presenting a stronger, more united front against the political control of medicine.

PRIZE ESSAY CONTEST

The *Journal* announces with pleasure the selection of the essay on Preventive Medicine by Miss Miriam D. Manning, a fourth-year student at Tufts College Medical School, as the winner of its 1949 prize essay contest. Miss Manning's essay will be published as the Medical Progress report on June 30. The prize was \$100.00. The second prize, consisting of a two years' subscription to the *Journal*, was won by Miss Suzanne Agnew, a member of the graduating class at the University of Minnesota Medical School.

The subject chosen for the next competition is "Recent Advances in the Study of Poliomyelitis." The conditions are the same as those that were published for the contest recently ended.

Manuscripts are to be between four and five thousand words in length, clearly typewritten in English, double or triple spaced with references listed at the end in numerical arrangement according to the form used by the *Quarterly Cumulative Index Medicus*. They must be in the hands of

the editor by March 15, 1950. All manuscripts will become the property of the *Journal*.

A cash prize of \$100.00 will be paid for the best essay of those found to be suitable for consideration, the paper will be published in the "Medical Progress" series that forms a regular part of the contents of the *Journal*, and the author will receive a hundred free reprints.

A second prize will consist of a two-year subscription to the *Journal*.

The editors wish to emphasize that in establishing this competition they are as much interested in encouraging good medical writing as they are in promoting the collection of scientific material. In judging papers that may be submitted, particular attention will accordingly be paid to clarity, simplicity and general literary excellence.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

DOBSON—William M. Dobson, M.D., formerly of Northampton, died on May 4. He was in his sixty-seventh year.

Dr. Dobson received his degree from Tufts College Medical School in 1907. He was a member of the American Psychiatric Association and the New England Society of Psychiatry. Two daughters and a sister survive.

DORION—Kinton F. Dorion, M.D., of Lawrence, died on January 29. He was in his seventy-fourth year.

Dr. Dorion received his degree from Laval University in 1902. He was a fellow of the American Medical Association. His widow, two daughters and a son survive.

GWINNELL—Alfred W. Gwinnell, M.D., of Boston, died on May 3. He was in his seventy-second year.

Dr. Gwinnell received his degree from Tufts College Medical School in 1911.

LOUGHRAN—James F. Loughran, M.D., of Lowell, died on April 17. He was in his eightieth year.

Dr. Loughran received his degree from Harvard Medical School in 1896.

Three sons and a sister survive.

MURPHY—John M. Murphy, M.D., of Brockton, died on April 24. He was in his sixty-eighth year.

Dr. Murphy received his degree from Tufts College Medical School in 1906. He was a fellow of the American Medical Association.

His widow, a son, a brother and two sisters survive.

SULLIVAN—John A. Sullivan, M.D., formerly of Pittsfield, died on April 8. He was in his sixty-fourth year.

Dr. Sullivan received his degree from Albany Medical College in 1910. He was a fellow of the American College of Surgeons and the American Medical Association.

His widow, a brother and two nephews survive.

NEW HAMPSHIRE MEDICAL SOCIETY

DEATH

RONDINELLA—Annina C. Rondinella, M.D., of Wellesley, Massachusetts, died on March 11. She was in her seventy-sixth year.

Dr. Rondinella received her degree from Woman's Medical College of Pennsylvania in 1899, and was assistant dean for several years. She was formerly a member of the medical departments at Vassar College and Connecticut College for Women and was consulting ophthalmologist emerita at Wellesley College. She was a fellow of the American Medical Association and a member of the Association for the Advancement of Science.

A brother and two nieces survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS

The June schedule for Consultation Clinics for Crippled Children in Massachusetts under the provision of the Social Security Act follows:

CLINIC	DATE	CONSULTANT
Haverhill	June 1	William T. Green
Lowell	June 3	Albert H. Brewster
Salem	June 13	Paul W. Hugenberger
Plymouth	June 15	Frank A. Slowick
Worcester	June 17	John W. O'Meara
Springfield	June 21	Garry deN. Hough, Jr.
Hannus	June 23	Paul L. Norton
Brockton	June 23	George W. Van Gorder
Fall River	June 27	David S. Grice

Physicians referring new patients to clinics should get in touch with the district health officer to make appointments. Patients are seen by appointment only.

SCHOOL MEDICINE IN MASSACHUSETTS

To no one are the deficiencies of school medical services more acutely a source of vexation than to the average school physician. Most school physicians, sooner or later, experience a sense of frustration and aimlessness regarding the methods and objectives of their school work, though often at the outset of their incumbency they may have high enthusiasm. School physicians are public-health officers, therefore, it is the responsibility of those who develop public-health policies to aid in working out a plan by which the health requirements of school children can be better understood and satisfied and by which the special health potentialities of medical services in these large groups of school children can be better utilized than hitherto by the physician directing each school health program. It will be necessary to provide some money—necessary perhaps to conduct a demonstration program in some selected school area, and necessary to seek the more active co-operation of the Massachusetts Medical Society. Since school medical inspections were initiated in this country, right here in Boston, when in 1894 the city was faced with a severe epidemic of the dreaded diphtheria, the improvement of school medical services should be of special interest in Massachusetts. One resolution announced by the Panel on School Health at the recent Massachusetts Health Conference favored the development of a section on school health by the Massachusetts Medical Society. The development of such a section should receive consideration.

To work for a brighter future, it is not necessary to lay the blame on the past, whether the dissatisfying experience was the result of low salaries or the low salaries the result of dissatisfying experience. The fault appears to lie with all who failed to realize until quite recently that school medicine has greater

possibilities than the mere duplication and underwriting of the work of the general practitioner. Strangely enough, the most suggestive, stimulating and penetrative analyses of school health possibilities have by no means all emanated from the medical profession. An example of this is the American Child Health Association, of which Herbert Hoover was president, which published in 1925 its health survey of eighty-six cities and later that of seventy cities and finally, before its liquidation, published the study known as *Physical Defects Pathways to correction*.

Supported partly by funds from the liquidating committee of the American Child Health Association, partly by the Metropolitan Life Insurance Company and the Milbank Memorial Fund and by Social Security funds from the Children's Bureau, a fourth study known as the Astoria Demonstration Study was completed in a borough of New York City. These surveys provided much that was suggestive and constructive, and it is regrettable that the published reports are not more widely read.

Not until quite recently, however, has it become apparent that at least two, and probably three, wide fields are especially open to school medical practice. These are emotional health, child health education (I think I should also include adult education in child health), and studies of physical growth and the significance of deviations from standards, studies designed for use in large groups. Examples of such standards are the grids and graphs based upon various semiannual or more frequent measurements. In no way do I mean to imply that present activities of the school physician are to be abandoned. The search for physical defects and their correction and the prevention of communicable disease will not be less, but the physician's activities in the field of emotional health and of health education will be a great deal more.

Recognition of the importance of emotional health and the influences by which a child's emotions are swayed or damaged has not come too soon. Most parents are little aware of the importance of heedless acts or even inopportune absences upon the emotional health of their children. It is extremely important that parents be educated to an appreciation of these influences to prevent hurts that they do not wish to inflict. The problems of the child, whether physical or emotional, are best handled through prevention. It is a long hard row to rehabilitate a child with a tuberculous hip. How much better to prevent by eliminating the source. It is perhaps a longer and harder task to reclaim a happy and productive social being from an emotionally damaged child or—even worse—from the chronic delinquent.

The number of children and adolescents whose potential achievements are limited and crippled by emotional ill health is known to be extremely

large. Emotional ill health is, in fact, the most common disease of the white race. Who has not suffered from its effects? What a huge loss to Society this disease entails! How many Lincolns, Holmeses or Churchills have sought the solitude of lesser fields rather than public life, because of emotional crippling! One speaks nowadays of "total health" meaning not merely the absence of detectable physical disease but also the full enjoyment of all the potentialities with which a person was endowed at birth.

The prevention of emotional ill health is a yet unappreciated gigantic task. It is to be obtained through education, not only of the child but also, even more especially, of its parents. Of the available community resources, especially since the curtailment of state child-guidance centers or clinics, the school physician, aided by alert and sympathetic teachers, nurses and counsellors, has the finest opportunity to provide such education.

We are thus upon the threshold of the second field of normal school health service—that of health education. By this I do not mean that the school physician should embark upon formal education. That function he should leave to trained educators. But he can teach by example during his examinations, inspections and other contacts with children and teachers as well, and should explain, as he proceeds, what he does and why he does it. He will also seek every opportunity to educate—the child by example and the parent, the teacher and the nurse by lectures and personal talks.

On the other hand, direction of the much more highly developed preventive aspects of the school health program will require a man who will know how to teach by example, who will know how environment can affect child health, who will know how to cope with an unfavorable environment and who will explain to parents their true relations to the emotional health of their children. Such responsibilities, which will require special training, can only mean that the practice of school health will be recognized as a specialty. The specialty has already been named by others, and its representatives are styled "pediatrician psychiatrists." Medical schools already furnish instruction designed to cover this field, but few men so equipped are yet available.

There are other reasons for a radical change in the type of school medical adviser who today is usually a man engaged also in general practice, and of these none is more important than the conflicting demands of his school health duties with those of general practice. It must be acknowledged, I think, that even today the proper demands of the school health program are incompatible with general practice. The hours of the school day will be none too long for the demands upon the school physician. An ideal school health program cannot permit the urgent demands of obstetrics, sur-

gery or other emergencies to interfere with the essentially regular school medical work. Furthermore, there is the problem of an adequate salary.

While discussing the problem of providing a trained, full-time school physician with the Board of a neighboring city, one of the Board members stated, "Why! Such a physician would require a salary of ten to twelve thousand dollars! It is more than we pay our superintendent. Your idea is impracticable." It is true that a pediatrician-psychiatrist school physician would expect to make twelve thousand dollars. But is that price too high? Is it not rather that the community has for many years indulged in the practice, so far as schools are concerned, of expecting too much for too little? It is also true that although the practice of school health is incompatible with general practice, with its demanding emergencies, there is no reason why the hours or interests of school work should prevent a substantial and remunerative consultative practice so that to the specialist a salary considerably less than twelve thousand dollars, since it is to be only a part of his income, would be attractive.

Some say that the general services of the full-time, trained staff of the organized communities are the answer to this problem. My own opinion is that one must look forward to such clinical facilities in rural communities—and be fortunate indeed to obtain them—as the best solution in areas of low resources. But I believe that the school needs its specialist physician—one who has the responsibility of school work at heart, who has the special interest in school children that is necessary, who will watch his children at play and at work, who will know their parents and their special problems, and who will have studied the school environment including each teacher and other school personnel. If it is objected that the average school population is too large for such detail, I shall answer that the large school population requires that the physician recognize his responsibility so to train the teacher's observation that he can count on her efficiency, so that he may delegate to her much of the important function of screening her pupils and concentrate himself upon those most in need of his study.

Shall one attempt to place a figure of value in dollars against the loss to society not by death, which has been estimated elsewhere, but by emotional ill health whether or not it is followed by delinquency? I believe that six or even twelve thousand dollars is a modest fee to pay for the means of helping to prevent such crippling, which is annually produced in any city.

It is hardly necessary to say that a sudden change from present methods to school medicine administered by a specialist is not to be expected. However, the future is not without promise. The Commissioner of Public Health in Massachusetts has an active interest in the development of better school medicine. At present the postgraduate ed-

ucation of physicians concerned with school work seems the most promising line of attack. An example of such education is the course first given last year, under the sponsorship by the Department of Public Health with the co-operation of the Harvard School of Public Health.

Such a course will probably be given annually. It is limited to forty participants. Interest on the part of school physicians is indicated by the fact that applications for most of these forty chairs were received this year within three weeks of the time of announcement, one from as far away as North Adams, one from Northampton and one from Greenfield.

ALLAN R. CUNNINGHAM, M.D.
Consultant in School Health

MISCELLANY

ISRAELI MEDICAL SCHOOL

The Hebrew University-Hadassah Medical School, the first medical school to be established in the new State of Israel, opened its doors May 17, 1949, as a joint undertaking of the Hebrew University and Hadassah, the Women's Zionist Organization of America. Until security conditions permit continuation of construction on Mt. Scopus, the site of the present 400-bed Rothschild-Hadassah-University Hospital, the School will be housed in four hospital units, totaling initially over 300 beds, in the city of Jerusalem proper.

UNIVERSITY PROFESSOR

Dr Edwin J. Cohn, professor of biological chemistry in the Harvard Medical School and chairman of the Division of Medical Sciences in the Faculty of Arts and Sciences, has been appointed one of the four University Professors of Harvard University.

Long recognized for his work on proteins and the fractionation of blood, Dr. Cohn now becomes one of the four scholars of the University, especially chosen for work on the frontiers of knowledge.

CORRESPONDENCE

PUBLIC RELATIONS THAT MAY BACKFIRE

To the Editor: In the annual report for the year ending March 31, 1949, of The Institute of Living at Hartford, Connecticut, the psychiatrist-in-chief, Dr. Burlingham, discusses at some length what has been happening to psychiatry from publicity. A few quotations from this will give a very good idea of what Dr. Burlingham thinks of the effects of ill advised publicity on psychiatry. These quotations follow:

When psychiatrists emerged from comparative obscurity a few decades ago, they had high hopes as to what could be accomplished in the sphere of public relations and education. Their objectives were to awaken the public to the long-neglected needs of the mentally ill.

Regardless of where the responsibility rests, the facts are that hordes of people are being given the impression that they need the services of psychiatrists, they are then being advised that the shortage of psychiatrists makes it quite impossible for them to get psychiatric help. They are being warned that one out of twenty-five per-

sons will wind up in a mental hospital, they are being presented with the terrifying picture of the horrible conditions in mental hospitals. Something should be done to stop this onslaught of injudicious publicity, or at least to disidentify it from scientific psychiatry. Publicity is a two-edged sword, publicity accidents are as common as publicity successes. It is absolutely necessary for us to be conservative and modest in all of our public statements. Overemphasis and overclaiming are inevitably followed by loss of public confidence and respect, which often as not manifests itself in ridicule and satire. Symptoms are already evident that such a reaction to psychiatry is setting in. We must ask ourselves if the efforts to arouse the public have gone out of balance.

As I read the constant inflow of pamphlets and letters and listen to the radio extolling the virtues of this or that medical project, I am impressed by their frequent overstatements, particularly the overenthusiastic claims, often being made. The idea for example is being given to the public that, if only enough money is given, the important problems of the cause and cure of many diseases surely will be solved, or that all that is needed to this end is the construction of new institute buildings or more hospital beds for research. A sort of dreamland of obliteration of suffering from disease seems in creation by these statements, but I wonder if there will not be an awakening from such dreamlands of publicity, if there will not come a future backfire from them as has seemingly come in the field of psychiatry. I fear that this may happen, and so I think it behooves organizing publicity campaigns for medical projects to be more cautious in their statements and promises than they now are.

HENRY A. CHRISTIAN, M.D.

20 Chapel Street
Brookline, Massachusetts

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Diseases of the Nose and Throat. A Textbook for Students and Practitioners. By Sir St. Clair Thompson, M.D., F.R.C.P. (London), F.R.C.S. (England), L.L.D. (Hon.) (Winnipeg), and V. E. Negus, M.S. (London), F.R.C.S. (England), surgeon for diseases of the throat, nose and ear, King's College Hospital. 8°, cloth, 1004 pp., with 44 plates, 13 in color, and 369 illustrations. Fifth edition. New York: Appleton-Century-Crofts, Incorporated, 1949. \$16.00.

This standard textbook was first published in 1911. In this fifth edition the text has been thoroughly revised, and many chapters partially or completely rewritten. Major changes have been made in the subjects of malignant lesions of the nasopharynx, the pharynx and the larynx, simple neoplasms of the nasopharynx, treatment by sulfonamides, penicillin, radiotherapy and vitamins (combined to form a new chapter), allergy and nasal physiology, and laryngeal paralysis. Some rearrangement of the material has been made to provide a more logical text. This book, written by two British physicians, naturally reflects the British aspects of the subject. Likewise, the printing was done in Great Britain, and the sheets bound in the United States. The type, printing and illustrative work, including the color and radiographic plates, are excellent. The book should be in all medical libraries as a reference work and should prove valuable to all physicians interested in the subject.

A-B-C's of Sulfonamide and Antibiotic Therapy. By Perrin H. Long, M.D., F.R.C.P., professor of preventive medicine, Johns Hopkins University School of Medicine, and physician, Johns Hopkins Hospital. 12°, cloth, 231 pp. Philadelphia: W. B. Saunders Company, 1948. \$3.50.

This small manual represents the experience of the author in the use of the sulfonamides and antibiotics over a period of

twelve years. It is intended for the general practitioner and surgeon and should prove useful as a reference source in their daily practice. The volume is well published.

Plaster of Paris Technic. By Edwin O. Geckeler, M.D., professor of orthopedic surgery, and chief of the fracture service, Hahnemann Medical College and Hospital, Philadelphia. Second edition. 8°, cloth, 220 pp., 234 illustrations. Baltimore: Williams and Wilkins Company, 1948. \$3.00.

This second edition of a standard monograph, first published in 1944, has been revised, and many illustrations have been added. The book is mainly illustrative, with a small amount of text. It is recommended to orthopedists and to all persons using plaster and to medical libraries as a reference source.

Die Funktionelle Organisation Des Vegetativen Nervensystems. By W. R. Hess, o.ö. Professor der Physiologie an der Universität Zürich. 8°, cloth, 226 pp., with 80 illustrations and 1 table. Basel: Benno Schwabe and Company, 1948. 18.50 fr.

This well written monograph constitutes a comprehensive survey of present-day knowledge of the functions of the vegetative nervous system. There are nine chapters, beginning with peripheral autonomy and ending with dynamic principles. A comprehensive bibliography of eleven pages concludes the text. There is a good index. The book is well published in every way. It is recommended for all medical libraries and should be available to all neurologists.

A Textbook of General Physiology. By Philip H. Mitchell, Ph.D., Robert P. Brown, Professor of Biology, Brown University. Fourth edition. 8°, cloth, 927 pp., with 201 illustrations. New York: McGraw-Hill Book Company, Incorporated, 1948. \$7.50.

This standard college textbook, first published in 1923, has been thoroughly revised in this fourth edition. Extensive changes have been made in the chapters on excitation and contraction, the structure of living matter, permeability of cells and nutritive requirements. The chapter on biologic oxidation has been entirely rewritten, and a chapter on intermediary metabolism has been added. Lists of references are added to the various chapters, and a good index concludes the text. The book is well published and is recommended to all medical libraries as a reference source.

Bailey's Text-Book of Histology. Revised by Philip E. Smith, Ph.D., professor of anatomy, College of Physicians and Surgeons, Columbia University, and Wilfred M. Copenhaver, Ph.D., associate professor of anatomy, College of Physicians and Surgeons, Columbia University. Twelfth edition. 8°, cloth, 781 pp., with 455 illustrations. Baltimore: Williams and Wilkins Company, 1948. \$7.00.

This standard textbook, intended primarily for the use of first-year medical students, was first published in 1904 and since that time nineteen printings have been made, it was translated into Spanish in 1948. This twelfth edition has been revised throughout, and some extensive sections have been rewritten. Many new illustrations in color and half-tone have been included. Lists of selected references have been appended to the various chapters. There is a good index. The publishing is well done, and the volume is recommended to medical libraries as a reference source.

Management of Common Gastro-Intestinal Diseases. By Thomas A. Johnson. 8°, cloth, 280 pp., with 16 illustrations and 4 charts. Philadelphia: J. B. Lippincott Company, 1948. \$7.00.

This monograph in the *American Practitioners Series* is the joint work of twenty-two specialists in the field of gastroenterology. The authors, in short papers, epitomize the results of their experience in the treatment of a selected group of important gastrointestinal diseases. The book is written primarily for general practitioners and should prove of value to that class of physicians. The type and printing are excellent, but the use of a heavy filled shiny paper is uncalled for in a book of this type.

Edinburgh Post-Graduate Lectures in Medicine Volume IV 8°, cloth, 582 pp., with illustrations London Oliver and Boyd, 1948 18/- net.

This fourth volume of a standard series brings together in one place forty-one articles by different authors on subjects in the fields of medicine, surgery, pathology and therapeutics, already published in the *Edinburgh Medical Journal* during 1945-1947. An index has been supplied and the publishing, which is excellent in every way, is an outstanding example of good bookmaking. The series should be in all medical libraries.

Detailed Atlas of the Head and Neck By Raymond C. Truax, M.D., Ph.D., associate professor of anatomy, College of Physicians and Surgeons, Columbia University, and Carl E. Kellner, artist, Department of Anatomy, College of Physicians and Surgeons, Columbia University 4°, cloth, 162 pp., with 136 illustrations New York Oxford University Press, 1948 \$10.00

This beautiful atlas is the culmination of years of work by an anatomist and an artist. The color plates are excellent and compare favorably with foreign work of the same type. There is a comprehensive index to structures. The volume should be in all medical libraries and available to all surgeons who are interested in head surgery. The price is not expensive for this type of book.

Fatal and Rickettsial Infections of Man By Thomas Rivers, M.D., director of the hospital, The Rockefeller Institute for Medical Research 8°, cloth, 587 pp., with 77 illustrations, 6 plates Philadelphia J. B. Lippincott Company, 1948 \$5.00

This treatise is the joint work of twenty-seven authors. The early chapters discuss the general and special aspects of the subject. The remaining chapters consider the various viral and rickettsial diseases. The material is well arranged. Bibliographies are attached to the various chapters. There are large author and subject indexes. The type and printing are excellent, but the use of a heavily filled paper is not justified when all the color plates are inserts. The book is outstanding and should be in all medical libraries and available to all physicians and others interested in the subject.

Technique of Treatment for the Cerebral Palsy Child By Paula F. Egel, cerebral-palsy director, Children's Hospital, Buffalo, New York 8°, cloth, 203 pp., with illustrations St. Louis C. V. Mosby Company, 1948 \$3.50

Miss Egel has had extensive experience in treating various types of cerebral palsy in children in institutions and in the home according to the methods of Dr. Phelps. The techniques used are outlined in detail and should prove invaluable to persons called upon to treat these patients. Mr. Tanner, in an appendix, presents a plan for the organization of a cerebral-palsy department in a children's hospital.

The illustrations are excellent, and the outline drawings present in detail the exercises for conditioned motion. There is a good index. The monograph should prove invaluable to nurses and other persons having to deal with cases of palsy.

Liver Injury, Transactions of the Seventh Conference, January 15 and 16, 1948, New York, New York Edited by F. W. Hübner, M.D., 8°, paper, 95 pp., with illustrations New York Josiah Macy, Jr., Foundation, 1948 \$1.50

The subjects discussed at this conference included radioactive methionine, protein formation, portal hypertension, hepatic blood flow, plutonium, liver-cell regeneration, hepatic excretory functions and serum lipids in liver disease. The complete series of conferences is essential for medical libraries.

Studies from The Rockefeller Institute for Medical Research Reprints, Volume 136 8°, paper, 607 pp., with illustrations New York Rockefeller Institute for Medical Research, 1948 \$2.00

This volume presents in collected form the results of investigations carried on by research workers of the Rockefeller Institute or under grants and originally published in scattered periodicals and other publications. The period covered is approximately the last half of 1947 and the first half of 1948.

Radioactive Indicators: Their Application in Biochemistry, Animal Physiology, and Pathology By George Hevesy 8°, cloth, 556 pp., with illustrations New York Interscience Publishers Limited, 1948 \$10.00

This outstanding work in a new field presents a survey of work carried out with radioactive indicators in the subjects of animal physiology, pathology and biochemistry. The pertinent literature has been analyzed, and the references are appended to the text throughout the book. The material is well organized proceeding from the general to the special aspects of the subject. The type, paper and printing are excellent. The volume should be in all medical and all libraries and should be available to all persons interested in the subject. It should have a long life as an authoritative reference work.

A Treatise on Contemporary Religious Jurisprudence By I. H. Rubenstein, of the Illinois Bar 8°, cloth, 120 pp. Chicago Waldman Press, 1948 \$2.50

This monograph is devoted to a discussion of the civil, legal and criminal aspects of fortune telling, faith healing and pacifism. The part on faith healing appeared previously in the February 6, 1941 issue of *New England Journal of Medicine*. The text, which is profusely documented with citations from court records, is well written, and the material is well arranged in a typical legal style. An index would have made the volume more useful. Because of the documented section on faith healing the volume should be in the reference collections of all medical libraries.

The Mechanism of Abdominal Pain By V. J. Kinsella, M.B., Ch.B. (Svd.) F.R.C.S. (Eng.) 8°, cloth, 230 pp., with 17 illustrations Sydney Australasian Medical Publishing Company Limited, 1948 32/6

The author contends that the mechanisms of splanchnic pain do not differ essentially from those of somatic pain, and presents evidence to support his contention. He believes that true visceral pain and tenderness have an adequate anatomic basis and gives reasons for a relief in direct visceral tenderness. He stresses the fundamental inadequacy of experiments on pain in animals. The author postulates a neuro-humoral basis for abdominal pain to replace the neuronal theory, and considers that this simple conception replaces that of indirect mechanisms and makes the clinical examination of the abdomen more simple and exact. A list of references and an index conclude the text. The book is well published and should be available to all persons interested in the subject.

Treatise on Surgical Infections By Frank L. Meloney, M.D., associate professor of clinical surgery, College of Physicians and Surgeons, Columbia University, and associate visiting surgeon, Presbyterian Hospital, New York City 8°, cloth, 715 pp. New York Oxford University Press, 1948 \$12.00 Oxford Medical Publication

This book is the result of investigations carried on by the author and his associates during the past twenty years. It includes experience with the sulfonamides and the antibiotics. It is written especially for operating-room personnel, laboratory workers and surgeons. It emphasizes high standards of sterile technique in the operating room and the necessity of close co-operation of the laboratory and the surgical clinic. A number of chapters are devoted to the treatment of infections by surgery, chemotherapy, zinc peroxide, bacteriophage and penicillin. The material is well written. Lists of pertinent references are appended to the various chapters. A comprehensive index concludes the text. The book is well published. A good type is used, and the illustrations are excellent. The book is recommended for all medical libraries as a standard reference work and should be available to all surgeons and laboratory workers.

A Public Relations Workshop: A manual of practical public relations techniques prepared for the guidance of the national membership of the American Nurses' Association 8°, cloth, 32 pp., with 34 illustrations New York American Nurses' Association, Incorporated, 1948 \$3.00

This manual was prepared by Edward L. Bernays, counsel on public relations, for the purpose of making available to

nursing organizations the modern technics of public relations in all fields of publicity, including the press, radio and television, movies, direct mail and public meetings. The type, printing and paper are good, but the oblong size of the volume is awkward and hothersome. The same data could have been presented to advantage in a regular octavo form. The material in the book could be valuable to other than nursing organizations.

Your Baby The Complete Baby Book for Mothers and Fathers By Gladys Denny Shultz and Lee Forrest Hill, M.D. 8°, cloth, 278 pp., with illustrations. New York: Doubleday and Company, Incorporated, 1948. \$3.50.

This de luxe volume is intended for parents, including fathers, and presents instructions and advice on how to care for babies from the time of their birth through their second year and for preschool children from two to six years of age. The preliminary chapters are devoted to various aspects of pregnancy. The concluding chapters discuss formulas and recipes and common ailments and accidents. The illustrations, photographic reproductions and line drawings are excellent and form an important part of the book. The volume should appeal to obstetricians and pediatricians, who might profitably refer it to their patients.

Polio and its Problems By Roland H. Berg. With a foreword by Basil O'Connor, president of the National Foundation for Infantile Paralysis, Inc. 8°, cloth, 174 pp., with 24 illustrations. Philadelphia: J. B. Lippincott Company, 1948. \$3.00.

Dr. Berg has written a popular history of epidemic poliomyelitis beginning with the widespread epidemic that swept over the northeastern section of the United States in 1916 down to the present time. He relates in simple language the progress that has been made in combating the disease during the past thirty-odd years. The text has been printed with a good, large type on a soft nonglare paper pleasing to the eye. There is a good index. The book is recommended for all public libraries and for all medical-history collections.

An Account of the Weather and Diseases of South Carolina By Lionel Chalmers, M.D., of Charles-Town, South Carolina. In two volumes. Volume I. 8°, paper, portrait, 58 pp. London 1776. Selections reprinted, Charleston: South Carolina Medical Association, 1948. Free.

The Committee on Historical Medicine of the South Carolina Medical Association, in commemoration of the centennial of the Association occurring in 1948, issued this facsimile reproduction of an important early American imprint specially pertinent to the medical history of South Carolina. The original publication is very scarce, and the opportunity to obtain this excellent reproduction should be taken advantage of by all medical libraries and medical historians.

Hospital Trends and Development, 1940-1946 Edited by Arthur C. Bachmeyer, M.D., director, University of Chicago Clinics and director, hospital administration course, University of Chicago and Gerhard Hartman, Ph.D., superintendent, State University of Iowa. 8°, cloth, 819 pp., with illustrations. New York: Commonwealth Fund, 1948. \$5.50.

This composite volume covering the whole field of hospital administration and service comprises a large number of selected articles condensed from their original form in many periodicals published during the past few years. The makeup is excellent, but the lack of an index detracts from its reference value. The book is recommended for all medical, public-health and hospital libraries and to all hospital administrators.

The Alcoholic Woman Case Studies in the Psychodynamics of Alcoholism By Benjamin Karpman, M.D., chief psychotherapist, St. Elizabeths Hospital, Washington, D.C. 8°, cloth, 241 pp., 3 diagrams. Washington: Linacre Press, 1948. \$3.75.

This monograph presents three extensive case histories of alcoholic women who had one factor in common: an unsatisfactory childhood environment characterized by parental stupidity or incompetence. In all 3 cases the acquaintance with alcohol was incidental and gradual, and gave no

hint that it would become a possessive force in their lives. The patients were treated with the method of "objective psychotherapy." This monograph should prove of value to psychiatrists and psychoanalysts.

The Clinical Application of Psychological Tests Diagnostic Summaries and Case Studies By Roy Schafer, M.A., staff psychologist, Austen Riggs Foundation. Foreword by David Rapaport, Ph.D., Menninger Foundation. 8°, cloth, 346 pp. New York: International Universities Press, Incorporated, 1948. \$6.75.

This monograph presents a method of applying a battery of six clinical psychologic intelligence and personality tests to a series of appropriate cases. Two of the chapters are devoted to case studies of psychopathic disorders. The book is a sequel to the two-volume treatise by Rapaport, Gill and Schafer, entitled *Diagnostic Psychological Testing* (Chicago, 1945). The volume should be in all psychiatric and psychologic collections.

A Method of Anatomy Descriptive and Deductive By J. C. Boileau Grant, M.C., M.B., Ch.B., F.R.C.S. (Edin.), professor of anatomy in the University of Toronto. Fourth edition. 4°, cloth, 852 pp., with 800 illustrations. Baltimore: Williams and Wilkins Company, 1948. \$7.00.

This fourth edition of a standard textbook has been thoroughly revised, and many parts of the text have been rewritten. First published in 1937 there have been thirteen printings to date, which speaks well for its popularity. The illustrations have been revised by addition and deletion, the total being brought to 800 for this edition. The type, printing and diagrammatic drawings are excellent. The book is recommended for all medical libraries as a standard reference source and should prove valuable to all persons interested in anatomy.

BOOK REVIEW

The Ciba Collection of Medical Illustrations A compilation of pathological and anatomical paintings Prepared by Frank H. Netter, M.D. F°, cloth, 222 pp., with 191 full color plates. Summit, New Jersey: Ciba Pharmaceutical Products, Incorporated, 1948. \$6.50.

During the past eight years the Ciba company has published from time to time a series of educational illustrations, dealing with anatomy and pathology, which have been distributed to the medical profession as loose sheets in folders as published. The complete series is now brought together in one volume for the convenience of the many physicians who expressed a desire for such a publication. In reply to a letter issued by the company concerning the volume, 36,000 replies were received in the affirmative.

The material has been divided into four major sections as follows: lungs and chest, gastrointestinal tract, male reproductive organs and male and female mammary glands, and heart and aorta. The large color plates are accompanied on the same page by explanatory text. The artist, Dr. Netter, has long been engaged in medical illustrative work. His early illustrations were done in pure water color, but lately he has used casein paint, egg tempera and poster color in conjunction with the water color. Likewise, he has often employed colored pencils or pastels for shading over the painting or for working in fine detail.

In the illustrations in this book it has been the aim to stress clarity and simplification of detail. In the anatomic plates a schematic treatment has been adopted in the interest of detail. Likewise, color has been arbitrarily used to give emphasis and clarity. The arteries have been illustrated in bright red, and the veins in strong blue.

In the pathological illustrations, emphasis is placed on accurate color and realistic representation, and there is considerable simplification by the elimination of extraneous tissues, which obscures the essential pathologic condition.

The text is preceded by a table of contents listing each individual plate, and concluded with an index of subjects. The color work, both gross and minute, is excellent. The volume is an outstanding example of good bookmaking. It may be obtained only from the company.

THE METABOLISM OF THE RADIOACTIVE ELEMENTS CREATED BY NUCLEAR FISSION*

JOSEPH G. HAMILTON, M.D.†

BERKELEY AND SAN FRANCISCO, CALIFORNIA

THE appearance of new agents that carry with them a potential menace to the health and security of the public is bound to be accompanied by a very understandable attitude of fear. The highly dramatic introduction to the world at large of the release of atomic energy has produced an unprecedented degree of concern for public safety. Frequently, the concern expressed has assumed the proportion of panic owing to the lack of sufficient basic information on the part of those presenting their evaluations of the problems posed, by this twentieth-century version of Pandora's box.

For example, considerable apprehension has been displayed concerning the disastrous effects that might follow the contamination of an inhabited area as the result of an underwater or subsurface explosion of an atomic bomb, which of course would release very large quantities of the radioactive fission products. There is no question that this type of action would serve to contaminate a considerable area to a dangerous degree. However, it is highly important that the inhabitants in the immediate vicinity realize that they are not all going to acquire the atomic-age version of the fate of the radium-dial painters, moreover, it is appropriate that steps be taken to keep to a minimum the incidence of radioactive poisoning after such an episode. Should such a problem ever arise, information and instruments are in hand to approach it intelligently and with a gratifying degree of effectiveness.

The work described in this article is but a small part of the many phases of the medical research activities within the atomic-energy program,‡ which were initiated during the war by the Manhattan Project and are now being continued by the Atomic Energy Commission. Space does not permit even

a partial enumeration of the many fields of investigation that are relevant to the medical aspects of the release of nuclear energy. It is important to indicate that these manifold activities are continuously accumulating the knowledge necessary to ensure the protection of the nation against the hazards inherent in the widespread development and applications of atomic energy. It is pertinent to recall that throughout the entire wartime period of activity of the Plutonium Project, there was not a single known episode of manifest radiation injury to the thousands of persons who worked on this program. The extent of scientific information, the number of trained and experienced personnel, and the availability of instruments for the detection of radioactivity is at a far higher level than is commonly supposed. Thus, the necessary safeguards for the peacetime applications of atomic energy are keeping pace with the rapid progress of this new field. At the same time the security of the nation has been strengthened against the possible consequences of military action in the event of an international disaster.

The phenomenon of nuclear fission in both the controlled release of atomic energy in the chain-reacting uranium pile and the instantaneous detonation of an atomic bomb is associated with the immediate emission of very energetic and penetrating neutrons and gamma rays. If an appreciable quantity of the fissionable element, such as uranium or plutonium, undergoes fission, a radioactive residue is left. This is due to the fact that the two atomic nuclei produced by the cleavage of a uranium or plutonium nucleus are unstable and thus radioactive. For this reason the radiation from either a chain-reacting pile or an atomic bomb continues after fission has ceased. These radioactive fragments from the fission of uranium and plutonium are called fission products and include radioactive isotopes of 34 different elements extending from zinc to the rare earth europium.¹ The explanation for the large number of different elements produced by fission is that the fissioning nucleus does

§This work was performed under Contract No. W-7405-eng-48-A with the Atomic Energy Commission.

not divide into two equal parts but rather splits into nuclei of varying sizes. The fissionable element employed in the present chain-reacting piles is uranium, and coincidental to the formation of the fission products is the production of neptunium, which is the radioactive parent of plutonium.² Thus, the menace of radiation from the release of nuclear energy is not limited to the duration of the fission reaction but continues on afterward. The relative intensity of radioactivity arising from nuclear fission decreases with time, owing to the fact that the fission products are composed of a mixture of a large number of radioactive isotopes whose half lives range from a fraction of a second to almost a million years. The mixture of fission products emits both beta rays and penetrating gamma rays. The quantities of these radioactive substances that are created are enormous. The large chain-reacting piles at Hanford are operated to produce plutonium. This requires that after an appropriate interval the uranium in the pile be removed and plutonium isolated from the uranium and accompanying fission products by a very elaborate and complicated series of chemical processes. These piles produce plutonium in kilogram quantities, and at the same time a comparable mass of fission products is created. The quantity of radioactivity of the fission products with moderately long half lives falls in the range of hundred of millions of curies. The magnitude and potential dangers associated with this program become apparent when one makes a comparison to the history of the radium industry. Up to the time of World War II there had been isolated about 1 kilogram of radium, which possesses by definition 1000 curies of radioactivity. A large number of cases of radium poisoning had been reported, notably in the luminous-dial industry, a considerable proportion of which terminated fatally.

Radioactive substances can produce injury either by external or by internal radiation of the body. Of the two, the potentialities for injury are greater if the radioactive substance is within the body. The history of the circumstances surrounding the radium industry is illustrative of the point, for it appears fairly certain that the preponderance of fatal injuries arose from internal irradiation rather than external exposure. The medical program of the Plutonium Project, which was created during the war years under the direction of Dr. R. S. Stone, was faced with the responsibility of protecting the personnel against quantities of radioactivity that were of the order of a millionfold greater than had been encountered by the radium industry over a period of half a century. Here the problem had to be met quickly in the haste of wartime urgency for the thousands of scientists and technicians working on the Atomic Energy Project. One of the many research programs that arose from these needs was a survey of the metabolism of the various ele-

ments created by the release of nuclear energy. A summary of a portion of this work is presented here, and more detailed accounts of these and related studies have been published elsewhere.^{3, 4}

It is appropriate to mention a few of the salient factors involved in the problem of radioactive poisoning, for it was these considerations that shaped the pattern of the research to be described. To evaluate a potential hazard of a given radioactive element, it is necessary to consider the half life, radiation characteristics, route of entry into the body, assimilation, distribution, retention, excretion and relative susceptibility of the different organs or tissues to the radiations emitted by the deposited material. Radiation injury, both acute and chronic, is a function of the intensity of the irradiation and the duration of the exposure to the irradiation. A radioactive substance, either as an element or as a compound, may enter the body by one or more of four routes—namely, the lungs, the digestive tract, through cuts or abrasions, and the intact skin. Once the material has been absorbed, regardless of the portal of entry, it will be distributed to the many tissues of the body, where it will be taken up in widely varying concentrations and be retained for different intervals. The degree of injury will vary with the character of the radiation and the radiosensitivity of the irradiated organ or tissue. For example, alpha particles are relatively more destructive to most living tissue than beta or gamma rays, when the biologic effects are compared on the basis of equivalent amounts of total ionization in the tissue. Concerning variations in vulnerability to radiation, the bone marrow, which is the center of hemopoiesis, is very sensitive, whereas structures such as liver, brain and muscle are relatively radioresistant.

If the assimilation, distribution, retention and excretion of a given radioelement are determined, it is possible to make an estimate of the amount of exposure to such a substance that might be expected to produce either acute or chronic injury. If the tracer or metabolic studies are done in animal experiments, as in the investigations described below, a variable is introduced by the extrapolation of such results from the animals to man. However, in most instances this error is probably not significantly greater than individual variations between different human beings in their response to a novel biologic experience such as is offered to the body by most of the radioelements associated with the release of nuclear energy.

The available information was very limited at the time of the inception of the Plutonium Project concerning the metabolic properties of the elements whose radioactive isotopes arise from fission. Among the 34 different fission-product elements there are 14 whose radioactive isotopes possess half lives ranging from days to years and are produced in relatively high abundance by the fission process.

Almost all the total radioactivity arising from the fission-product mixture after it has decayed for a week is contained in the radioactive isotopes of these 14 elements, which are listed in Table 1. These elements possess metabolic patterns that differ not only from radium but also, in most instances, from one another. Prior to 1942, only one of this group, radioiodine, had received sufficient attention regarding its metabolic properties to permit a reasonable evaluation of the amount that could be tolerated in the body without producing manifest injury.⁷ A second fission product,

namely, the passage through the intact skin — was not investigated. The absorption, distribution, retention and excretion were investigated with each substance for the three channels of administration. Extensive radioautographic studies were made of organs in which a high degree of selective localization and retention took place, that a correlation might be established between the accumulation of the radioelement and the microscopical anatomy of the tissue.

The animals were killed at regular intervals after administration of each radioelement. Twelve to

*Human studies.⁷

radiostrontium, had been subjected to some investigation before this time but not in enough detail to satisfy the requirements of the medical research program of the Plutonium Project.^{8,9} The remaining 12 fission products and strontium, as well as neptunium and plutonium, were subjected to tracer studies so that their potential capacity to produce injury as internal radioactive poisons to those exposed to these substances could be predicted.

These tracer studies included a survey of the metabolism of the fission products in the carrier-free state,* and neptunium and plutonium in the rat after oral ingestion, inhalation and parenteral injection. The fourth possible route of entry —

*The term carrier free signifies that the radioelement was not diluted with measurable quantities of the stable nonradioactive form of the same element.

fifteen organs and tissues were removed, and their radioactivity determined, as well as the fraction eliminated in the excreta. The usual intervals before the animals were killed after receiving the radioactive materials were one, four, sixteen and sixty-four days. In a number of instances the experiments were extended to intervals of one hundred and twenty-eight and two hundred and fifty-six days. In several of the studies it was necessary to conclude the experiments prior to the sixty-four-day interval owing to the relatively short half lives of several of the radioisotopes employed.

The most significant metabolic characteristics of the fission products, and of neptunium and plutonium, are listed in Table 1. It will be noted that 8 of the fission products, as well as neptunium and plutonium, are not absorbed to any significant

degree by way of the digestive tract. After parenteral administration over half the fission-product group, as well as neptunium and plutonium, are accumulated by the skeleton and eliminated from this organ very slowly. The 5 members of the listed fission products that are absorbed from the digestive tract are strontium, barium, tellurium, iodine and cesium. Xenon is readily and rapidly absorbed from the lungs after inhalation and is as readily eliminated from the lungs. Strontium and barium are deposited and retained to a high degree

ton as shown in Figure 1. In lanthanum, cerium, praseodymium and element 61, there is an initially high degree of accumulation by the liver, but they are quite rapidly excreted from this organ, presumably by way of the bile. It will be noted from Table 1 that with the exception of columbium⁹⁵, and possibly strontium⁹⁰, cerium¹⁴⁴ and 61¹⁴⁷ the rates of elimination of the different fission products accumulated in the skeleton are less than their rates of radioactive decay. The fission products that fall into this category include strontium⁸⁹, yttrium⁹¹, zirconium⁹⁵, barium¹⁴⁰, lanthanum¹⁴⁰, cerium¹⁴¹ and praseodymium¹⁴³. With the exception of iodine in the thyroid gland, the remainder of the fission products listed in Table 1—namely, ruthenium¹⁰³, ruthenium¹⁰⁶, tellurium¹²⁷, tellurium¹²⁹, xenon¹³³ and cesium¹³⁵—are rapidly excreted and at rates considerably greater than their half lives.

The rates of elimination from the skeleton of neptunium and plutonium are quite slow. The daily excretion of plutonium in the rat falls to 0.01 per cent of the amount remaining in the body a year after the intramuscular administration of this radioactive element. Since neptunium²³⁹, which is the principal radioisotope of this element produced in the chain-reacting pile, has a half life of only two days, it is not possible to observe its rate of excretion after an extended interval. However, it is obvious that its rate of elimination from the skeleton is far less than its rate of radioactive decay.

Radioautographic studies were made of the distribution of the radioactive isotopes of strontium, zirconium, columbium, cerium, element 61 and plutonium in 5-micron sections of undecalcified rat femurs.^{3 10 11} The metabolism of strontium in the skeleton is very similar to that of calcium and, as might be expected, the radioautographs revealed that the accumulated radiostrontium in the femur was fairly evenly distributed throughout the mineral structure of the bone in young rats (Fig. 2). It is assumed that the same results would be observed with barium, which possesses very similar chemical properties to those of strontium and whose metabolic characteristics are indistinguishable from those of strontium under the experimental conditions of these studies. The other radioelements studied by this technic revealed a startling deviation from the pattern of distribution observed with radiostrontium. Plutonium exhibits this phenomenon to a marked degree, and from Figure 3 it may be seen that most of this element is apparently deposited in the periosteum and endosteum, and in the region of the trabecular bone. These results suggest that plutonium in the trabecular structure is not incorporated within the mineral structure of the bone but rather is deposited in the covering of the trabeculae. The pattern of distribution in the

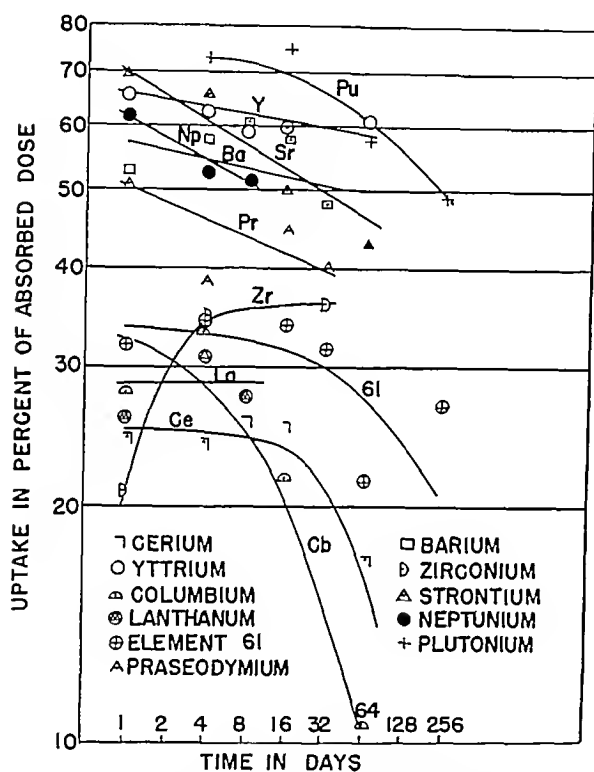

FIGURE 1 Deposition of Carrier-Free Fission Products and Neptunium and Plutonium in the Skeleton of the Rat after Parenteral Administration

by the skeleton. Iodine is accumulated and retained by the thyroid gland. Tellurium exhibits some deposition in the kidneys and blood, with a rapid rate of release from these organs. Cesium is distributed quite uniformly throughout all the tissues, the greatest accumulation occurring in the muscle, and is quite promptly excreted. The patterns of distribution of strontium, barium, tellurium, iodine and cesium in the body after oral and pulmonary absorption are indistinguishable from their metabolism after parenteral administration. With the exception of ruthenium, the remainder of the listed fission-product series, as well as neptunium and plutonium, show a considerable accumulation and varying degrees of retention by the skele-

bone of zirconium, columbium, cerium and element 61, as studied by this technic, resembles quite closely in most regards that observed with plutonium. A spotty distribution of cerium and element 61 has been observed within the cortical bone, which is believed to represent accumulation in the region of the small blood vessels. A similar effect is predicted for lanthanum and praseodymium in view of their closely related chemical and metabolic properties. A representative example of this pattern is shown for element 61 in Figure 4. The results obtained by the radioautographic studies suggest that the accumulation of these elements in the skeleton occurs in the superficial layers of the bone structure, and very possibly they are combined with proteins rather than being directly incorporated into the inorganic bone

significantly with time in the adult rat. Radioautographs from adult female rats that had received plutonium nearly a year before they were killed showed no significant differences in distribution in the bone when compared to bone radioautographs

FIGURE 2 Section of the Undecalcified Femur (Upper Photograph) and Corresponding Radioautograph (Lower) from a Young Rat that Had Received Radiostrontium One Week Before Death. Note the even deposition of radiostrontium throughout the mineralized structure of the shaft and the calcifying trabeculae beneath the epiphyseal plate (silver nitrate, hematoxylin and eosin stain $\times 3$).

FIGURE 3 Section of the Undecalcified Femur (Upper Photograph) and the Corresponding Radioautograph (Lower) from an Adult Rat That Had Received Plutonium One Week before Death.

from animals killed a few days after the administration of this radioelement.

The direct introduction into the lungs of soluble compounds of the carrier-free fission products, and neptunium and plutonium, demonstrated that the radioelements that were not absorbed from the digestive tract were retained by the lungs to a considerable degree for a prolonged interval.⁴ Fission products exhibiting these characteristics included yttrium, zirconium, columbium, ruthenium, lanthanum, cerium and praseodymium. Although these pulmonary studies were not conducted with element 61, it is assumed that its behavior would be comparable in view of its other metabolic properties, which are closely akin to the group of substances named above. The same phenomenon was

salts as is apparently the case with strontium and presumably barium. It is noteworthy that the distribution pattern for this group of elements, which are laid down so differently in the skeleton from strontium, apparently does not appear to change

observed with neptunium and plutonium. Radioautographs demonstrated that the deposited radioactive materials were distributed throughout the lungs, including structures below the ductus alveolaris. No accumulation in the bronchial tree, lymph

free fission products.^{12, 13} The inhalation of these different radioactive aerosols was followed by the initial retention of approximately 75 per cent of each material. The retention was almost equally divided between the lungs and the upper respiratory tract (Fig 5). The material in the upper respiratory tract was rapidly removed, presumably by ciliary action, and appeared in the feces, and the fraction remaining in the lungs was eliminated quite slowly. Eight months after exposure to a plutonium oxide aerosol, which is an insoluble compound of the element, $\frac{1}{4}$ per cent of the total quantity inhaled still remained in the lungs. Comparable values were observed with plutonyl nitrate, a soluble compound of the element, and with the long-lived fission-product mixture. There was very little absorption from the lungs, and subsequent

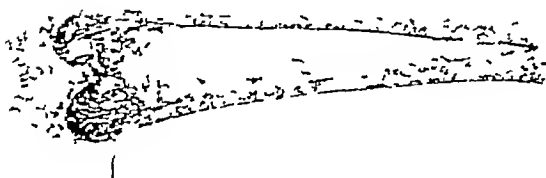

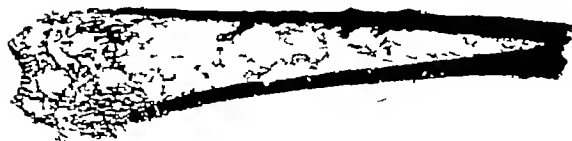

FIGURE 4 Section of the Undecalcified Femur (Upper Photograph) and Corresponding Radioautograph (Lower) from an Adult Rat that Had Received Element 61 Four Days before Death

Note the superficial deposition of this radioactive element on the surfaces of the shaft and trabeculae. The spotty areas of accumulation within the shaft are believed to be depositions of element 61 in the immediate vicinity of the small blood vessels in the cortical bone (silver nitrate, hematoxylin and eosin stain $\times 3\frac{1}{2}$).

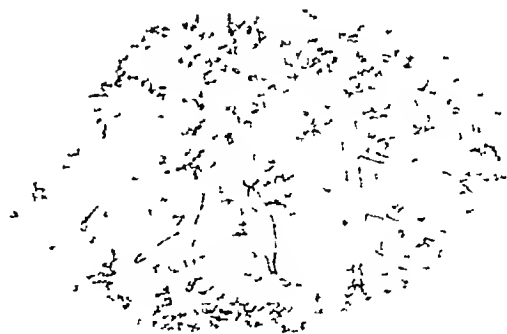

FIGURE 5 Section of the Lung (Upper Photograph) and Corresponding Radioautograph (Lower) from a Rat Killed Immediately after the Inhalation of a Plutonium Oxide Aerosol. Note the deposition of plutonium on the walls of the bronchi and throughout the alveolar structure (hematoxylin and eosin stain $\times 4$).

nodes or blood vessels was noted even after several months. Some absorption took place through the lungs for all the substances retained by this organ, and, except for ruthenium, most of the absorbed material was deposited in the skeleton, as would be expected from the parenteral metabolic studies. Fission products that are absorbed through the digestive tract — notably, strontium, barium, tellurium, iodine and cesium — were found to be quite readily absorbed through the lungs.

These experiments, which were quite qualitative in character, were later supplemented by a large series of aerosol studies using several different compounds of plutonium and a mixture of carrier-

deposition in the skeleton, after inhalation of the plutonium oxide and fission-product aerosols in an insoluble form. However, nearly 10 per cent of the plutonium, when inhaled as an aerosol of the soluble plutonyl nitrate, was absorbed through the

lungs in the first twenty-four hours and deposited in the skeleton. From the qualitative data obtained from tracheal-intubation studies using soluble compounds of the individual fission products, and the plutonyl nitrate aerosol experiments, it appears probable that the inhalation of aerosols of soluble compounds of all fission products, and neptunium, would result in a significant degree of absorption from the lungs.

Radioautographs of pulmonary tissue from the aerosol studies revealed that, immediately after inhalation, the active material was deposited in both the bronchial tree and the structures below the respiratory bronchioles. Within a day the material in the bronchial tree had vanished (Fig. 6). Presumably, it was moved out by ciliary action and swallowed with the sputum. The large fraction remaining in the lungs was quite evenly distributed throughout the alveoli, and the pattern of distribution showed little change with time for intervals extending to two hundred and fifty-six days after the initial exposure. The slow and continued release of active material from the alveoli probably also took place primarily by way of the bronchial tree. This deduction is based on the observation that the fecal excretion of plutonium and the fission-product mixture closely corresponds to the elimination of these materials from the lungs.

The outstanding characteristic of 9 of the fission products described in this report, as well as neptunium and plutonium, to be accumulated and tenaciously retained by the skeleton has a most ominous significance. Justification for this opinion is borne out by the tragic situation that has surrounded the radium industry. There is evidence that the prolonged retention of 1 microgm of radium may result in the appearance of bone tumors with a fatal outcome. Somewhat larger quantities of radium, in the range of 10 microgm deposited in the skeleton, are frequently associated with aplastic anemia and occasionally leukemia. These conditions are presumably the result of the prolonged bombardment of the very radiosensitive bone marrow and the bone itself by the radiations arising from the radium deposited within the skeleton. The gloomy picture of radium poisoning is darkened further by the fact that, to date, no successful method has been developed for removing significant quantities of radium from the body once it has been locked in the mineral structure of the bone.

The fission products that localize in the skeleton are similar to radium in that they also tend to be tenaciously held in that organ, and, to date, no satisfactory procedure for removing these substances from the bone has been developed.^{14, 15} A number of considerations reduce the relative menace of these fission products and neptunium¹⁹ as radioactive poisons in comparison to radium. In the first place they give up much less energy per dis-

integration, and the density of ionization is relatively much less since they emit only beta and gamma rays. Moreover, on the basis of an equal amount of ionization per unit volume of tissue, alpha particles are biologically considerably more destructive than beta and gamma irradiation. Secondly, with the exception of strontium⁹⁰ and ⁶¹La¹⁴⁷ the more abundant fission products that are accumulated in the skeleton possess half lives of less than a year, whereas the half life of radium is

FIGURE 6 Section of the Lung (Upper Photograph) and Corresponding Radioautograph (Lower) from a Rat Killed One Day after Inhalation of an Aerosol of Plutonium Oxide

The plutonium has disappeared from the bronchial surfaces, but it is widely distributed throughout the alveolar structures (hematoxylin and eosin stain $\times 4$)

approximately sixteen hundred years. Most of these fission products have half lives in the range of two weeks to two months. Thirdly, with the exception of strontium and barium, a negligible degree of absorption of these fission products and neptunium takes place through the digestive tract. However, with this group of radioelements there is one consideration that tends in part to counterbalance the considerations listed above, and that is the property possessed by a number of them to concentrate themselves in the immediate vicinity

of the bone marrow as contrasted to the more diffuse distribution of radium throughout the mineral structure of the skeleton. This behavior tends to enhance their radiotoxicity on the basis of both geometrical considerations and a minimal amount of self-absorption of the beta radiations, which are quite soft for several of the fission products under discussion. Plutonium shares the dangerous characteristics of radium—namely, a long half life (22,400 years), the emission of alpha particles, and the selective deposition and prolonged retention by the skeleton. In addition, the property of accumulating in the regions immediately adjacent to the bone marrow gives plutonium a significantly greater degree of radiotoxicity than an equivalent amount of radium. The only two metabolic properties of plutonium that tend to reduce this hazardous quality are the facts that it is absorbed to a negligible degree from the digestive tract and, presumably, that it is absorbed much less readily from the lungs than radium. Extensive studies have been made in an attempt to develop procedures that might effect the release of plutonium deposited in the bone. To date, practical progress in this direction has been discouraging.^{14, 15}

In conclusion it should be said that there is no new major mystery surrounding the problem of protection against the radioactive products associated with the release of atomic energy. The physical phenomenon of radioactivity and its biologic actions have been known and subjected to intensive investigation for half a century. Recently, consideration has to be given to a much larger

quantity of radioactivity arising from a somewhat greater number of radioactive elements than those which normally occur in nature. Although some of the problems presented by this new situation are formidable, to say the least, in retrospect many other formidable problems have been successfully passed by those working in the medical and related biologic sciences.

THE RADIATION SYNDROME*

ELIZABETH E. PAINTER, Ph.D.,† and AUSTIN M. BRUES, M.D.‡

CHICAGO, ILLINOIS

IN EARLIER studies of radiation effects in mammals, dosages of 1000 r and above have generally been employed locally or over large areas of the body. Actually, when irradiation is given as a single total-body dosage, the quantity necessary to kill 50 per cent of the animals in thirty days or less is relatively small: 175 to 250 r for the guinea pig, 325 r for the dog, 350 r for the goat, 530 r for mice, 600 r for rats, and 800 r for rabbits.^{1,2} Where the LD₅₀ for man lies is questionable, but it is probably somewhere between those for the goat and the mouse.³

Since Hiroshima, various writers⁴⁻⁷ have reported the effects of very high instantaneous dosages of radiation. The fact that the victims of the atomic bombing showed a more complicated picture than the radiation syndrome alone is due not only to the blast effects but also to thermal effects that produced severe, superficial flash burns in a large proportion of the affected population. The ultraviolet light given off at the moment of detonation may also have been a factor.⁸ In other respects the persons exposed to radiation from the atomic bomb appear to have shown a clinical picture extraordinarily similar to that which has been seen in laboratory animals.

In the 1920's the work of Warren and Whipple⁹ and of Ivy et al.¹⁰ contributed much to knowledge of the gastrointestinal changes following radiation. Their work indicated that these changes may be responsible for the conditions leading to early death as well as changes of the blood-forming organs. Much of the literature on the effects of radiation upon the stomach and the intestines has been reviewed by Desjardins.¹¹ During this period studies on a variety of physiologic systems were presented by Swann.¹² Thorough blood studies were made on animals by Levin¹³ and on man by Lapatsanis.¹⁴

In the next decade the work of many investigators in the field of radiation centered on the measurement and standardization of dosage, on the question of "tolerance" and on the treatment of radiation sickness in man during and after x-ray therapy. Radiation sickness was compared with all types of shock and was treated in like manner. Much of the work was qualitative and not conclusive. Reviews by Pohle,¹⁵ by Steinberg¹⁶ and by Medinger and Craver¹⁷ are helpful in their coverage of the literature, but are somewhat discouraging so far

as the solution of the problem is concerned. For radiation therapy, they suggest dividing the doses or giving continuous radiation for a long time at a very low rate (0.8 to 0.9 r per hour) to prevent the occurrence of the initial phase of radiation sickness. It appears that of the drugs studied, sodium chloride, benzedrine (amphetamine), benadryl and epinephrine¹⁸⁻²⁰ are of some therapeutic value, whereas liver extract, components of the vitamin B complex and vitamin C, and pentose nucleotides are not clearly restorative. Vitamin C, pentose nucleotides and nicotinamide will lengthen the survival time for mice when they are given for several days prior to exposure to x-rays. They will have little or no effect on survival time when given after irradiation.⁶ Estrogenic hormones also appear to exert a protective effect when given several days before irradiation.²¹ Steinberg¹⁶ and others believe that further investigations should be made on the adrenal cortex and its possible alterations to throw light upon the development of more adequate therapeutic measures. Recently, Ellinger²² has attempted to establish a pharmacologic basis for use of substances in the treatment of radiation damage. He has found that the mortality in mice can be reduced by daily doses of desoxycorticosterone and that the fat index (accumulation of sudanophil fat) in mice can be reduced by daily doses of components of the vitamin B complex and vitamin C. The effectiveness of adrenocortical material has not been verified universally.²¹

Early in the 1940's Warren and his co-workers²³ presented a thorough review of the pathology associated with radiation damage of normal tissues. Later, Warren briefly reviewed some specific biologic changes following radiation. It is the purpose of this paper to summarize the theoretical aspects of the biologic action of ionizing rays upon the organism and to outline the clinical manifestations of the radiation syndrome. The references selected for the following discussion represent both a review of the literature and experimental data gathered during the past five years.

THEORETICAL ASPECTS

Crowther,²⁵ in an analysis of studies of other investigators using simple systems such as single cells and unicellular organisms, proposes that the biologic action of radiation is specific upon the nucleus, in that this structure in the resting stage is twenty-five times as sensitive as the cytoplasm of the cell. Two contrasting theories are proposed. The one that he calls the "poison" theory postulates

*From the Argonne National Laboratory.

†Assistant professor of physiology, University of Illinois College of Medicine.

‡Director, Biology Division, Argonne National Laboratory, associate professor of medicine, University of Chicago, the School of Medicine and Institute of Radiology and Biophysics.

that, by means of photochemical action on the substance of the nucleus, a certain amount of some unspecified poisonous material accumulates and diffuses to the outlying structures, which then manifest the changes observed. The second or "target" theory assumes the occurrence of a change wherever a pair of ions is produced within the sensitive structure and enables calculation of this "sensitive volume." Since genes are hit so readily, Crowther believes that the strong genetic effect is consistent with the discontinuous distribution of the x-ray energy being absorbed. He favors the second theory and is supported in his contention by Reboul²⁶ in his mathematical presentation of the biologic effects of radiation. The target theory is discussed in detail by Lea²⁷ as a likely explanation for gene mutations or chromosome breakage following the passage of an ionizing particle through such structures.

Zirkle²⁸ points out that the variations in relative biologic effectiveness of different types of radiation can be explained by differences in specific ionization of these rays in the tissue. To determine the specific ionization, the average ionization per unit length of alpha or beta tracks in the tissue must be calculated, the unit of expression being the number of ion pairs produced per centimeter of the ionizing track in tissue. This increases progressively from fast beta rays to gamma rays, and then to hard and soft x-rays, fast neutrons and alpha rays — that is, the alpha rays have the greatest specific ionization. By the term relative biologic effectiveness, Zirkle implies the use of some definite criteria for determining the effectiveness, such as gene mutations, inhibition of cell division and threshold erythema.

When comparisons of two or more types of ionizing radiations are made upon simple systems, viruses, bacteria, drosophila, chick fibroblasts and so forth, Zirkle finds that the biologic effectiveness decreases as the specific ionization increases. For more complicated systems, like the higher phyla of plants (seedlings of flowers and vegetables) and of animals (mouse, rabbit, pig and man), biologic effectiveness increases, in general, as the specific ionization increases.

Another hypothesis is that of Failla,²⁹ whose thesis is illustrated by the experimental work of Sugiura^{30, 31}. The latter was interested in the mechanism of the radiosensitivity of mouse sarcoma 180 cells and the part played by the host tissue in their "takes," since it has been generally assumed that the lethal dosage of x-rays for tumors growing in animals is much smaller than the dosage required to kill the same tumors *in vitro*. He found that there is a critical period for the host cells during the first two to forty-eight hours after radiation, at which time there is disorganization of these cells and, parallel with this, a decrease in the number of "takes" of tumor transplants. At six or seven days after radiation, however, the "takes" are 100 per

cent successful. Further experimentation indicated a relation between these differences and hydration phenomena — that is, the ions produced by the radiation give rise to chemical changes in the constituents of the host cells with an alteration in their normal state and subsequent increase in their osmotic pressure. Ionizing radiation, therefore, initiates the swelling of cells. The swelling coupled with other changes caused by the radiation leads to cell death. The relation of chemical changes produced by radiation to the above phenomena requires much further explanation.

That chemical changes occur in aqueous systems as a result of ionizing radiation is now well understood.³² The production of hydrogen peroxide and other oxidants in irradiated water is used by Barron³³ in explanation of the specific radiation sensitivity of certain enzymes (those having sulfhydryl groups) in contrast to the more radio-resistant enzymes, which at the same time are less sensitive to oxidative inactivation. Fricke's³⁴ work on the reduction of oxygen to hydrogen peroxide by irradiation of its aqueous solution was the introduction to this concept. The oxidation theory of chemical alteration is supported by workers whose investigations show that there is an increased resistance to the action of x-rays when the blood flow through an area being irradiated is reduced,³⁵ or when animals are partially dehydrated before exposure to radiation.²

In his recent book, Lea²⁷ summarizes all the possible modes of biologic action of radiations. His main thesis is that the biologic effects are due to chemical changes induced by radiation. The greater part of these changes is attributed to the direct action of radiation with production of ionization in particular molecules and the indirect action of ionized water inside and outside the cells. No doubt other molecular effects of radiation are concerned in radiation effects, but the changes in water are best understood and, because of the abundance of water in living matter, may be the most important.

THE RADIATION SYNDROME

The clinical sequence of the radiation syndrome is dependent upon several factors. Obviously, it can be clearly defined only through constant observation of the same animal. It is dependent upon whether the total dosage is given homogeneously to the whole body or whether it is confined to certain parts of the body. Localization may be accomplished by intense homogeneous radiation of part of the body or by exposure to soft radiation (alpha or beta rays) that may be directed toward external surfaces of the body or through deposition of radioactive isotopes having the tendency to localize in certain tissues or cells. Thus, partial body radiation may involve either a segment of the body or a particular group of tissues.

Radiation may be given by single, intermittent or continuous treatment, and the dosage rate may be varied. These factors will influence the syndrome considerably.¹⁶⁻¹⁷

Despite the complexity of the problem as indicated above, it is found that the general features of the clinical course are similar whether ionization in the tissue is produced by penetrating external radiation²⁰⁻²⁶⁻²⁸ or by alpha or beta emitters from internally deposited radioactive materials.²⁻²⁹ Slight variations in the clinical course are indicated by mortality waves and by coincidental clinical observations. It is interesting to note the correlation of the underlying changes occurring on a cellular level with such diverse forms of damage as beta-ray exposure to skin.⁴⁰ These separate and distinct time periods for gross pathophysiologic changes in skin were originally defined by Miescher⁴¹ as occurring on or at the end of the first day, the first week and the first month after irradiation. Telangiectasis occurs at about one year. The mechanisms involved in the production of these three erythemas and of the telangiectasis have been elaborated on by Pohle,⁴² Borak⁴³ and others.

If single supralethal dosages of total-body radiation are given to guinea pigs and mice, they will die under the beam with generalized cellular destruction.⁴⁴⁻⁴⁵ Dogs and rats will die in four to six days with severe dehydration.⁹⁻⁴⁶

At single total-body dosages equivalent to killing within thirty days of 50 per cent of the animals (325 r for dogs), the manifestations are somewhat different from those described above and are spaced over a sufficiently long period to allow for detailed physiologic studies. At such dosages, the gross clinical changes may be classified under four periods in the different species: initial shock or radiation sickness, beginning after a latent phase of one hour following the radiation and lasting sometimes as long as twenty-four hours, acute period lasting from nine to twenty-one days, subacute period lasting from thirty to two hundred days, and chronic period, from two hundred days on. Careful study of the syndrome will indicate additional phases within the above. Manifestations differ in various species, but the general pattern is seen in all.

Initial Shock (Radiation Sickness)

After an LD₅₀ of external radiation, there occurs a latent period of one to two hours in the different species, during which no significant physiologic changes are observed. The dog, rat, mouse, guinea pig, goat and man show signs of radiation sickness during the first six hours. This condition is characterized by prostration, diarrhea, urination, lacrimation and decreased food and water consumption. Some rabbits as well as chickens will die at three to forty-eight hours. In addition, rabbits show granulocytosis during the first twenty-four hours and a marked fall in blood pressure, approxi-

mately 50 to 60 per cent below the control levels one or two hours after irradiation. The change in pressure is due in part to autonomic factors as shown by partial protection with atropine or by vagotomy and in part to circulating factors as shown by transfusion experiments. Control studies on normal recipients from which half the blood volume had been removed and gradually replaced with the same quantity of blood from normal donors showed a 5-mm change in blood pressure, whereas normal recipients transfused in a similar manner with blood from irradiated donors showed a 26.5-mm drop in pressure. These circulatory changes are accompanied by leakage of plasma and its constituents from cutaneous vessels, observed as diffusion of the blue dye, T-1824, and of fluorescein.²⁰⁻⁴⁷

In man and in the dog, nausea, vomiting and anorexia occur during this early period, but there appears to be no significant change in blood pressure. For the most part, changes in blood chemistry in all species examined are slight.

The extent to which early treatment of radiation sickness alleviates or delays the clinical symptoms that occur at nine to twenty-one days (acute period) has not yet been determined.

Acute Period

This is the period when most of the animals given a thirty-day LD₅₀ of external radiation die. Generally, animals show recovery from the initial lethargic state a few hours after irradiation and remain in apparently good clinical condition until the seventh or eighth day. The depression that follows may be either gradual or abrupt and may occur at any time in the next few days. Before clinically visible changes appear, however, there are alterations in many physiologic systems. The most sensitive systems—that is, those showing the earliest changes with the lowest dosages of radiation—are the blood-forming organs, the gastrointestinal tract and the gonads. The absolute lymphocyte count declines abruptly, whereas the count of granulocytes declines more gradually (after the initial granulocytosis in rabbits). Diminution in number of circulating lymphocytes is the most sensitive evidence of exposure yet found. Evidence of the changes in other systems is manifested on the third or fourth day by increased sedimentation rate of the blood cells and prolonged clotting time. On the sixth to the tenth day, there is an increased plasma clearance of phenol red (with return to normal about the twelfth to the fourteenth day), an increase in the plasma volume as the red-cell volume decreases, rise in blood sugar, later followed by a fall, increase in plasma histamine, heparin, cholesterol and acetone bodies, diminution of plasma nonprotein nitrogen, urea nitrogen, "polypeptide nitrogen" and total proteins followed by a late increase, decrease in fecal and urinary coproporphyrins, elevated urobilinogen and bilirubin, lowering

of gastric acidity, reduced absorption of glucose by the intestine and delayed emptying of the intestine, and ulcers begin to appear in mouths of dogs.¹ The relation of these numerous findings to the underlying physiologic and structural changes and to compensatory processes is not in all cases clear.

The late (or terminal) changes occur precipitously three or four days before death, and some of them may appear briefly in survivors before a gradual recovery sets in. These include scattered petechiae and diffuse hemorrhages in the skin, a marked rise in heart rate, a gradual fall in blood pressure, an increase in body temperature and, in some animals, edema of the neck and mediastinal regions. The cardiovascular damage has been observed most frequently in the dog. Changes in the heart are indicated by the change in the electrocardiogram, which shows a slight increase in the PR interval, a low take-off and an inverted T wave in Leads 1 and 2. This has been most obvious in animals that, on autopsy, showed extensive hemorrhages in the cardiac muscle. Changes in the peripheral circulation are apparent in many ways: there is difficulty in drawing blood from small vessels, clumping of red cells with loss of plasma from vessels can be observed microscopically, and slight trauma to skin results in ecchymosis or edema. On autopsy, widespread hemorrhages and petechiae are found throughout all the tissues, including the central nervous system and the kidneys.

A highly significant factor in the bleeding tendency has been described by Allen and Jacobson,⁴⁸ who observed that a greatly increased heparin concentration ran parallel to the prolonged clotting

by direct and indirect metabolic measurements. At this stage the picture is typical of a general toxic reaction. Toxins may be expected in the presence of bacterial infections occurring with the extreme leukopenia and may also come from the products of tissue breakdown or of extravasated blood.

It may be of interest to mention threshold dosages of total-body x-ray that will just produce certain of the physiologic effects discussed above. These are approximately as shown in Table 1, according to Prosser.⁴⁹

Subacute Period

Animals surviving a single LD₅₀ of radiation for thirty days or longer fall into this category. Dogs receiving daily x-ray dosages of 25 r or below or low dosages of the internal emitters, plutonium or strontium⁵⁰ (radium in man⁵¹) will die between thirty and two hundred days.

The characteristic changes during this period are severe anemia, emaciation, loss of hair and pigmentation of the skin, terminally, ulcers are found in the duodenum and jejunum of dogs. The animals that receive the internal emitters or daily dosages of x-rays do not show the early shock-like symptoms, but they may show from two to four depression waves between the original injection, or the first exposure to radiation, and death. These waves are manifested by reduction in the red-cell count, by general lethargy and by decreased food and water intake. Hematologic changes develop very gradually and show fluctuations with the depression waves, as do the changes in other physiologic systems. Several days prior to death there occurs an increase in heart rate and an increase in body temperature similar to the changes observed in dogs in the terminal phase of the acute period.

Chronic Period

In animals receiving still lower dosages of x, alpha or gamma rays, decreased life-span, graying of dark-haired animals and the development of tumors constitute the chronic changes after irradiation. In mice, lymphomas, lymphatic leukemia and lung tumors are readily induced by total-body irradiation. Many species develop tumors of certain tissues after local irradiation by alpha-emitting or beta-emitting substances. Especially noteworthy are the multiple skin tumors resulting from external beta irradiation and bone tumors following absorption of radium, strontium⁵⁰, plutonium and other radioactive isotopes.⁵² In addition to high incidences of malignant tumors in areas receiving relatively heavy dosages of radiation, the normal tumor incidence in various species of animals is increased (or tumor development is accelerated) after either a single high dose or repeated or continuous exposure at a low level.⁵³ The degree of enhancement of the normal tumor incidence ap-

TABLE 1 *Effects of Threshold Dosages of Total-Body X-Rays*

DOSEAGE r	EFFECT
25	Lymphopenia (dogs, rabbits, rats)
50	Granulocytopenia (dogs)
	Reduction in platelet count (dogs)
	Reduction in blood pressure (rabbits)
	Elevation of basal metabolism (rats) ⁴⁸
	Inhibition of intestinal absorption of glucose (rats)
100	Granulocytopenia (rabbits)
	Elevation of sedimentation rate (dogs)
200	Anemia (dogs, rabbits)
	Absence of reticulocytes (dogs)
	Prolongation of clotting time (dogs)

time. The progressive hemorrhages were stopped and the clotting time was returned to normal by the administration of toluidine blue or protamine, both of which inactivate the heparin.

In this later period there is also evidence of liver dysfunction as shown by the changes in bile-pigment metabolism. Plasma nonprotein nitrogen and urea nitrogen show a marked rise, associated with the increase in body temperature, with the decreased kidney function and with an increase in total tissue breakdown. The latter has been determined

pears proportional to the amount of absorbed radiation, although its occurrence at low radiation levels (below 0.5 to 1 r daily) has not been clearly demonstrated, owing to the experimental difficulty of showing the low incidences that might be expected. Whether a threshold exists for carcinogenesis or effects on longevity is therefore unknown.

A noteworthy feature of the carcinogenic effect of radiations is the duration of the latent period, which, even under the most intense local stimulation, is rarely less than six months. It appears that radiation carcinogenesis is little dependent on species, in contrast to chemical carcinogenesis, in which the metabolism of the carcinogen may be a factor.

THERAPY

As mentioned above, adequate methods of treatment for radiation damage are lacking. The main objectives in the management of patients are to maintain adequate fluid and acid-base balance, to control infectious processes, to combat the hemorrhagic phenomena and to correct anemia and blood-volume changes.

Investigations have been most successful along the lines of increasing survival time, and of reducing the bleeding tendency. In the latter case, protamine and toluidine blue offer some promise. Penicillin and other antibiotics appear indicated for the control of infection. It appears, in general, that other forms of therapy are as yet not established (for example, adrenocortical material and rutin), must be given prior to irradiation or (as in several adjuvants mentioned above) apply only to the initial reaction as seen during the day following x-ray therapy.

DISCUSSION

No single clinical reaction is peculiarly specific for radiation damage. A similar preterminal course with leukopenia and high sensitivity of dividing cells is found with such agents as the nitrogen mustards⁵⁴ and urethane⁵⁵, the acute terminal course with fever and petechiae is characteristic of acute infections and of many diseases. There are striking similarities to anaphylactic shock and to the nonspecific (alarm) reactions to a variety of diverse toxic agents given in sublethal amounts,⁵⁶ and to the agranulocytic states accompanying drug sensitization. Many of the delayed effects of radiation can be duplicated by various toxic chemicals, such as anemia and leukemia in benzol poisoning, or tumor induction by hydrocarbons or ultraviolet light.

The relation between the initial physical and chemical effects of radiation remains largely to be worked out. It seems reasonable to believe that the primary effects all occur during radiation and for a brief period thereafter, since the lifetime of the chemical products of ionization in water is short.

With the exception of the initial reaction, the acute phenomenon of the radiation syndrome follows a latent period during which cell damage and atrophy of the more sensitive tissues occur. Since these tissues (blood-forming organs, intestine and gonads) are proliferative, it is tempting to suggest that damage to chromosomes (which is known to lead to cell death at a subsequent cell division) accounts for the damage. The picture may well be more complicated than this. In any case, many of the features of the radiation syndrome can be accounted for by destruction of the sensitive cell types. There is some evidence that agranulocytosis, rather than lymphopenia, correlates with the lethal dose among the various species of animals.⁵⁷ Many of the early changes in the syndrome, such as increased renal blood flow and elevated sedimentation rate, suggest the presence of circulating toxins, whereas many of the late changes appear to be associated with hemorrhage due to the release of heparinoid material into the blood, probably from injured cells.

The nature of toxic materials that may be involved in the shock-like state is far from clear. It will be recalled that in certain forms of traumatic shock in which such toxins are present, bacteria have been clearly shown to be responsible.⁵⁸

The events leading to the chronic phenomena are still less well understood. The fact that radiation induces genetic changes has suggested that carcinogenesis is due to similar changes in somatic cells resulting in mutant cells that have the characteristics of neoplasia, but various other explanations may be entertained. The shortening of life span has been loosely termed "increased aging," but evidence for this involves all too meager understanding of the aging process, and will await study of the various pathologic states that lead to shortening of life, among which tumor formation is probably only one.

SUMMARY

The radiation syndrome, produced by a single total-body thirty-day LD₅₀ of external radiation or of internal emitters of alpha or gamma rays, is characterized by three separate and distinct periods: the initial shock reaction or radiation sickness, the acute and the subacute. The initial shock may last from three to forty-eight hours. Occasionally rabbits and chickens die during the initial period. Other animals, such as dogs, rats, guinea pigs and goats, do not die, but show prostration, diarrhea, urination, lacrimation and decreased food and water consumption. In addition, man and the dog often vomit.

The acute period lasts from nine to twenty-one days, during which most of the animals die. The preterminal changes and the sharp delineation of the terminal signs are discussed in detail. Some of the radiation effects are directly due to destruc-

tion of certain tissue elements. Many others are indirect and may be attributed to infections, toxic agents, hypoxia and other secondary factors.

Animals surviving thirty days or more fall into the subacute category, where fluctuations of recovery and depression of the leukocytes do not permit the use of the white-cell count for determining the progressive changes of radiation damage. A severe anemia, emaciation and graying of dark-haired animals are the usual signs of the radiation syndrome in this phase. The chronic phase is characterized by shortening of life and sporadic increase in tumors.

Nearly every physiologic system shows damage after total-body irradiation. The effects are non-specific. Many of the same manifestations are shown in the animal organism by the administration of the nitrogen mustards or urethane, in anaphylactic shock, agranulocytosis, the "alarm reaction" of Selye and benzol poisoning. Damage to the radio-sensitive cells will explain a great part of the picture, but much further understanding of the syndrome is required in the interest of prevention and therapy.

VARICOCELE*

Symptomatology and Surgical Concepts

RAYMOND O. OLSON, M.D.,† AND ERIC P. STONE, M.D.‡

FRAMINGHAM, MASSACHUSETTS

IN RECENT years the treatment of symptomatic varicocele has become a subject of renewed endeavor. The interest was stimulated by the degree of disability this condition caused among members of the armed forces during World War II. Low scrotal-vein ligation, the operation in vogue prior to 1942, had fallen into disrepute because of persistence of symptoms and the frequency of surgical complications. For these reasons a new operative technic, which had been popularized in Latin America, was tried by Army surgeons.^{1,2} Reported series of cases¹⁻⁴ in which this operation was performed and evaluated showed the procedure to be surprisingly effective.

In civilian life the discomfort and disability associated with varicocele continue to interfere with the efficiency of thousands of workers. In an attempt to relieve those who sought relief at this hospital, this newer technic of high ligation of the internal spermatic vein was adopted. This paper presents a critique of the varicocele syndrome and the results obtained in 25 cases.

PATHOLOGICAL PHYSIOLOGY

The venous drainage of the scrotal contents can be compared to that of the extremities. Both deep and superficial systems are present. This concept of dual drainage was first expounded by Ivanisovich⁵ in 1918, and is shown diagrammatically in Figure 1. His studies demonstrated a primary or deep system consisting of the internal spermatic vein, the ductus deferens vein, and the external spermatic vein. The latter two anastomose with the internal spermatic veins at the level of the external inguinal ring. The superficial or secondary drainage system was found to consist of the superficial and deep inferior epigastric veins, the superficial internal circumflex and the scrotal tributaries of the superficial and deep external and internal pudendal veins. These veins communicate freely with each other and with the primary system through the cremasteric branches of the external spermatic vein at the level of the external inguinal ring. The numerous convoluted veins of the pampiniform plexus coalesce as they course upward from the testicle until they become

one large vein in the upper portion of the inguinal canal. This, the internal spermatic vein, then traverses the retroperitoneal space to empty on the left side into the renal vein at a 90° angle and, on the right, to empty obliquely into the vena cava. Study of the lengthy internal spermatic veins⁶ has

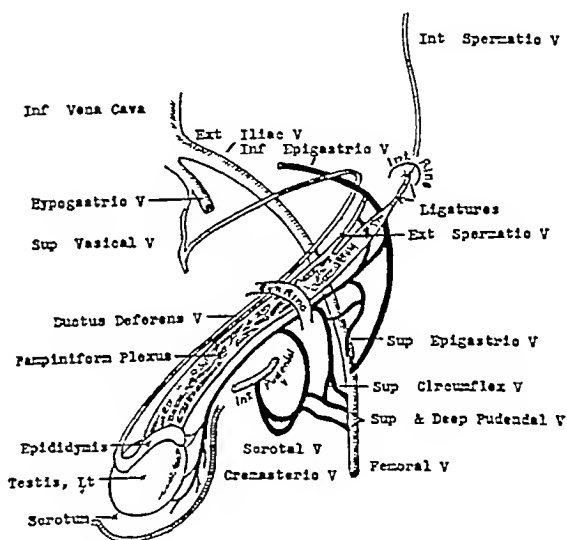

FIGURE 1. Diagram of the Venous Drainage of the Scrotal Contents (Adapted from Jarrett and Clark¹)

Primary system — internal spermatic, ductus deferens and external spermatic veins (in white). Secondary system — superficial epigastric, superficial internal circumflex and cremasteric veins, and through scrotal tributaries the superficial and deep pudendal and the internal pudendal veins (in black).

shown them to be devoid of valves except at their point of emptying. Congenital and degenerative changes lead to valvular deficiency. It is this combination of a long vein and valvular incompetence that constitutes the etiology of varicocele. This results in a retrograde flow down the internal spermatic vein, causing overdistention of the pampiniform plexus in the upright position. The reverse venous flow can readily be shown at operation. If a distal segment of the internal spermatic vein is occluded and the vein stripped proximally between the fingers, immediate refilling of the stripped portion is noted on release of the proximal finger occlusion. The marked preponderance of left-sided varicocele can readily be appreciated as being due

to the mechanical disadvantage in preventing backflow offered by the right-angled junction of the spermatic and renal veins as contrasted to the oblique entrance of the right spermatic vein into the vena cava. Further study of the venous anatomy makes obvious the fact that the point of anastomosis of the superficial and deep systems, at the external ring, is of crucial importance. It was disregard of this anatomic feature that caused the failure of the low ligation procedure. Venous interruption at the external ring leads to disruption of both systems of drainage, with a poorly draining scrotum. Utilization of the more recent conception of venous drainage led to the ligation of the internal spermatic vein, which is physiologic and therefore successful.

CLINICAL PICTURE

It has been estimated that 10 per cent of males have varicoceles. Of this group 98 per cent are left-sided and approximately a third are actively symptomatic. The age group most frequently affected ranges from fifteen to thirty years. Consideration of the altered venous physiology involved allows one to predict the symptoms of varicocele. The patient notes gradually increasing scrotal enlargement and pendulousness during the course of a day of erect posture. This process is hastened by exertion. A sense of heaviness of the scrotum is followed by dull, dragging, aching, constant, pulling pain felt in both the scrotum and groin. The pain disappears slowly with rest in the supine position. In short, the pain is of the traction type caused by a heavy scrotum pulling on the spermatic cord. Other symptoms are to be viewed with the suspicion that they are due to other pathologic entities. Sharp or stabbing pain should cause one to suspect the concomitant presence of orchalgia, epididymitis or hernia. Occasionally, local venous thrombosis secondary to trauma may give sharp localized pain in the scrotum for a short time. Some explanation must be offered for small symptomatic varicoceles in view of many large ones that do not cause discomfort. It is our opinion that all patients with varicocele can be found to have symptoms, if closely questioned. The pain threshold is so variable that some patients are bothered more than others. Such variability of response is seen in many diseases. Although an overlay of psychiatric disturbance undoubtedly adds to the patient's degree of response to his disease, we do not believe that it is necessary to ascribe such an implication to every patient with varicocele.

Physical examination should do much to clarify the picture. The "bag of worms," scrotal pendulousness and asymmetry and enlarged, soft spermatic cord are familiar to all. Painful testis or epididymis does not belong in the varicocele syndrome, and should lead to suspicion of other etiologic factors. Javert and Clark¹ have shown the presence of co-

existent hernia in 25 per cent of their cases. The finding of hernia is much facilitated by examination in both the erect and the supine position. This allows more accurate evaluation of a possible hernial sac by fostering collapse of the distended vein while the patient is supine. In most cases, then, it should be possible to explain symptoms, whether severe or merely annoying, as due to varicocele, a coexistent varicocele and hernia or one of the ill defined syndromes of orchalgia or chronic epididymitis.

TREATMENT AND OPERATIVE TECHNIC

Although Ivanissevich⁵ recommended retroperitoneal ligation of the internal spermatic vein as early as 1918 this method was not appreciated in the United States until Bernardi, in 1942,⁴ reported his superior end-results from ligation at the internal inguinal ring. Present-day textbooks have as yet not assimilated the new literature and still offer a pessimistic outlook. Considerable emphasis is given to ascribing symptoms as due to overcongestion from unfulfilled sexual desires, scrotal fixation in psychoneurosis and other ill defined causative factors. Reassurance and the wearing of a suspensory are suggested as therapy. Surgery is considered unwise. The complications of the low ligation procedure — hemorrhage, painful thrombosis, testicular atrophy, epididymitis, hydrocele and recurrence — are admitted to be very frequent. The reason for this is now obvious. The procedure obstructs the venous drainage almost completely at the level where the anastomoses of the superficial and deep systems occur. It further fails to care for the gravity retrograde flow in the incompetent internal spermatic vein. The basic disorder is attacked at its source by the newer procedure, and the complications listed above are avoided. At the same time a concomitant hernia can be searched for. The region of anastomosis is spared. Adequate testicular suspension can be obtained.

The technic followed in this series varies only slightly from that described by Javert and Clark.¹ Through an oblique inguinal incision the external oblique fascia is split through the external ring to allow better exposure and a more effective herniorrhaphy. The spermatic cord is completely freed to the level of the internal ring. It is believed that this step allows for better eventual testicular suspension. The cremasteric fascia is opened longitudinally, and the internal spermatic vein isolated. Usually, one large vein, approximating a pencil in size, is found and is ligated at the internal ring, as is a secondary smaller vessel if present. In this series 15 patients had one vein, and 10 presented two veins, which in all cases were found to anastomose retroperitoneally. A 2-cm to 5-cm segment of the vein is excised, and the proximal end allowed to retract retroperitoneally. Careful search is then made for a hernial sac. If found, it is dissected free, and the sac ligated. It

is to be remembered that at this point forceful traction may pull down peritoneum and in so doing create a false sac that does not constitute a true hernia and does not need ligation.

Testicular suspension, which is next carried out, is considered very important for the final result. Three techniques are followed: the distal vein stump is pulled proximally and sutured through the cremasteric fascia to the internal oblique muscle, the cremasteric fascia is closed transversely, and a further tightening of the lax spermatic cord is obtained by suture of the conjoint tendon under the cord to the shelving inguinal ligament. This lifts the cord by the mere presence of tissue beneath it. The external oblique is then resutured above the cord. Silk-suture material is used throughout the procedure. Postoperatively, the patient wears a suspensory for two weeks. He is allowed to be am-

On physical examination the varicocele was classified as large in 10 cases, moderate in 10, and small in 5. It was considered significant that 3 of 5 patients with small varicoceles had atypical symptoms. Only 1 patient was thought preoperatively to have a hernial sac. The incidence of hernia at operation was 12 per cent, with 3 small indirect sacs found. Moderately large lipomas of the spermatic cord were removed in 4 cases, and this proved to be the lesion present in the patient thought preoperatively to have a hernia.

The results have been grouped on a symptom basis to show the effect on prognosis of close evaluation of the symptom complex. A poor result was the case in which the patient continued to have scrotal pain even though it might vary in degree or type from the presenting complaint. In the typical symptom group of 21 cases, 20 were good re-

TABLE 1 Results according to Type of Symptoms

bulatory on the first postoperative day and actually is eligible for discharge on or after the sixth postoperative day.

EVALUATION OF CASES

This series is small but does suggest certain trends in the varicocele syndrome. In 25 cases, the ages of the patients ranged from twenty to fifty-three years, and 20 were between twenty and thirty years old, which is in accord with the usually quoted figures of age frequency of symptoms. The duration of known scrotal enlargement showed a range of one to twenty years, with an average of four and two-fifths years. The duration of symptoms was much less, with a span of four months to five years and an average of two and a fifth years. Both enlargement and symptomatology showed a tendency to increase with time. Analysis of symptoms revealed that 21 of 25 patients had only the basic symptom complex of scrotal enlargement with dull, aching, dragging, scrotal and groin pain at the end of the day or after prolonged exertion. The pain was annoying as a rule, but in a few cases it was sufficiently distressing to require hours of bed rest for relief. The 4 atypical cases presented such variations as morning pain, sharp stabbing pain, localized scrotal pain, tender testes and intermittent attacks of pain. The effect of the type of symptoms on prognosis is discussed below.

Results over periods ranging from three to twenty-four months. In the case regarded as a failure, twenty months after operation the varicocele was gone, but scrotal and epididymal pain in intermittent attacks persisted. Study of the patients with atypical symptoms revealed 3 out of 4 to have poor results. All had small varicoceles. Over a twenty-month follow-up period, 2 were symptomatically unchanged, and the third had intermittent attacks of pain. The varicoceles were gone. All originally presented elements of sharp scrotal pain in addition to testicular or epididymal tenderness. Under our present criteria they would not be considered as candidates for this procedure. Table 1 shows the breakdown of cases in terms of follow-up period and type of symptom. It is to be noted that we learned early the futility of operation in the atypical cases. The large percentage of good results among the patients with typical symptoms further emphasizes the importance of early, careful evaluation. In view of the marked emphasis placed on psychogenic factors in the literature, it is interesting to note that a group of 4 patients were being or had been treated for psychoneurosis. All presented symptoms that were considered typical of varicocele. The surgical results were excellent in 4 gratified patients. We were encouraged by this experience to believe that, in spite of known psychoneurosis, typical varicocele

syndrome with a physiologic basis can occur and can be helped by appropriate surgical operation

The cosmetic results of high ligation have been completely satisfactory. All 25 cases showed a progressive shrinkage of the "bag of worms" from the day of operation to the completion of the process,

FIGURE 2 Preoperative Appearance, Showing the Engorged Pampiniform Plexus

usually within a month. Testicular suspension was very gratifying in that scrotal pendulousness was corrected as much as 4 or 5 cm. in some cases. All patients had scrotums that looked well within normal limits when the process of vein shrinkage, skin retraction and testicular suspension had reached its end point. Figure 2 and 3 show a typically good result.

This type of operative procedure was singularly free of complications. In 3 cases there were localized areas of slightly painful vein thrombosis, which disappeared within a month. No wound sepsis was present, and hematoma formation, testicular atrophy, hydrocele formation, epididymitis and scrotal induration were not noted.

SUMMARY AND CONCLUSIONS

The concept of dual drainage of the scrotal contents is reviewed.

A definite physiologic basis and type of symptom is postulated for the varicocele syndrome. It is stressed that symptoms not conforming to this pattern should suggest other disease as the source of the complaints.

The technic and rationale of operation are explained. A series of 25 cases showing 84 per cent good results is analyzed.

The opinion is stated and in part substantiated that the role of psychoneurosis in this condition has been overemphasized in the past.

The possible coexistence of hernia and varicocele is mentioned, and the facility with which both defects can be repaired in one operation explained.

The pessimistic attitude found in the literature regarding the results of surgery in the treatment of this condition does not seem warranted. On the basis of these results it appears fair to prognosticate that a patient with typical varicocele symptoms can be relieved of his scrotal distress and dis-

FIGURE 3 Postoperative Appearance
Note the lack of dilated veins

tortion by the high ligation technic with very little risk of operative complication. The operation seems contraindicated in atypical cases in which the varicocele is but an incidental part of another pathologic entity causing symptoms of its own.

EOSINOPHILIA DURING INTENSIVE GOLD THERAPY*

EDWARD H. REISNER, JR., M.D.,† LYON LAPIN, M.D.,‡ AND OTTO STEINBROCKER, M.D.§

NEW YORK CITY

IN THE course of a study of intensive chryso-therapy with aurothioglycanilide (lauron) already reported,¹ serial hematologic observations revealed a constant and often striking increase in the eosinophil count, which is the subject of this report.

MATERIAL AND METHODS

Eighteen patients were treated with bi-weekly injections of gold. Sixteen received aurothioglycanilide (lauron), 1 received solganol-B oleosum, and 1 received myochrysine. The total dosage given ranged from 1 gm. to 10 gm. in a period of twenty-four to fifty-six days. Prior to every injection of gold, each patient received a complete

the amount of gold received or the duration of therapy (Table 1). The maximum eosinophil level occurred from ten days to fifty-six days after the start of therapy. In the patient who showed a count of 43 per cent during treatment an exfoliative dermatitis subsequently developed, but no other manifestations of toxicity occurred in the group. Although

TABLE 2 *Eosinophil Responses and Toxicity in 33 Patients Treated with Gold on an Outpatient Basis*

GOLD PREPARATION	NO. OF PATIENTS TREATED	PATIENTS WITH EOSINOPHIL COUNTS OF MORE THAN 5 PER CENT	NO. OF TOXIC REACTIONS

Gold sodium thiosulfate	15	3	2
Other types	3	0	2
	33	12	8

there was no direct correlation between the amount of drug received and the degree or time of appearance of eosinophilia, the mean eosinophil increase for 8 patients receiving 10 gm. of gold salt was 14.9 per cent, compared with 6.2 per cent for 10 patients who received 3 gm. or less.

As a result of this experience the records of 33 consecutive patients treated with gold salts in the arthritis clinic as outpatients were reviewed, with reference to eosinophilia and toxic reactions. The results are shown in Table 2. Of 15 patients treated with aurothioglycanilide, 9 showed eosinophil counts in excess of 5 per cent, compared with 3 of 18 given other gold preparations. There was no significant difference in the frequency of toxic reactions in the two groups. The mean total dose of aurothioglycanilide employed was 1.99 gm., compared with 0.72 gm. of other forms of gold, chiefly gold sodium thiosulfate.

blood count, platelet count and prothrombin-time determination.

RESULTS

No toxic reactions in the blood were observed with reference to any component. A constant increase in the eosinophil count was observed in every patient, and in all but 3 cases the maximum eosinophil count was in excess of 5 per cent of all white cells—a figure chosen as the upper limit of normal. The intensity of eosinophilia was not related to

DISCUSSION

Eosinophilia as an accompaniment of chrysotherapy has long been recognized, and the subject is thoroughly reviewed by Sundelin.² Opinion is equally divided in the literature concerning whether or not eosinophilia is a contraindication to further gold therapy. Some observers regard it as a favorable prognostic sign.³ The most careful study is that of Sundelin, and his conclusions based on an analysis of 700 cases were that eosinophilia was no contraindication to further gold therapy, since it often subsided while therapy was continued. In

§Associate professor of clinical medicine, New York University Postgraduate Medical School; visiting physician, Bellevue Hospital.

patients with eosinophilia all kinds of complications of gold therapy were more prevalent, but in many cases the eosinophilia occurred after the complication and could not, therefore, be used as a warning of its imminence

Eosinophilia has been observed in the course of streptomycin therapy,⁴ liver therapy of pernicious anemia⁵ and the administration of many other therapeutic substances. It can be produced in animals by the injection of heavy metals.⁶ Some eosinophilia is a common occurrence in allergic and hyperergic states. It is generally accepted that the eosinophils play some role in the response to sensitization to foreign proteins. Recent reports suggest that this mechanism works through the endocrine system via the adrenal cortex.⁷ Steinberg⁸ has advocated serial bone-marrow studies during chrysotherapy as a guide to therapy. Since the significance of eosinophilia during gold therapy is still in question, we do not consider such a procedure warranted.

In our cases, although there was no direct relation in any case between the eosinophil level and the duration or intensity of treatment, the groups receiving larger amounts of gold showed a greater eosinophil increase. The frequency of eosinophilia was clearly higher in the patients receiving aurothioglycanilide, which again was probably due to the larger amounts of gold that were given with this preparation. In this short series of patients there was no greater frequency of toxicity in the aurothioglycanilide group despite the greater eosino-

philia. Our observations agree with the conclusions of Sundelin that although marked eosinophilia should excite caution it is not a contraindication to further treatment that is otherwise indicated.

SUMMARY

In 18 patients receiving intensive chrysotherapy, eosinophil counts from 5 to 45 per cent were observed in all cases.

This was not related to individual dosage or duration of treatment, but, as a general rule, the patients receiving more gold showed a higher mean eosinophil increase.

There was no direct relation between eosinophilia and toxic reactions, although the 1 case of exfoliative dermatitis encountered developed in the patient with the maximum increase of eosinophils.

MEDICAL PROGRESS

NEUROPHYSIOLOGY, 1942 - 1948*

JOHN F. FULTON, M.D.

NEW HAVEN, CONNECTICUT

THE war years gave valuable impetus to studies on the nervous system, but few of the many important advances during these years stemmed from wartime research per se. The subject of neurophysiology has come to have such vast ramifications that it would be imprudent to attempt to cover the entire field in a brief review. I propose, therefore, to restrict this summary to the newer disclosures in the motor sphere. Developments in sensory physiology must be relegated to another occasion and a better informed reviewer, and likewise the many studies on the special senses, particularly the notable work on night vision carried out in Sweden, England and the United States. In planning the present summary I have followed in general the subject sequence of my monograph, *Physiology of the Nervous System*,¹ but I have included nothing described therein, except on occasion for historical setting.

MOTOR UNITS

In 1929 Denny-Brown² observed that when a single unit of a muscle, such as the cat's soleus, was activated, the muscle as a whole might develop as much as 10 gm of tension. In their classic paper on the motor unit published in 1930, Eccles and Sherrington³ obtained similar average values — that is, after maximal stimulation of the muscle and recording of the total tension developed, the motor fibers supplying the muscle were enumerated, by division of the number of fibers into the total tension, average figures were obtained of 5 to 10 gm for soleus, and as much as 30 gm for the medial head of the gastrocnemius. Clark⁴ counted the muscle fibers in the preparations that Eccles and Sherrington had used and found that each nerve fiber innervates from 100 to 150 muscle fibers, thus accounting for the relatively large tension capable of being developed by single ventral-horn cells. Eccles and Sherrington were aware of the fact that there were large differences in nerve-fiber diameters, and they assumed that the large fibers innervated large units and that the smaller ones probably innervated lesser units. They incidentally proved conclusively that the small fibers (some only 2 or 3 microns) come from the ventral horn and not from the sympathetic chain.

Recently, Kuffler and his associates,^{5,6} working on frogs, have suggested that the small-nerve motor system of the skeletal musculature belongs to a special reflex group and that it can be activated independently of the large-fiber system. According to Kuffler et al., the large-fiber system produces the quick-twitch response with a single volley, whereas the small-fiber system causes appreciable muscle shortening only on repetitive excitation. The shortening is said to be "local" although considerable tension can be generated. The authors believe that a given muscle fiber may be innervated by both the small and the large fibers, but they add that this anatomic detail has not yet been conclusively demonstrated. They believe that, depending upon which fiber system stimulates the muscle, the muscle itself responds either with a local slow shortening or by a rapid shortening from a propagated disturbance. They draw the general conclusion that the large-fiber system is designed for rapid phasic movements, and the small-fiber for prolonged states of tension such as would be required for the maintenance of posture. Their hypothesis thus implies that a simple muscle fiber could be made to execute a sustained postural contraction at one time or a quick, all-or-none, twitch-like contraction at another.

Kuffler's observations as such are of considerable interest, particularly on account of his ingenuity in separating, both by reflex means and by compression of the nerve trunk, the large-fiber impulses from those of smaller diameter. The interpretations placed on the observations stand as a reversion to the long-abandoned dualistic theory of muscle function — that is, there are two sets of peripheral mechanisms, one for the execution of phasic movement and the other for postural tone, in the same muscle fiber. To be sure, many muscles have rapid white fibers admixed with slower-acting red fibers, and Denny-Brown⁷ clearly demonstrated that the slower red fibers are selectively employed for maintenance of postures, but they are activated in all-or-none fashion just as the white fibers.

An alternative explanation of Kuffler's findings suggests itself if the small-fiber system innervates fewer muscle fibers than the large-fiber system, one would anticipate that repetitive stimulation would be necessary to develop measurable tension at the tendon. This leaves unexplained Dr. Kuffler's claim

*From the Department of Physiology, Yale University School of Medicine.

†Sterling Professor of Physiology, Yale University School of Medicine.

that the action potentials developed at the end plates of the small-fiber system are not propagated. If this is borne out in future work, Kuffler and Gerard have presented the physiologic world with a conundrum that will occupy neurophysiologists for some years to come.

A more plausible explanation of the effects of small-fiber stimulation has been offered by Leksell,⁸ who has succeeded in selectively stimulating these small-fiber units (gamma fibers) in both cats and frogs. He was unable to detect any certain contractile effects that could not have been attributed to unblocked large fibers, but he found that with the muscle taut, stimulation of the gamma fibers had a definite effect on the afferent discharge from the muscle's proprioceptors.

Selective activation of the gamma fibers led to a considerable increase in afferent discharge provided the muscle was subjected to a certain amount of stretch. In slack muscles this effect did not appear. It is concluded that the gamma fibers serve as regulators of sensory activity originating in the muscle.

Sherrington, in 1894, had found that small fibers of the ventral roots innervated the muscle spindles. Until more forceful contrary evidence is presented than that offered by Kuffler et al. it seems reasonable to conclude either that the small motor fibers innervate the muscle spindles and thus regulate proprioceptive afferent discharge, as Leksell has suggested, or that they are all-or-none motor fibers innervating small skeletal-muscle units. The Kuffler-Gerard evidence that the small fibers are concerned with postural contraction except as they may influence the stretch receptors appears to me unconvincing.

Isolation of single units has also been achieved for human nerve and muscle by Kugelberg and Skoglund.⁹ Using two muscles, the first dorsal interosseus (stimulated through the ulnar nerve at the elbow) and the peroneus (stimulated through the peroneal nerve at knee level), they have been able to compare artificially evoked responses from nerve stimulation with the natural discharges of single motoneurons of the same muscle during voluntary contraction. They find, on nerve stimulation with slowly rising currents, that small spikes appear first, followed later by larger ones, which correspond to the units of higher threshold (and presumably of larger size).^{*} Precisely the same sequence was observed on volitional activation of these muscles—that is, small, low-threshold units discharged first, followed later by the larger, high-threshold units. The work of Kugelberg and Skoglund appears particularly significant since it indicates that some, at least, of the smaller units (which, one may assume, are innervated by nerve fibers of small diameter) give rise to all-or-none

contractions. This, however, does not preclude the possibility that others are concerned with proprioceptive regulation as Leksell⁸ has suggested.

THE SPINAL CORD

The human spinal cord was intensively studied during the war period owing to the large number of cases of spinal injury that came under observation in military establishments. During World War I a spinal transection was equivalent to a death sentence. A few patients survived for periods of a year or two as a result of fastidious nursing care, but the great majority succumbed to bedsores and ascending genitourinary infections within a few weeks of injury. Through the work of the late George Riddoch^{10, 11} in 1916–1917 the way was pointed for adequate care of such patients—how through the development of the bladder reflexes, the bladder itself could be kept free of infection and, through careful nursing, the skin could be kept clear and healthy. Now with the powerful adjunct of the sulfonamides, penicillin and streptomycin it has become possible to keep patients with spinal paraplegia healthy and free of infection for indefinite periods. With this therapeutic triumph has come increasing knowledge of the reflex status of spinal man.

Thanks to the work of Freeman,¹² Deaver,¹³ Munro¹⁴ and others who have studied more than a thousand cases of spinal injury during the war period, it is clearly established not only that flexor reflexes and mass withdrawal reactions return, but also that knee jerks and other strongly developed extensor reflexes may be regained and that they may be put to useful purpose in rehabilitating such patients and in making them ambulatory. During World War I it would not have been thought possible for a patient with complete spinal transection to become ambulatory and capable of attending to his own rectal and bladder functions. One of Freeman's patients, wounded in World War II, dresses himself in the morning, attends to his own toilet, swings himself on crutches into his own car and drives to work. Fiercely proud of his independence he declines assistance at any point of his daily routine. As a watchmaker he has an income of between three and four thousand dollars a year. In Dr. Freeman's series there are 30 other patients with spinal paraplegia that are similarly self-reliant and self-supporting. In the past there has been nothing more hopeless or pitiable than cases of spinal transection. Now, as the result of intelligent application of sound physiologic principles, such patients have reasonable hope for a useful life, and there are several authentic cases of women with complete spinal transection who have conceived and borne normal offspring.^{15, 16} Ambulation technics such as those described by Deaver, combined with diligent bladder care and other observances of detail in management, have enabled

^{*}Kugelberg and Skoglund⁹ are unwilling to commit themselves regarding whether there is a direct relation between spike size and unit size. Although such caution is commendable it would be contrary to all that is known of electrophysiology if there were not a direct relation.

more than half the patients with spinal injuries sustained in the war to find a place in society

Hope for promoting regeneration in the severed spinal cord still haunts the imagination of neurologists and neurosurgeons, and Freeman is of the belief that ways and means will be found to bring about voluntary control of musculature distal to a spinal transection. Sugar and Gerard¹⁷ report that they have obtained regeneration in the spinal cords of rats, but Davidoff and Ransohoff¹⁸ have been unable to confirm their results in cats. Brown and McCouch,¹⁹ similarly have failed to obtain evidence of cord regeneration in dogs and cats even when the cut ends of the cord were sealed together with prothrombin. The late Richard Meagher and Franc Ingraham, in unpublished studies, believed that they had bridged the gap in spinal pupes by planting an intercostal nerve rootlet from above the transection into the distal cut end of the spinal cord. Their histologic results were, however, unsatisfactory, and publication was on this account withheld. Freeman¹² describes a patient with transplanted spinal roots who has developed paresthesias and muscular twitchings in segments below the transection a year after operation.

THE THALAMUS

There have been few physiologic contributions to the knowledge of thalamic function since the publication of Earl Walker's²⁰ monograph, *The Primate Thalamus*, published in 1938. The projections to and from the dorsomedial nucleus of the thalamus and the rostral areas of the frontal lobes, and particularly from areas 9, 10, 11 and 12 of Brodmann and possibly from Walker's area 13 (Glees²¹), indicate that the dorsomedial nuclei are concerned with the effects induced by the operation of frontal lobotomy. Especially relevant in this connection is the fact that the operation has been used extensively for the relief of intractable pain, and it thus appears that the medial nuclei are in some way concerned with establishing the general character of pain reaction, but the precise nature of this relation remains to be worked out. After frontal lobotomy and the presumed degeneration of the dorsomedial nuclei that follows (Freeman and Watts²²), patients state that they still feel their pain but that it has ceased to bother them.²³

The large nucleus ventralis posterolateralis (VPL), which is the chief end station for the spinothalamic projections, has been studied in some detail by Chang and Ruch²⁴ in the spider monkey. Walker and others had previously shown a high degree of topographical lamination from the various spinal segments, the cervical being situated most medially and the sacral segment most laterally. The spider monkey, in addition to the usual lumbar segments, has three sacral roots and a caudal plexus usually made up of eight caudal roots that innervate the complex musculature of the prehensile tail. The

dendrites for the tail were carefully mapped by Sherrington's method of "remaining sensibility," and the degeneration resulting from dorsal root section and from section of caudal segments of the spinal cord were traced by Chang and Ruch²⁵ up the spinal cord into the dorsal column and into the thalamus. It was found that the large caudal projections to the thalamus were located in a sharply defined, comma-shaped area lying just lateral to the sacral projections (Fig. 1). Thus, in the spider monkey, one finds an even more precise topographi-

cal representation in the thalamus than in forms that lack the extra prehensile appendage

THE HYPOTHALAMUS

There have been few notable advances in knowledge of hypothalamic function since the publication in 1940 of the hypothalamus volume of the Association for Research in Nervous and Mental Disease, except for the recent disclosures concerning sham rage and for certain developments in the sphere of heat regulation and metabolism

Sham Rage

Wheatley²⁶ has found that sham rage may be induced in enduring fashion in cats through placement of bilateral Horsley-Clarke lesions in the nucleus hypothalamicus ventromedialis—that is, in the infundibular or middle region of the hypothalamus. Lesions in this region also interrupt the large tract of pallidohypothalamic (Fig. 2) fibers, as well as part of the fornix column. Wheatley's animals behaved in closely similar fashion to those of Fulton and Ingraham²⁷ after bilateral prechiasm-

lesions made by direct surgical interference. It was not clear from these studies, however, exactly what pathways or centers must be interfered with, but Wheatley's experiments have greatly reduced the possible alternatives. Kennard²⁸ has induced conspicuous sham rage in cats by radical removal of both frontal lobes, she also observed it in animals in which only the orbital surface was involved, but it is not clear from her protocols whether the rhinencephalon or its projections had been encroached upon.

Quite recently Bard and Mountcastle²⁹ have offered a highly significant body of data—if indeed they have not actually solved the major anatomic problem. They find it possible in cats to remove

expression are normally under the control of the olfactory center of the brain and that the hypothalamic centers normally governed by this region begin to discharge uncontrollably once connection is severed between them. It is not yet clear, however, how the autonomic centers in the neocortex correlate their activities with that of the rhinencephalon on the one hand, and with the hypothalamus on the other. As pointed out elsewhere in this review, there is evidence of close functional connection between the orbital surface—that is, area 13, which is a part of the neocortex—and the posterior hypothalamic nuclei, but there is still little evidence pointing to which nuclei in the hypothalamus receive projections from the rhinencephalon.

Kidney Function

Harris,³⁰ in a detailed study of the effects of stimulating the hypothalamus at the site of origin of the pituitary stalk (through the use of an implanted electrode activated by remote control), was able to induce in conscious rabbits sharp inhibition of a water diuresis, increase in urinary chloride and marked increase in estrus. These three effects could be duplicated by intravenous injection of posterior-lobe extracts. This is in keeping with the studies of Mary Pickford,³¹ who finds that application of small quantities of acetylcholine (for example, 8 microgm) to the supraoptic nucleus and to no other part of the hypothalamus causes prompt suppression of the diuresis through stimulation of the supra-opticohypophysial system. The effect was augmented by eserine salicylate and removal of the pituitary body abolished it. These studies afford further evidence of the part that the nervous system plays in regulation of kidney functions.

Metabolic Functions

That other visceral and metabolic functions are regulated by the nervous system is also evident from the studies of Brobeck,³² who describes important neurogenic factors in the genesis of obesity. In his review he points out that Hetherington and Ranson, in 1939, succeeded in confirming beyond doubt the observations of Bailey and Bremer that lesions confined to the hypothalamus may produce obesity whether or not the pituitary body is damaged. Earlier studies had pointed toward the same conclusion, but of all those who investigated the problem, only Hetherington and Ranson were able to prepare animals with lesions that completely spared the hypophysis. Only their data, therefore, appeared unequivocal. After the appearance of Hetherington and Ranson's report, Brobeck³² began to study the nature of the deficit responsible for the obesity—that is, the source of the energy surplus that leads to the accumulation of the large quantity of fat. It now seems to be generally agreed that most of this extra energy is derived from ingestion of an excessive quantity of food, and that

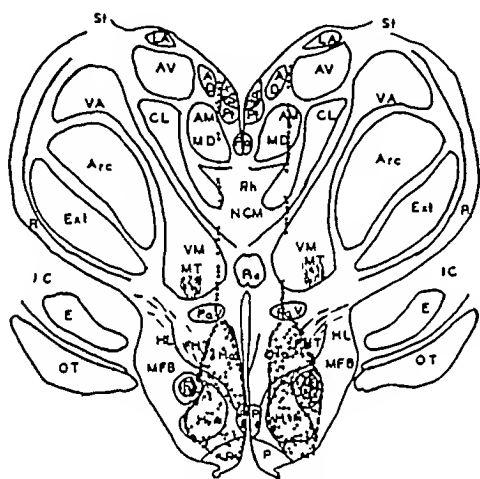

FIGURE 2 Diagram Showing Restricted Lesions in the Two Ventromedial Hypothalamic Nuclei (Hvm)

the entire neocortex (both sides) and then observe that such a decorticate preparation shows no sign of anger or affect even when subjected to severe nociceptive stimulation such as pinching of the tail with heavy forceps. Unless the stimulation becomes exceedingly intense, the animal usually purrs, and its general behavior is that of an animal responding to pleasurable stimulation irrespective of whether the stimulus would normally be pleasurable or not.

If, however, the rhinencephalon is involved bilaterally, an animal that previously showed pleasurable reactions immediately shows the sham-rage pattern of behavior to any form of stimulation. These important findings, which were communicated in December, 1947, at the meeting of the Association for Research in Nervous and Mental Disease, indicate that the mechanisms of emotional

the most important deficit exhibited by the affected animals concerns their regulation of food intake. The degree of the obesity appears to be a measure of the severity of the overeating. This is true in all species thus far studied—in rats, cats, dogs and monkeys.^{23, 24}

There is, however, certain evidence that overeating, or hyperphagia, is not the only disturbance present, since certain animals with hypothalamic lesions tend to gain weight because of a depression of either basal heat production or energy output as locomotor activity. But Brobeck in 1946 found that neither of these changes contributes significantly to the development of obesity in animals fed ad libitum, inasmuch as both the basal heat production and total energy output tend progressively to rise above normal levels as animals become obese. Only when food intake is restricted do reduced activity and basal heat loss lead to an abnormal gain of weight.

Since lesions of the hypothalamus may interfere with regulation of each of the four factors involved in energy exchange—namely, food intake, activity, heat loss and body weight—it follows that the hypothalamus must be the level at which processes of energy metabolism are regulated and integrated by the central nervous system.

THE FRONTAL LOBES

No part of the brain has received a larger share of attention during the past five years than the frontal lobes. This has been due, in large measure, to the growing interest in the operation of frontal lobotomy, inaugurated in 1935–1936 by Egas Moniz, of Lisbon,²⁵ and introduced into the United States the following year by Freeman and Watts,²⁶ who in 1942 published their much discussed monograph.²⁷ The operation had its origin in a preliminary communication given in 1935 before the International Neurological Congress in London on the behavioral changes observed in 2 chimpanzees after bilateral removal of the forepart of the frontal lobes.²⁸ After the procedure the animals failed to exhibit frustrational behavior, temper tantrums and so forth, and Professor Moniz, on the basis of this admittedly imperfect evidence, concluded that interruption of the projection systems from the more forward of the frontal areas might relieve anxiety states in man. Removal of the forepart of the frontal lobes in the chimpanzees had been extensive, involving areas 9 and 10, and parts of 11 and 12 of Brodmann,²⁹ but it had not encroached upon the orbital surface, now designated areas 13 and 14 in Walker's³⁰ modification of the Brodmann scheme. From the experimental standpoint, therefore, there was no clear-cut indication of what part of the 9, 10, 11 and 12 complex need be removed to abolish frustrational behavior. It is also probable that areas 24 and 25 on the cingulate gyrus were involved,

the rhinencephalon thus being brought into the picture.

Despite absence of such basic experimental data, the lobotomists have gone ahead, and it is estimated that by January 1949 nearly 10,000 radical lobotomies had been performed in the United States and England and on the Continent. Penfield³¹ and his colleagues at Montreal,³² although recognizing the potential value of the operation, have been more conservative and have carried out a number of gyrectomies involving various parts of the frontal lobe in the hope of obtaining more precise evidence of the region concerned in the relief of anxiety states. His cases, as reported in December, 1947, are still too few to admit of precise evaluation, but it appears that areas 10 and 12 on the lateral surface have little influence, the more medial projections probably being the ones most intimately concerned.

Area 24

The anterior portion of the cingulate gyrus, known in the older literature as the anterior limbic area and in Brodmann's map as area 24 (Fig. 3), had

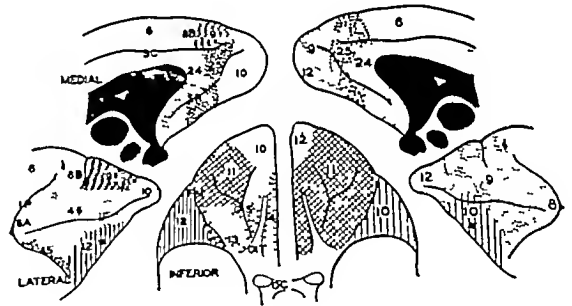

FIGURE 3 Walker's³⁰ Modification of Brodmann's²⁹ Map. Walker's cytoarchitectural map of the prefrontal lobe of *Macaca mulatta* (left) is compared with Brodmann's map of *Cercopithecus* (right). The numerical designations in Walker's map are derived from Brodmann's designations of comparable areas in the human cerebral cortex and hence do not necessarily have anything in common with Brodmann and Vogt's designations for the monkey.

been little studied until recently, but it was generally thought to be part of the rhinencephalon and therefore olfactory in function. Wilbur K. Smith³³ discovered that it had autonomic affinities, for on stimulation he obtained dilatation of the pupils, piloerection and cardiovascular changes that consisted of either an abrupt fall of pressure and slowing of the pulse or a slow rise with acceleration of the pulse, depending upon what part was stimulated. As with area 13, respiratory arrest generally occurred on excitation of area 24, with widespread relaxation of the skeletal musculature. McCulloch,³⁴ independently of Smith, had found that strychninization of area 24 led to relaxation of existing mus-

cular contraction, holding in abeyance of motor afterdischarge and suppression of motor response to stimulation of any motor focus in the cerebral cortex. Area 24 is thus to be classified with areas 4s, 8s and 2s as a powerful suppressor region. Smith also described vocalization as one of the effects of stimulating area 24, but this was not noted by McCulloch or by Ward⁴⁶ in his more recent study of the cingular gyrus. He has, however, confirmed Smith and McCulloch in all other details.

Ward⁴⁵ has also studied the effects of ablating area 24 in a group of monkeys. The behavioral changes were striking, and the animals after such a lesion, particularly if it were bilateral, appeared to lose "social conscience" thus

Immediately following either unilateral or bilateral subpial resection of the rostral cingular gyrus in the monkey there is an obvious change in personality. The monkey loses its preoperative shyness and is less fearful of man. It appears more inquisitive than the normal monkey of the same age. In a large cage with other monkeys of the same size, such an animal shows no grooming behavior or acts of affection toward its companions. In fact, it treats them as it treats inanimate objects and will walk on them, bump into them if they happen to be in the way and will even sit on them. It will openly eat food in the hand of a companion without being prepared to do battle and appears surprised when it is rebuffed. Such an animal never shows actual hostility to its fellows. It neither fights nor tries to escape when removed from a cage. It acts under all circumstances as though it had lost its "social conscience" [This is probably what Smith⁴⁶ saw and called "tameness"]. It is thus evident that following removal of the anterior limbic area, such monkeys lose some of the social fear and anxiety which normally governs their activity and thus lose the ability to accurately forecast the social repercussions of their own actions.

Ward has had the opportunity of making a similar lesion in a degenerated schizophrenic human being, and he believes that the procedure did as much for the patient as a more radical lobotomy would have done. Further studies on the effect of regional ablation of the cingulate are urgently needed both in animals and in man.

Area 13

More precise localizing data have been obtained for the posterior orbital gyrus (area 13) and for the medial orbital gyrus (area 14). In 1894 Spencer⁴⁷ had found that faradic stimulation of the orbital gyrus caused profound changes in respiratory movements and also in the level of the systolic blood pressure—this being true in dogs, cats, rabbits and monkeys. The studies of Spencer, however, were lost sight of until rediscovered by Bailey and Sweet⁴⁸ in 1940. Meanwhile, Bailey and Bremer⁴⁹ had shown that stimulation of the central cut end of the vagus nerve in the isolated head caused marked changes in the electroencephalogram of the posterior orbital gyrus and in no other part of the cerebral mantle. They concluded that this region of the orbital surface contained the chief central representation of the autonomic system. In 1943 Ruch and Shenkin⁵⁰ carried out bilateral ablations of area 13 and

found thereafter that the monkeys exhibited profound restlessness, pacing back and forth in their cages incessantly, when measured in activity cages, their motility was found to have increased 500 to 600 per cent.

More recently, Fulton, Livingston and Davis⁵¹ have confirmed Ruch and Shenkin's results on the effects of ablation, and Delgado,⁵² who studied their animals, has disclosed that skin temperature of the extremities and the ear lobes after bilateral removal of area 13 rises 8 to 10° and approaches the rectal temperature. In the light of this observation, Delgado suggests that the hypermotility that follows orbital gyrectomy may be a compensatory phenomena to assist in maintaining body temperature in the face of excessive heat loss. This release of vasoconstrictor tone must also cause a considerable decrease in peripheral resistance, which no doubt accounts for the rather striking falls in blood pressure that Freeman and Watts,⁵³ and others, have reported after their lobotomies—for in the Watts operation the line of incision passes down to the sphenoidal ridge and thus involves the posterior orbital gyrus. It has been suggested, indeed, that orbital gyrectomy may be the operation of choice for the relief of essential hypertension.

Equally significant have been the studies of Delgado and Livingston,⁵³ and of Livingston, Chapman and Livingston⁵⁴ on the effects of stimulation of area 13 in animals and man, particularly their disclosure of the importance of rate of stimulation. Wyss,⁵⁵ of Geneva, had found that the effects on respiration of stimulating the central end of the vagus nerve varied profoundly with the rate at which the nerve was stimulated, thus, at 70 per second, breathing movements could be arrested at expiration whereas at 20 per second inspiratory effects were obtained, at other rates respiratory movements could be made to increase in both depth and rate. Since there had been some discrepancies in the earlier reports on stimulation of the orbital surface, Delgado and Livingston,⁵² in the light of Wyss's observation, studied the effect of changing the frequency of the stimulus and obtained results corresponding closely with those reported by Wyss for the central end of the vagus. The responsiveness not only of area 13 but also of the cortex in the depths of the presylvian sulcus varies with frequency. Thus, the latter was entirely unresponsive at the higher rates (180 per second), but began to give responses at 60 per second (slowing), at 6 per second there was respiratory arrest in inspiration, and at 30 per second augmentation of inspiratory and expiratory amplitude.

It had been reported in man that the orbital surface was completely unresponsive to electrical stimulation (Penfield, Foerster and so forth). The importance of controlling frequency, however, had not been appreciated, and Livingston and his colleagues, after having negative results when they

stimulated the orbital surface with a 60-cycle stimulator, found striking respiratory effects, such as those seen in Figure 4, when they stimulated at 10 per second, the electrodes being of the needle concentric type, thrust down to the orbital ridge through a leukotomy burr hole (with the patient under pentothal anesthesia). Other details concerning the responses of the human orbital gyrus stimulation are found in the legend of Figure 4. It will be noted that respiratory effects can be separated from vasomotor effects, the latter being most conspicuously obtained from the more medial foci on the orbital surface.

The pathways from area 13 have still to be worked out, the main projection appears to pass through

are sometimes obtained on stimulation. Owing to its proximity to the olfactory nerve, it has been less carefully studied than the more lateral parts of the orbital surface. Fulton, Livingston and Davis⁵¹ noted that when the posterior part of area 14 was incised bilaterally, the animals (monkeys)

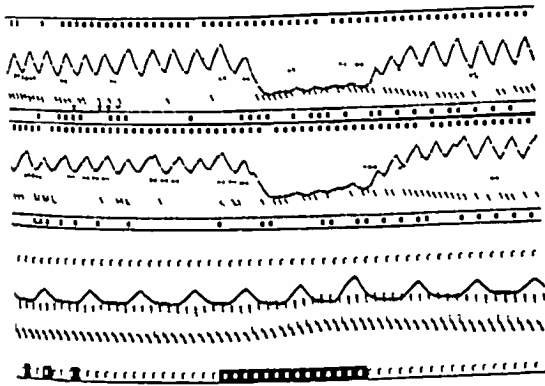

FIGURE 4 Photographic Record of the Respiratory and Blood-Pressure Response (Femoral Artery) to Stimulation of the Orbital Surface of Man under Light Pentothal Anesthesia

All stimulations are of ten seconds' duration and are at 10 cycles per second. The signal at the bottom of each strip identifies and delimits onset and duration of stimuli. The first two strips show responses, from two different orbital loci, of prompt respiratory responses, an arrest in expiratory position and blood-pressure rise after a short latent period. The third strip shows the response in a region where no respiratory effect is obtained but where there is a moderate blood-pressure response. (Reproduced from Livingston, Chapman, Livingston and Kraitsir⁵⁴ with permission of the publishers.)

the anterior end of the internal capsule, and thence to the supraoptic nuclei of the hypothalamus. Glees⁵⁶ has made a preliminary study of the anatomic degenerations following lesions in this region, and a large proportion of the fibers appear to be unmyelinated. Ward and McCulloch⁵⁷ find that when strychnine is injected into the orbital surface, the supraoptic nuclei, as well as some of the posterior hypothalamic ones, become specifically activated (Fig 5). It thus seems probable that area 13 has primary subcortical connections with the hypothalamus.

Area 14

Less is known about functional localization in area 14 (medial orbital gyrus). Vasomotor responses

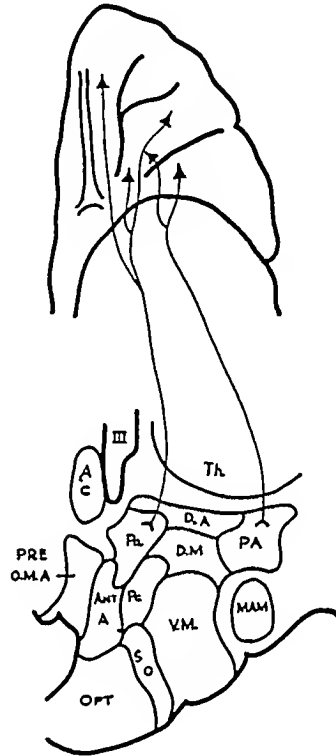

FIGURE 5 Diagrammatic Representation of Homolateral Projections from Areas 13 and 14 (Orbital Gyrus) of the Monkey to the Hypothalamus

Pa = paraventricular nucleus, PA = posterior hypothalamic area (Other abbreviations are explained by Ward and McCulloch⁵⁷)

develop conspicuous sham rage similar to that described after corresponding lesions in cats by Fulton and Ingraham²⁷. In their recent analysis of sham rage, Bard and Mountcastle²⁹ observed that the entire neopallium can be removed without the appearance of sham rage so long as the rhinencephalon remains intact. If, however, the rhinencephalon is encroached upon bilaterally, even though the neocortex remains intact, sham rage invariably occurs. It therefore appears that lesions of the posterior part of area 14 must interrupt projections to and from the rhinencephalon. Sham rage has not been encountered after bilateral lesions of area 13.

The fact that the orbital surface was spared in the 2 chimpanzees on which the operation of frontal lobotomy was based and the fact that profound autonomic changes develop when area 13 is involved and further that sham rage may follow posterior

lesions of 14, suggest that in the operation of frontal lobotomy, the orbital surface should be spared. The work of Ward indicates that more attention should be given to the specific function of the cingulate gyrus, which is known to be intimately associated with the olfactory center of the brain and hence with the emotional life of man.

Renal Circulation

It was pointed out above that the supraoptic nuclei in the hypothalamus regulate tubular reabsorption of the kidney through controlling the secretion of the posterior pituitary body, and it has recently been shown that the nervous system also regulates the renal circulation. Trueta and his colleagues^{58, 59} have discovered that the glomerular circulation can be shunted reflexly into the medullary vessels of the kidney and so completely abolish urine formation. Cort⁶⁰ has proved that this renal shunt can be activated in the spinal animal through stimulation of any large sensory nerve, the reflex being abolished by section of the lesser splanchnic nerve. He finds, moreover, in cats that the shunt can be activated by stimulation of the vasomotor center in the medulla, the posterior hypothalamic nuclei and also areas 13 and 6 of the cerebral cortex. This clearly provides a physiologic explanation of emotional anuria.

(To be concluded)

EDITH E. PARRIS, *Assistant Editor*

CASE 35221

PRESENTATION OF CASE

A thirty-nine-year-old woman was admitted to the hospital complaining of grossly bloody urine accompanied by small clots for one week.

During the same interval urinary frequency, dysuria and nocturia were present. In the week before admission she also had severe right-costovertebral-angle pain on motion of the right leg. There had been no leg edema, and no weight loss.

Her general health had always been good except for one episode of slight hematuria four years before admission.

Her menses were regular, with twenty-eight-day intervals. There had been no bleeding between periods, except for a two-week period two months before admission, when she bled "off and on."

Physical examination showed a nontender right-upper-quadrant mass. On pelvic examination a small mass was palpable on the posterior aspect of the uterus near the top.

The blood pressure was 120 systolic, 70 diastolic. The temperature was 98.8°F, the pulse 112, and the respirations 24.

The white-cell count was 6900, with 79 per cent neutrophils, 15 per cent lymphocytes, 3 per cent monocytes and 3 per cent eosinophils. The hemoglobin was 7.5 gm.

The specific gravity of the urine was 1.015, with a $++$ test for albumin. The sediment contained 50 red cells and 25 white cells per high-power field. The urine culture was negative. The nonprotein nitrogen was 17 mg per 100 cc.

On intravenous pyelography the kidneys were within normal limits as to size, shape and position. There was a soft-tissue swelling at the hilus of the

right kidney, which appeared to be due to dilatation of the pelvis. After intravenous administration of dye it was excreted promptly, outlining nonobstructed urinary passages on the left. Excretion on the right was slower, and there was dilatation of the calyces on the right. The large, dilated pelvis showed only a small amount of dye in its margins, which suggested that the pelvis and the bases of the calyces were filled by nonopaque material. The right ureter was not visualized. The bones of the lumbar spine and pelvis were not remarkable.

On the third hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. SAMUEL VOSE: The picture of this case as presented in the abstract is that of a woman very seriously ill who had a mass in the region of the right kidney, gross hematuria and what was presumably an acute anemia (hemoglobin of 7.5 gm), with a negative past history referable to the urinary tract except for one episode of slight bleeding four years previously and a small amount of vaginal bleeding two months prior to entry into the hospital. The bleeding must have been very severe to reduce the hemoglobin to this point. The laboratory findings are not particularly helpful except to demonstrate that she had anemia, and the intravenous pyelogram showed a filling defect in a hydronephrotic kidney.

Gross hematuria is one of the most important and interesting conditions that occur in disease of the urinary tract. Since there are some forty-odd causes for it, it is sometimes difficult and always interesting to try to figure out. One of the three factors involved in a situation such as this regards the source of bleeding. In this case there is no definite evidence of the source. Dr. Colby told me that cystoscopy showed clear urine from both ureters. We assume that the bleeding was coming from the right kidney, but actually that is an assumption rather than a fact. Recently we had a patient with bright-red blood spurring from the right ureter. An intravenous pyelogram showed a left ureteral calculus. If the bleeding had not been seen we would have assumed that it was coming from the left kidney. The only reasonable assumption here is that it was coming from the right kidney, which presumably was the mass in the right side.

As to the cause of the blood, assuming its source to be in the kidney, this was in all probability acute

surgical bleeding. There is no evidence of nephritis—no casts in the urine and nothing in the history to indicate blood dyscrasia. Of this surgical group there are three main causes, traumatic, inflammatory and neoplastic. There is no history of trauma and no evidence on the x-ray film of stone, and a traumatic origin is not likely. Many of the acute inflammatory bleedings are from a hemorrhagic type of cystitis. Dr. Colby tells me that the bladder was normal. Pyelonephritis of some type must be considered. Inflammatory bleeding usually is not of the profuse type that we see here. The bladder is ruled out, but certainly a tumor of the kidney, either cortical or pelvic, must be seriously considered.

In analyzing a few of the symptoms, we see that she did have an attack of acute pain in the costo-vertebral angle, which always brings up the probability of an obstructive lesion of some sort, which might be blood clot or primary hydronephrosis. Certainly, there was some obstruction. She had no evidence of fever or chills, to indicate an acute inflammatory condition as a probable cause of pain. The previous bleeding, of course, is somewhat in favor of neoplastic disease. It does not seem possible, however, that blood would occur from a neoplasm and not recur some time during the four-year period since she had had trouble. The bleeding from the vagina reported two weeks prior to entry is difficult to explain except on the basis of the vaginal examination, which showed a small mass in the posterior surface of the uterus, probably a small fibroid. There may have been others that caused bleeding. That is purely speculative. It does bring up the remote possibility of endometriosis. That is unusual in the kidney—probably it is more common in the bladder. Perhaps we cannot rule it out completely. On physical examination the mass in the right upper quadrant was not tender at the time of examination. Evidently, the acute obstruction that caused the pain had been to some extent relieved.

The laboratory work shows one interesting finding, a negative culture on the urine, with a few white cells and red cells. A negative culture in the presence of white cells or other evidence of infection always raises the question of tuberculosis. We have to have more evidence one way or the other to know whether this was present. That is not too important to answer so far as the acute difficulty is concerned, and apparently it was not something that entered the minds of the men in charge as a likely probability.

Will Dr. Wyman show us the x-ray films?

DR. STANLEY M. WYMAN: The right kidney is fairly well outlined on the plain film. There is no evidence of stones. Intravenous dye appears promptly on both sides. Dilated calyces are seen, and there seems to be definite thinning of the cortex of the kidney lateral to the dilated calyces. What

appears to be a large pelvis is also imperfectly outlined. Within the pelvis and all the calyces there are multiple, round, rather smooth, lobulated, filling defects. The left kidney appears perfectly normal as far as can be seen.

DR. VOSE: In the standing position the right kidney drops well down below the iliac crest. Here is a kidney that was definitely hydronephrotic and undoubtedly had been for a good many months, probably years. The cortex is very thin. One can hardly see it, and this is something that does not take place in a short time as in an acute hydronephrosis. The filling defect may be a part of the cause of hydronephrosis, or it may be secondary to the hydronephrosis. My opinion is that it is secondary, that the hydronephrosis has been there for many years, and that the condition that caused the bleeding is of apparently recent origin.

This comes down to two or three conditions: tumor in the pelvis, nonopaque stone or hydronephrosis with secondary inflammation and bleeding with collection of blood clots in the kidney pelvis. There is also the outside possibility of tuberculosis. There is a little bit about the pyelogram that suggests a necrotizing papillitis, but she does not appear to have been ill enough to have that. There is no history of diabetes and not enough cortical necrosis to be consistent with that diagnosis. There is a possibility of some rare type of cyst in the kidney pelvis, but I think that tumor, nonopaque stone and a blood clot are the most likely causes of the filling defects. It is almost a toss of the coin to determine which one. I would bet on primary hydronephrosis due either to intrinsic disease in the upper ureter or at the ureteropelvic junction or to a very low kidney with an abnormal implantation of the ureter with secondary infection and hematuria as my first guess, papillary tumor of the renal pelvis as my second, and nonopaque stone as the third.

DR. FLETCHER H. COLBY: I think that Dr. Vose came as close as he could in this bizarre picture. Our preoperative diagnosis was papillary tumor of the renal pelvis. We decided that that was the most likely diagnosis in view of the fact that while this kidney had numerous rather large filling defects present in the upper portion, renal function was sufficiently well preserved so that the kidney excreted the dye in reasonably good concentration. Therefore, neoplasm involving the pelvis and not the parenchyma was more likely. The kidney was approached through a thoracoabdominal incision, and with that exposure the entire kidney and the renal blood supply were readily accessible. The kidney was enlarged, and the pelvis dilated, and through the pelvis one could feel round, rather soft masses. One of these masses was felt a little bit below the ureteropelvic junction. Believing that we were dealing probably with a primary tumor of the renal pelvis, probably papillary carcinoma,

we enlarged the incision and removed the entire kidney and ureter intact with a portion of the bladder wall

CLINICAL DIAGNOSIS

Papillary tumor of renal pelvis

DR VOSE'S DIAGNOSIS

Primary hydronephrosis, with secondary infection and hematuria?

Papillary tumor of renal pelvis?

ANATOMICAL DIAGNOSIS

Hamartoma of cloacal tissue in renal pelvis

PATHOLOGICAL DISCUSSION

DR TRACY B. MALLORY The specimen brought to the laboratory was entirely unlike anything that I had ever seen. The entire pelvis was filled with these polypoid masses, which had a myxomatous, almost gelatinous character. My thought was that

clearly characteristic of Brunner's glands, others looked like small-bowel epithelium, with numerous Paneth cells present, and some looked like large bowel. None of the ordinary textbooks of pathology contain descriptions of such a tumor and in a long review of renal tumors by Melicow,¹ based on 199

FIGURE 1

they must consist of myxomatous tissue. The large tumor appeared to be attached to the renal pelvis in two spots, and there was an entirely separate tumor a short way down the ureter, which can be seen at the extreme left of the picture. When the microscopical sections came through they were most surprising and confusing. The tumor consisted of multiple acini of varying size embedded in an abundant fibrous myxomatous stroma. The acini were quite variable in character, some of them were lined with transitional epithelium of the usual type seen in the urinary passages, and others with obviously intestinal types of epithelium, some were

FIGURE 2

cases, nothing similar was reported. However, in the collection of material in the registry in the Army Medical Museum² they do have such tumors both in the bladder and in the renal pelvis. The explanation that has been offered and seems reasonable is that they arise from fetal nests of cloacal tissue. The cloaca of fetal life eventually separates and differentiates into the urinary passages anteriorly and the bowel posteriorly two ways, into intestinal epithelium or into transitional epithelium. That is I believe the most reasonable explanation of the tumor. I think it is entirely benign as far as one can judge from our usual microscopical criteria, and I believe that this other tumor part way down the ureter represents a second lesion of the same type rather than extension or metastasis from the renal tumor. It is difficult to know what exact name to attach to it. I would call it a hamartoma of cloacal tissue.

DR COLBY Quite a number of years ago we had a tumor in the bladder that histologically, as

far as I remember, was identical, or very nearly so, to this. It consisted of myxomatous tissue in which there were mucous secreting glands with no evidence of cancer. We classified it as an embryonic rest in a urinary bladder.

DR MALLORY: Tumors similar to this can occur throughout the length of the urinary tract, in the bladder, ureters and pelvis of the kidney, and also can be found extending up the urachus even to the umbilicus.

DR LAMAR SOUTTER: Will the tumor metastasize?

DR MALLORY: I would not expect it to. It is such an unusual tumor that I am rather hesitant about being dogmatic about its degree of malignancy, but from the usual microscopical criteria I would not think it was malignant.

CASE 35222

PRESENTATION OF CASE

A forty-nine-year-old Italian housewife was admitted to the hospital because of an epigastric mass.

The patient's first admission to the hospital occurred twenty-three years before, when she gave a story of diarrhea and bloody stools of eighteen months' duration. Physical examination was not remarkable, but proctoscopy showed diffuse redness and ulceration of the mucous membranes as far as could be seen. A diagnosis of ulcerative colitis was made, and a double-barreled ileostomy was done, with considerable improvement. She continued to have occasional abdominal cramps and discharged bloody mucus by rectum for five or six years, but this gradually subsided until she was passing only a small amount of mucus by rectum every few weeks. The mucous discharge usually occurred during a cold. Eight years before the present admission she developed an empyema of the right chest following an unresolved pneumonia caused by Type III pneumococcus. Rib resection and drainage were required. Approximately two years prior to the present admission she noted a tight feeling and felt a lump just below the umbilicus. The mass did not increase in size during this period and produced no symptoms.

Physical examination revealed a well developed and well nourished, co-operative woman. The scar of the rib resection was well healed. There was a Grade II basal systolic murmur. The ileostomy in the right lower quadrant was in good condition. In the region of the umbilicus and extending to the left was a nontender, 5-cm. mass, which although slightly attached to the anterior abdominal wall

seemed freely movable. The ileostomy located to the right and below the umbilicus functioned well. Pelvic examination was negative.

The temperature, pulse and respirations were normal. The blood pressure was 130 systolic, 85 diastolic.

The urine showed a specific gravity of 1.014 and was entirely normal. The hemoglobin was 10 gm., and the white-cell count 10,000. A barium enema could not be done because of the severe pain that it caused. Films of the abdomen and intravenous pyelograms showed a peculiar layer of calcification that was seen in a semilunar fashion to extend to the left of the upper lumbar spine and suggested the margin of the calcified tumor. The left kidney was normal in size and excreted the dye in good concentration. The right kidney was rather small and hypoplastic and showed delayed excretion with rather wide calyces and pelvis filling one or two hours after the injection of dye. The right ureter was not well visualized. There was a suggestion of a mass in the right side of the pelvis and right side of the abdomen. A chest film showed some elevation of the right leaf of the diaphragm, with pleural adhesions that caused slight limitation of motion. There were old partial resections of several right ribs. There was some fibrosis, and increased markings in both lungs, mostly on the right. There was some thickened pleura over the right chest laterally. The heart shadow was not enlarged, but there was rather marked tortuosity of the aorta.

After preparatory transfusions an operation was performed on the sixth hospital day.

DIFFERENTIAL DIAGNOSIS

DR CHARLES G. MIXTER: This type of exercise is interesting and sometimes amusing to the audience but puts the discussor on the hot seat because there is a cat in the meal somewhere. I am sure that there is a festive feline lurking around here that is going to get me into trouble. "Films of the abdomen and intravenous pyelograms showed a peculiar layer of calcification." I suspect that that may be the cat in the meal.

We might make a brief review of the past history to see if we can find anything that might have a bearing on this patient's mass. In the first place she was an Italian, of about fifty years, and she had a history of ulcerative colitis that ran a more or less characteristic course requiring operation, and then presumably the large bowel quieted down and had remained more or less quiescent. That I think we should put aside for future discussion because it might have some bearing on the differential diagnosis. I believe we can forget about empyema following an unresolved pneumonia as far as the differential diagnosis is concerned, because I do not see how this would have any bearing on the mass at the umbilicus. It is true occasionally, and I have seen it in children, that a chronic empyema may

descend through the diaphragm and find a point at the umbilicus, but this case certainly would not fall in that category

The next thing to discuss is the abnormality of the kidney. The mass was on the left. The right kidney was a hypoplastic type of kidney with delayed excretion, and yet the urine was normal without anything of consequence in the sediment. That to my mind perhaps suggests a hypoplastic kidney, possibly of congenital origin, and I do not believe has anything to do with this picture. We might consider some retroperitoneal mass from the wolffian ridge, but this being on the right side and the tumor on the left makes it unlikely. Furthermore it presumably was attached to the anterior abdominal wall.

Perhaps it is all right to ask if a blood Wassermann or Kahn test was negative. Also, I should like to know about the gastrointestinal series, the gall-bladder studies or lateral films and whether the patient had a peritoneoscopy.

DR TRACY B. MALLORY: At the first entry, twenty-two years previously, the blood Wassermann test was negative. Dr. Wyman can show the x-ray films at any time.

DR MIXTER: I would like to see them. The patient had tortuosity of the great vessels, and, of course, we have to consider in the differential diagnosis an aneurysm but it is hard to link that up with slight fixation of the anterior abdominal wall. Certainly, no mention is made of pulsation.

DR STANLEY M. WYMAN: The chest films show the old defects in the right ribs, old pleuritis and a somewhat tortuous thoracic aorta. I can see no evidence of active disease in the chest. There are a few scars in the right-upper-lung field, which are possibly due to old tuberculosis. The calcification described lies in linear fashion, is somewhat lobulated, is situated just to the left of the third lumbar vertebra and extends over a distance of perhaps 5 or 6 cm. The right kidney shadow can be seen; it is very small. The left kidney is long and rather slender.

DR MIXTER: I believe that the calcification has considerable bearing on the differential diagnosis.

DR WYMAN: The later films from the pyelogram show the very small right kidney to have excreted a small amount of dye of poor concentration at the end of two hours and the calyceal system is greatly dilated, suggesting possibly an old infectious process. There is some soft-tissue density in the right pelvis, which is hard to define accurately but is present on all films. I am unable to say what it is. I cannot define it very well, but it may be linked up with this trouble in the right kidney.

DR MIXTER: What is this shadow?

DR WYMAN: The lower margin of the liver.

DR MIXTER: Is there any gross deformity of the bladder?

DR WYMAN: The bladder seems to have a fairly normal contour. How much of the shadow in the right abdomen is due to the ileostomy, I do not know.

DR MIXTER: The pelvic examination was reported negative. That, however, does not necessarily rule out a pedunculated mass.

Let us take a brief survey of the possibilities. In the first place I think that we can rule out any acute infection. The temperature, the patient's general condition and the duration of the illness over a period of two years are against anything of that nature. Furthermore, I think we can rule out cancer in all probability because the condition was stationary over two years. The patient did not show the inroads of a malignant process, although we have to bear in mind that carcinoma is a fairly frequent complication of ulcerative colitis — much more so than in the normal bowel. I believe we can rule that out also.

That boils it down pretty much to consideration of possible masses in the umbilical region. Let us first consider the masses that do not necessarily or frequently show calcification, because although that is suggestive it may lead us astray. The first one that comes to mind is the leiomyofibromatous type of tumor of the gastrointestinal tract, even a gastric tumor that has grown outward from the serosal surface might be located in this position, and sometimes remains very quiescent. But I still believe that this calcification is of sufficient importance so that I would not consider that diagnosis.

Fecal masses should be considered in all differential diagnoses, but here is a woman who had an ileostomy. Fecal masses almost invariably occur in the large bowel. Continuous pressure over a fecal mass will cause indentation almost invariably. We have none of the obstructive signs that would be present with a fecal mass, and it certainly would not persist over a period of two years. There are rare tumors, especially urachal cysts that occur below the umbilicus and are attached to the abdominal wall, it is true, but they are not freely movable. I think from the mobility of this tumor we can rule out any lesion within the anterior abdominal wall or anything too intimately in contact with it. There are omental and mesenteric cysts. It is true that all cysts may deposit a certain amount of calcium, and that may be true of omental and mesenteric cysts, but in my personal experience I have never encountered it and I believe it must be rare to find calcium deposits in such cysts. It is true that my experience was almost exclusively in children, in whom one would not expect to find calcareous deposits perhaps. They are silently growing and are generally brought to one's attention simply as an abdominal mass. They are freely movable, except when they reach enormous size, as particularly the mesenteric cysts. They usually occur in the upper small bowel, and often are dumb-

bell in shape Pancreatic cysts and liver cysts, particularly pancreatic cysts, may form calcareous deposits, but one would expect fullness in the epigastrium, certainly that is true of simple cysts of the liver I have seen one simple cyst of the liver that presented as a definite epigastric mass, which descended on respiration, and it would not fit into this category It is true that Meckel's diverticulum can attain enormous size, but it is not palpable except when it is accompanied by acute inflammatory reaction or perforates and forms an abscess So there again I think we can rule that out Let us now consider tumors that may be associated more commonly with calcification First let us consider calcified mesenteric glands Here we have, however, central foci that do not show a crescentic linear type of calcification that we see here Furthermore, a gland of this size would certainly be unusual Perhaps we should mention lithopedium, although the x-ray appearance would be different, and I think that is a far-fetched possibility We have to consider echinococcal cyst, a wandering cyst might be located in this region It is not uncommon to get a linear calcification, and this woman was an Italian There is no record of a complement-fixation test available

Hematomas may show calcification — although the calcification is usually more or less fuzzy and diffuse rather than linear

A gallstone may be palpable, and I have here one that I removed some years ago It is an interesting specimen and was readily palpable I could move it about the abdomen It made a perfect cast of the gall bladder In the case under discussion one would have to suppose that it had ulcerated through the gall bladder, wrapped itself in the omentum and worked its way down to the umbilicus The calcium deposit on the surface could well follow this type of shadow I think that is far fetched Calcification is frequently associated with any form of chronic abscess or infection

One thing we must consider is a pocket in the old ulcerative colitis that she had years previously, with a chronic abscess as well as calcification We cannot rule it out We have to consider other likely diagnoses

I do not believe this was a foreign body lying within the intestinal lumen It is true the human being is capable of all sorts of aberrations, and any cavity within the body may be a suitable receptacle for a foreign body Some of us have seen hairpins

introduced into the female bladder, and I have taken a rivet out of the male bladder But a foreign body introduced through an ileostomy would probably not stay in the intestine for nearly two years without either being extruded or causing difficulty On the other hand this patient was operated on twenty-three years before this admission I do not know what the sponge-count report was, but one of the things I have strongly in mind is that she had a sponge wrapped up in the omentum that caused this linear calcification such as we see in this film Sponges can lie quiescent for years I have removed one that was a movable mass in the abdomen, in a woman who had had an ovarian cyst removed some three or four years before The sponge had rolled itself up in the omentum and lay dormant over that period A sponge can show calcification of this type

Another calcified tumor that we must consider is uterine fibroid, pedunculated, or one that from torsion had separated by necrosis and then become engrafted at some other site, perhaps near the umbilicus Such tumors may show calcification of this type Another definite possibility is a pedunculated ovarian cyst, because ovarian cysts are prone to show a fine linear calcification I think I am right on that from the x-ray standpoint.

DR WYMAN Sometimes

DR MIXTER Particularly the dermoids have calcification that might follow this pattern

Time is drawing to a close and I must end my discussion, but I would say that there are three diagnoses I would particularly like to consider as possibilities I do not believe I would want to commit myself any further than that On the law of chances I would say first that this might be a foreign-body cyst, second, a dermoid, and third, a fibroid I believe the time is up, and as the old saying goes you never can tell what is in the box before you take the cover off I would like to know what operation showed

DR MALLORY Dr Warren, will you tell us your opinion and operative findings

DR RICHARD WARREN Our reasoning was not so astute as Dr Mixer's We had however more information that I am afraid did not get into the record There were two or three points that swayed us The first was that the patient had not had any passage of material by rectum for several years The record states that there was mucus passed every few months but that was inaccurate The

second point was that rectal examination was impossible because there was a complete block at the internal sphincter. Tying these facts together with the mass that was palpable in the region of the umbilicus we began to think this was inspissated material—accumulated colonic secretions. We could not explain the calcification. That bothered us a great deal.

CLINICAL DIAGNOSIS

Inspissated material in colon

DR MIXTER'S DIAGNOSIS

Cyst, due to foreign body

ANATOMICAL DIAGNOSIS

Mucocele of large bowel due to strictures in ulcerative colitis of defunctioned bowel

PATHOLOGICAL DISCUSSION

DR WARREN: We operated on the patient and found that she did have a greatly distended right colon—greatly distended with a mucoid type of material. The defunctioned terminal ileum was also distended to the same diameter as the colon. The material was under such tension that it was coming out through the interstitial spaces. Most of it was in the right colon, although there were patches on the left side as far down as the lower segment. This material was incarcerated in several

compartments. The lumen of the colon at the rectal end was closed off as it was at the defunctioned end of the double-barreled ileostomy. It was interesting also that the patient had had acriflavine colonic irrigation for a year or so following ileostomy.

DR MIXTER: I am surprised there was not a palpable, putty-like mass in the right side of the abdomen.

DR MALLORY: This picture shows the entire colon here and the terminal portion of the ileum, which, as one can see, is dilated almost to the size of the colon. The next picture shows the bowel after it was opened and here is one of these huge masses of inspissated secretion. As one passes along to the sigmoid there is another mass of mucus, not quite so large. The mucus, as Dr Warren said, had partially split the wall of the bowel so that we found mucus all through the layers of intestinal wall. This caused us considerable worry at first for fear we were dealing with colloid carcinoma, in which tumor cells may be very infrequent and one finds only great masses of mucus. Here and there, however, we could find remnants of intestinal epithelium, which were quite normal—not neoplastic in character. So I think this was clearly a mucocele of the large bowel resulting from multiple foci of obstruction.

DR MIXTER: Was there any true calcification?

DR MALLORY: We were not able to identify the calcification.

bell in shape Pancreatic cysts and liver cysts, particularly pancreatic cysts, may form calcareous deposits, but one would expect fullness in the epigastrium, certainly that is true of simple cysts of the liver I have seen one simple cyst of the liver that presented as a definite epigastric mass, which descended on respiration, and it would not fit into this category It is true that Meckel's diverticulum can attain enormous size, but it is not palpable except when it is accompanied by acute inflammatory reaction or perforates and forms an abscess So there again I think we can rule that out Let us now consider tumors that may be associated more commonly with calcification First let us consider calcified mesenteric glands Here we have, however, central foci that do not show a crescentic linear type of calcification that we see here Furthermore, a gland of this size would certainly be unusual Perhaps we should mention lithopedium, although the x-ray appearance would be different, and I think that is a far-fetched possibility We have to consider echinococcal cyst, a wandering cyst might be located in this region It is not uncommon to get a linear calcification, and this woman was an Italian There is no record of a complement-fixation test available

Hematomas may show calcification — although the calcification is usually more or less fuzzy and diffuse rather than linear

A gallstone may be palpable, and I have here one that I removed some years ago It is an interesting specimen and was readily palpable I could move it about the abdomen It made a perfect cast of the gall bladder In the case under discussion one would have to suppose that it had ulcerated through the gall bladder, wrapped itself in the omentum and worked its way down to the umbilicus The calcium deposit on the surface could well follow this type of shadow I think that is far fetched Calcification is frequently associated with any form of chronic abscess or infection

One thing we must consider is a pocket in the old ulcerative colitis that she had years previously, with a chronic abscess as well as calcification We cannot rule it out We have to consider other likely diagnoses

I do not believe this was a foreign body lying within the intestinal lumen It is true the human being is capable of all sorts of aberrations, and any cavity within the body may be a suitable receptacle for a foreign body Some of us have seen hairpins

introduced into the female bladder, and I have taken a rivet out of the male bladder But a foreign body introduced through an ileostomy would probably not stay in the intestine for nearly two years without either being extruded or causing difficulty On the other hand this patient was operated on twenty-three years before this admission I do not know what the sponge-count report was, but one of the things I have strongly in mind is that she had a sponge wrapped up in the omentum that caused this linear calcification such as we see in this film Sponges can lie quiescent for years I have removed one that was a movable mass in the abdomen, in a woman who had had an ovarian cyst removed some three or four years before The sponge had rolled itself up in the omentum and lay dormant over that period A sponge can show calcification of this type

Another calcified tumor that we must consider is uterine fibroid, pedunculated, or one that from torsion had separated by necrosis and then become engrafted at some other site, perhaps near the umbilicus Such tumors may show calcification of this type Another definite possibility is a pedunculated ovarian cyst, because ovarian cysts are prone to show a fine linear calcification I think I am right on that from the x-ray standpoint.

DR WYMAN Sometimes

DR MIXTER Particularly the dermoids have calcification that might follow this pattern

Time is drawing to a close and I must end my discussion, but I would say that there are three diagnoses I would particularly like to consider as possibilities I do not believe I would want to commit myself any further than that On the law of chances I would say first that this might be a foreign-body cyst, second, a dermoid, and third, a fibroid I believe the time is up, and as the old saying goes you never can tell what is in the box before you take the cover off I would like to know what operation showed

DR MALLORY Dr Warren, will you tell us your opinion and operative findings

PUBLIC HEALTH AND MENTAL HEALTH

MYSTERY and abstruseness continue to be associated with psychiatry and psychotherapy by people who know little about the subjects and by some who professedly know much about them. It is questionable whether the encouraging of awesome respect for this branch of medicine will do much toward advancing it on a sound basis.

An instance of comparative simplicity in concept and in teaching some of the principles of psychiatry is presented in a recently published pamphlet.* This pamphlet is the report on "An Institute on Mental Health in Public Health" held by the California State Department of Public Health and The

Commonwealth Fund last July. The Institute was attended by 27 health officers, and the teaching and discussion were conducted by 8 psychiatrists, 3 pediatricians with psychiatric training and 5 public-health leaders.

With the new impetus being given to the psychiatric implications in almost all human pursuits, it is understandable that the sphere of public health should be included in psychiatry's ambit. According to the pamphlet — a more comprehensive account is to be issued later — the Institute touched on many topics in its clinics, lectures and discussions, but its chief work and accomplishment was an inquiry into the understanding of "interpersonal relationships."

Health officers and health departments deal primarily with the prevention, amelioration and cure of disease. Concentration on the pathologic process is apparently the principal concern. The individual, with his particular personality, who has or may acquire the disease is considered secondarily or perhaps not at all. The Institute, in its daily meetings, revealed to its student members that it is people who have diseases, people with their fears, resentments, social, economic and emotional problems. It is an old story — the best care of the patient is care for the patient. Also, it seemed to become clear or clearer to the students that their own attitudes and personality problems could too frequently produce blind spots in their associations with other human beings, both patients and colleagues.

The pamphlet states "unless the health officer listens to the patient he cannot learn enough about the patient to know how to deal with him skillfully, and unless the health worker enters into a feeling relationship with the patient his advice and his questions are both likely to be fruitless." This is such a simple and apparently uninspiring conclusion that it may seem surprising and even disturbing that supposedly mature, intelligent public-health officers were pleased and delighted with the course.

It may well be that the students benefited from the opportunity to listen to and to discuss points and subjects that are relevant to what makes everyone tick. The "what," as described in the pamphlet,

*Smith, G. *Human Relationships in Public Health. Report of institute on mental health in public health* 18 pp. New York: The Commonwealth Fund 1949.

was not founded on disputable and unproved Freudian and neo-Freudian dogmas. That credits the teachers with perspective and wisdom.

Science will do better than it has to date if it proves anything more fundamentally constructive than the Golden Rule. A tip to science might be to extirpate self-interest in man without destroying or nullifying his constructive, altruistic energies.

AMERICAN BOARD OF PREVENTIVE MEDICINE AND PUBLIC HEALTH, INC

THE establishment of the American Board of Preventive Medicine and Public Health represents a significant step in medical progress. The Board, which is sponsored by the American Medical Association, American Public Health Association, Association of Schools of Public Health, Southern Medical Association and Canadian Public Health Association, has adopted requirements for certification that are in harmony with those of the various specialty boards previously set up. General qualifications, such as satisfactory moral and ethical standing in the medical profession, adequate medical training and internship in an approved hospital, and licensure to practice medicine in the United States. To be eligible for examination, applicants must also have had special training and experience in preventive medicine and public health for at least six years after internship (special academic training, or its equivalent, and field training or residency of at least two years of field experience in general public-health practice, including planned instruction, observation and active participation in a comprehensive, organized public-health program), each person to whom a certificate is issued must limit himself to the teaching or practice of public health as a specialty. Provision is made for the certification, without examination, of the Founders Group, consisting of practitioners of preventive medicine and public health who have achieved unquestioned eminence either in an academic status or through practical achievement in positions of responsibility. The standards thus set up appear to guarantee that diplomates of the new board will be men of the highest caliber in their field.

The newly recognized specialty is a matter of great interest to all physicians, since it is, in essence, the medical profession's answer to the challenge of providing adequate medical care on two crucial levels of medical practice. The setting up of the Board may be regarded as a forward step toward the goal of giving to every person "the basic essential, diagnostic, preventive and therapeutic measures that will enable him to enjoy a more productive life and become a greater asset to the community."* The significance of progress in this vital field, which has for years been the battleground between the proponents of free practice and those who demand state control is obvious.

NEW DIRECTOR OF MASSACHUSETTS GENERAL HOSPITAL

IN THE selection of a director to succeed Dr Nathaniel W. Faxon, who is retiring after twenty years of distinguished service, the trustees of the Massachusetts General Hospital have again demonstrated the excellent judgment that usually characterizes their decisions.

Dr Dean A. Clark, who will shortly assume the directorship of the hospital, is a native of Minnesota, a graduate of Princeton University and holder of the degrees of bachelor of arts and bachelor of science in physiology from Oxford University, where he studied three years as a Rhodes Scholar. He received his medical degree from The Johns Hopkins University School of Medicine in 1932, after which he served an internship in medicine at the Johns Hopkins Hospital. He then became assistant resident in medicine and neurology at the New York Hospital, National Research Council fellow in neurophysiology at the Cornell University Medical College, intern at Phipps Psychiatric Clinic, in Baltimore, and intern at Trudeau Sanatorium, in Trudeau, New York.

In 1938 and 1939 Dr Clark made a survey of group medical practice and medical service prepayment plans in various parts of the country. In the latter year he became a commissioned officer in the reserve corps of the United States Public Health Service, and for the next several years was en-

gaged largely in studies of the organization and administration of medical care programs. From 1941 through 1948 Dr. Clark also lectured or conducted courses on medical economics and the distribution of medical care in several colleges and universities. He is at present associate professor of public-health practice at Columbia University College of Physicians and Surgeons and lecturer in medical economics at the School of Public Health of the Uni-

DEAN A. CLARK, M.D., B.Sc. (Oxon)

versity of California. Since August, 1945, Dr. Clark has been on leave of absence from the Public Health Service devoting his time to the medical direction of the Health Insurance Plan of Greater New York.

Dr. Clark obviously brings to this important post a wide experience and unquestioned talent in medical organization and administration. In these times when new and better ways are being sought through which to deploy the services of medicine, expert guidance is needed in every area. The Massachusetts General Hospital is to be congratulated on having found such an able successor to its long line of illustrious administrators.

BIOLOGIC ENIGMA

MANY mysteries of the animal kingdom, according to a feature story released by the University of Wisconsin News Service, remain unsolved, although ardent naturalists have spent years in their investigation.

Thus it is not known why the Scandinavian lemmings make their periodic marches into the sea, why ocean salmon return to their home streams to spawn, nor, parenthetically, why the north Atlantic whale, with thousands of miles in which to roam, picks Cape Cod, Massachusetts, as a place to drive himself irreversibly ashore. The residents of that famous resort would like to know.

The Wisconsin scientists, intrigued by these biologic enigmas, have turned their attention to the migratory habits of bats, with particular reference to the locations that they select for their winter hibernation. Banding expeditions have been conducted in the abandoned mines, the caves and deserted houses of northern Wisconsin, but the bats discovered have been far fewer than those known to inhabit the region in the summer, and have been mostly males. When the search is extended, the belfries of the countryside will not be overlooked.

In the summer, females are discovered in great numbers in the local attics, where they bear (perhaps in place of gifts) their young. Apparently the hibernating males, despite their bachelor habits, have found an answer to the question (a sign of good breeding), "Shall we join the ladies?"

More light is shed on the same problem by the discovery that bats may be divided into two types: the social, who hibernate in colonies and presumably join the ladies, and the nonsocial, — the Chiropterous counterparts of the lone wolf and the bank beaver, — who, shunning the stag lines, are rarely found in groups and may migrate to distant climes in winter.

Perhaps the work with banding, Wisconsin News Service volunteers, will solve this mystery of the missing bats.

NOTES FROM THE MEDICAL EXAMINER

DEATH DUE TO CONFLAGRATION

Approximately 10,000 deaths per year in the United States are caused by burning or by other lethal attributes of conflagrations. In almost a quarter of these the victim is found dead at the scene of the fire. Such deaths are investigated by the medical examiner or coroner. Although the majority are due to the fire and are accidental, this is not invariably the case. Willful destruction of a dead body by fire may be an attempt to perpetrate an insurance fraud or to conceal a homicide. It is the purpose of this communication to review briefly the effects of conflagrations that are most frequently responsible for death on the premises and to discuss certain post-mortem characteristics of burned bodies that are likely to be of medico-legal importance.

One or several factors may be responsible for death during and because of a conflagration. Usually, smoke is inhaled before there is significant exposure to heat, and frequently the victim is unconscious or dead before there has been burning of the skin.

Although the composition of smoke varies enormously according to the type of fuel, the amount of oxygen available to support combustion, the temperature attained, and the extent to which the smoke has been diluted with air it almost invariably contains a dangerous amount of carbon monoxide. In a smoke-filled room the concentration of this gas is often so great as to cause loss of consciousness within a few minutes. In the case of smoldering fires dangerously high concentrations of carbon monoxide may be present in air that has so little visible smoke that it is erroneously regarded as safe to breathe. Even though the amount of carbon monoxide is not excessive carbon dioxide may be present in a concentration high enough to cause rapidly fatal asphyxia. Rarely is the oxygen content of smoke so low as to result in oxygen starvation.

If neither the carbon monoxide nor the carbon dioxide content of the smoke is high enough to cause asphyxia, various irritating combustion products may cause suffocation owing to rapidly developing edema of the air passages or lungs. Irritants contained in smoke derived from organic materials likely to be burned in an ordinary fire include acetic acid, aldehydes, ammonia, formic acid, furfural, pyroigneous acids, resins, saturated and unsaturated hydrocarbons and tar. Superheating of fats and certain oils causes the formation of highly toxic acrolein. Hydrogen cyanide and sulfide are both liberated in large amounts in the burning of wool. Highly irritating anhydrides of nitrogen are generated by the burning of various plastic and synthetic nitrocellulose compounds. All these

combustion products are injurious to the respiratory membranes and are capable of causing rapidly obstructive edema.

Failure to find evidence of smoke inhalation in the body of a person found dead at the site of a conflagration should lead to the suspicion that death occurred before the fire started. If the victim was alive and breathed smoke, carbon is usually present in the medium and small bronchi in amounts sufficient to cause a gray or gray-black discoloration. Usually, chemical irritants in the smoke cause an outpouring of mucus and the development of an intense hyperemia of the mucous membranes. As a rule the carbon monoxide content of the blood is significantly elevated.

It is true that some of the victims who die at the site of a conflagration do so because of burning when circumstances are such that fatal burning takes place before sufficient smoke has been inhaled to cause asphyxia or unconsciousness. Extensive and severe burning of the surface of the body may result in rapidly fatal circulatory failure because of peripheral vascular collapse and shock. If the victim is sufficiently close to flame to receive burns of the face the inhalation of heat may cause thermal injury of the larynx, with fatal laryngeal edema.

It is sometimes desirable to appraise cutaneous burns in terms of whether they were received before or after death. Fluid-filled blisters in association with cutaneous burning indicate vital reaction, unless putrefaction has started. If putrefaction has begun vesication may be a post-mortem artifact. Another artifact frequently encountered is the steam blister. When skin is superheated, whether it is live or dead, sufficient steam may be generated beneath an intact epidermis to cause it to become elevated. Such blisters either rupture immediately or collapse as soon as the skin cools and never contain fluid. The finding of a zone of edema and hyperemia at the junction of burned and unburned tissue is evidence of vital reaction. Although recognition of vital reaction establishes the fact that burning occurred during life, its absence does not necessarily exclude the possibility of ante-mortem thermal injury. Burning that began before death may be completely obscured by the continued application of heat after death.

The continued application of heat after death may cause the skin to contract and split with the formation of deep fissures that to the inexperienced observer resemble knife wounds. Protracted exposure of the dead body to intense heat causes the extremities to flex and to assume curiously distorted attitudes. The bones of a badly burned body become so brittle that they can be broken by the stream of water from a fire hose or in the removal of the body from the place of the fire. If the neck is badly burned the laryngeal cartilages often warp in such a manner as to occlude the airway. The hyoid bone may become so fragile as to break on manipulation.

Expansion of the intracranial contents by heat may cause the cranial sutures to separate and the calvarium to fracture in an explosive manner. Such thermal changes in the skull are often accompanied by massive epidural extravasation of blood from the great venous sinuses. Unless there is unmistakable external evidence of violence to the head the diagnosis of ante-mortem head injury in a case of a badly burned body should be made with great caution. The finding of subdural or subarachnoid bleeding or cerebral contusion or laceration may be prerequisite to recognition that skull fracture was probably ante mortem and due to physical violence rather than to heat.

No matter how badly burned the body, an adequate post-mortem examination may provide information to identify the dead person, to determine the time of death in relation to that of the fire and to establish the cause and manner of death. The physical characteristics of the body may not be consistent with those of the person it is supposed to represent. Death may have resulted from some other cause before the fire. It may be found that the decedent perished by fire because he was incapacitated by antecedent disease, injury or intoxication.

Professor of Legal Medicine
 Harvard Medical School

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

PROGRAM FOR PREMATURE INFANTS

The program for the care of premature infants, established by the Division of Maternal and Child Health of the Massachusetts Department of Public Health in 1937-1938, was the first state program in the United States. At that time state-wide publicity was provided. During the ensuing years there have been many changes in local medical, nursing and board-of-health personnel so that it seems advisable again to outline the program in order that all concerned with the care of the premature infant may be cognizant of the facilities available for their care.

At the beginning of the program 48 hospital centers outside Boston adequately equipped to care for premature infants were established on a geographic basis so that infants born outside these centers would have a relatively short distance to travel for care.

Since then the licensing of hospitals has come into the Department of Public Health, with resulting improvement in standards of nursery care in many hospitals having maternity service other than the original centers. There are also in the city of Boston several hospitals equipped for care of premature infants brought in from outside areas.

In 1937 and 1939 legislation was passed allowing for transportation, if requested by physician and parent by the local boards of health, to hospitals equipped for care and for payment of reasonable hospital expenses of such infants by local boards of welfare when parents need such help without the parents' being deemed on public relief.

To facilitate these services the physician delivering the premature infant in the home is required by law to report such a delivery by telephone as soon as possible, and also in writing within twenty-four hours to the local boards of health and welfare. For premature infants born in the hospital the hospital superintendent is responsible for reporting to the local board of welfare of the town where the infant was born. The board of welfare of the town of settlement will reimburse the board of welfare of the town where the infant was born for hospitalization, provided the expense is incurred within ten days prior to the notice.

Thus, Massachusetts has made provision for reporting of all premature births, for transportation and for payment for hospitalization of the premature infant, and a group of hospitals is equipped to give adequate care.

The facilities for transportation and hospitalization appear to be the factors in the program that are least well known by physicians. It is thus the purpose to endeavor to bring these to the attention of the readers of the *Journal*. A number of hospitals have transportation facilities in the form of heated ambulances and baskets or cases for carrying premature infants that will keep the baby warm in transit. It is suggested that physicians make inquiries of the hospital, board of health or visiting-nurse association in the towns in which they practice regarding the methods of obtaining this service in emergency. It is further suggested and even urged that the premature infant be transported to the nearest hospital adequately equipped for care instead of being subjected to a long journey to a distant center. This may prevent infant deaths. It would be advisable to telephone to the hospital of choice in advance to ensure admission of the patient and to obtain any transportation facilities that the hospital is able to provide.

In 1947 a series of regional institutes for hospital administrators were conducted for the discussion of hospital nursing standards. Standards for care of the premature infant were included.

Before the war a refresher course was provided for all nursery supervisors in the hospital centers. Changes in personnel have occurred, and refresher courses are now being given again to new nursery supervisors, 26 nursery supervisors will have completed this course by July 1. It is planned to continue these courses until all are accommodated.

In communities where public-health nursing service in the field of infant-health supervision is available, help can be given to the mother after the

infant leaves the hospital. Under the supervision of the physician the public-health nurse will help the mother to prepare for the baby's homecoming. She will also demonstrate bathing and other care recommended by the physician and will make periodic visits to the home and progress reports to the physician. This is a good preventive health measure and also gives the mother confidence in caring for her baby. When such assistance is desired the physician or the hospital should notify the public-health nurse of the date of discharge as far in advance as possible.

FLORENCE L. MCKAY, M.D.

Director, Division of Maternal and Child Health

DIRECTIONS FOR IMMEDIATE CARE OF PREMATURE INFANTS

The Massachusetts physician who delivers a premature infant in one of the approved hospitals listed in Table 1 will have full physical and nursing

facilities at hand for the baby's care. Should a physician be present at or called in after a premature delivery in another hospital or at the mother's home, his primary responsibilities are to

keep the infant under the best possible circumstances until it is admitted to an approved nursery, and to see that this admission is promptly accomplished.

The immediate care of the infant should be largely a matter of ensuring warmth and protection from potential sources of infection. The only word necessary regarding feeding is a warning against any attempts in that direction until the baby has been

placed under proper nursing care and environment, and even then a day or two without feeding is recommended.

Warmth should be a matter of seeing that the body temperature does not fall after birth rather than of applying heat once the baby becomes cold. Any covering that is clean, soft and prevents heat conduction is satisfactory. A sterile towel, or, failing that, a clean towel, wrapped about the body and scalp, with several thicknesses of soft blanket wrapped over towel and infant, is ideal. A hemostat may be left on the cord until a proper tie can be applied in the nursery to which the infant is sent. Thus covered, the infant may be laid near a radiator or stove or in whatever warm area is available. Serious burns may result from the hasty use of hot water bottles, which should not be needed if the procedures mentioned above are performed expeditiously.

Protection from infection means, mainly, protection from people. Speed in removal to a proper premature nursery will accomplish this and better than will any other activity. It may here be stated that these infants have remarkable powers of survival for the first several hours after birth, so that it is usually not necessary that they be frequently unwrapped or otherwise disturbed for inspection.

A list of hospitals with nurseries properly equipped and staffed for care of premature infants is presented in Table 2. It should be possible to trans-

Expansion of the intracranial contents by heat may cause the cranial sutures to separate and the calvarium to fracture in an explosive manner. Such thermal changes in the skull are often accompanied by massive epidural extravasation of blood from the great venous sinuses. Unless there is unmistakable external evidence of violence to the head the diagnosis of ante-mortem head injury in a case of a badly burned body should be made with great caution. The finding of subdural or subarachnoid bleeding or cerebral contusion or laceration may be prerequisite to recognition that skull fracture was probably ante mortem and due to physical violence rather than to heat.

No matter how badly burned the body, an adequate post-mortem examination may provide information to identify the dead person, to determine the time of death in relation to that of the fire and to establish the cause and manner of death. The physical characteristics of the body may not be consistent with those of the person it is supposed to represent. Death may have resulted from some other cause before the fire. It may be found that the decedent perished by fire because he was incapacitated by antecedent disease, injury or intoxication.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

PROGRAM FOR PREMATURE INFANTS

The program for the care of premature infants, established by the Division of Maternal and Child Health of the Massachusetts Department of Public Health in 1937-1938, was the first state program in the United States. At that time state-wide publicity was provided. During the ensuing years there have been many changes in local medical, nursing and board-of-health personnel so that it seems advisable again to outline the program in order that all concerned with the care of the premature infant may be cognizant of the facilities available for their care.

At the beginning of the program 48 hospital centers outside Boston adequately equipped to care for premature infants were established on a geographic basis so that infants born outside these centers would have a relatively short distance to travel for care.

Since then the licensing of hospitals has come into the Department of Public Health, with resulting improvement in standards of nursery care in many hospitals having maternity service other than the original centers. There are also in the city of Boston several hospitals equipped for care of premature infants brought in from outside areas.

In 1937 and 1939 legislation was passed allowing for transportation, if requested by physician and parent by the local boards of health, to hospitals equipped for care and for payment of reasonable hospital expenses of such infants by local boards of welfare when parents need such help without the parents' being deemed on public relief.

To facilitate these services the physician delivering the premature infant in the home is required by law to report such a delivery by telephone as soon as possible, and also in writing within twenty-four hours to the local boards of health and welfare. For premature infants born in the hospital the hospital superintendent is responsible for reporting to the local board of welfare of the town where the infant was born. The board of welfare of the town of settlement will reimburse the board of welfare of the town where the infant was born for hospitalization, provided the expense is incurred within ten days prior to the notice.

Thus, Massachusetts has made provision for reporting of all premature births, for transportation and for payment for hospitalization of the premature infant, and a group of hospitals is equipped to give adequate care.

The facilities for transportation and hospitalization appear to be the factors in the program that are least well known by physicians. It is thus the purpose to endeavor to bring these to the attention of the readers of the *Journal*. A number of hospitals have transportation facilities in the form of heated ambulances and baskets or cases for carrying premature infants that will keep the baby warm in transit. It is suggested that physicians make inquiries of the hospital, board of health or visiting-nurse association in the towns in which they practice regarding the methods of obtaining this service in emergency. It is further suggested and even urged that the premature infant be transported to the *nearest* hospital adequately equipped for care instead of being subjected to a long journey to a distant center. This may prevent infant deaths. It would be advisable to telephone to the hospital of choice in advance to ensure admission of the patient and to obtain any transportation facilities that the hospital is able to provide.

In 1947 a series of regional institutes for hospital administrators were conducted for the discussion of hospital nursing standards. Standards for care of the premature infant were included.

Before the war a refresher course was provided for all nursery supervisors in the hospital centers. Changes in personnel have occurred, and refresher courses are now being given again to new nursery supervisors, 26 nursery supervisors will have completed this course by July 1. It is planned to continue these courses until all are accommodated.

In communities where public-health nursing service in the field of infant-health supervision is available, help can be given to the mother after the

ANNUAL ORATION

SOME RESPONSIBILITIES OF MEDICAL EDUCATION*

C SIDNEY BURWELL, M D †

BOSTON

TO DELIVER the Annual Oration of the Massachusetts Medical Society is an honorable privilege, for which I am grateful

For almost fourteen years, as dean of the Faculty of Medicine, I have had the chief responsibility for the administration of the Harvard Medical School. This experience is the reason for my choice of subject and presumably the basis of the Society's choice of an orator. The organization and progress of medical education have been my chief preoccupation for these fourteen years, and I welcome the opportunity to place on record my faith and my optimism regarding it. As I have contemplated medical schools in general and the Harvard Medical School in particular, I have been asking myself with special insistence what are these schools for, and what are they trying to accomplish? Even a general answer to these questions could be useful. In the next few weeks I shall leave the dean's office to return to teaching and research, hoping, as one may say, to regain my amateur standing, and so I speak with a particular sense of freedom and entirely for myself, not as a dean, but as a private citizen who has had some experience with these problems.

There are many reasons why it is pleasant to meet in Worcester. One is that it gives an opportunity to look at medical schools from a distance of some forty miles—a circumstance calculated to permit a view of the forest without being lost among the trees.

Members of the medical profession are not apt to consider the Army and the Navy as academic organizations, or to expect them to excel in educational enterprises. Nevertheless, some of the training programs of the armed forces during the war held lessons for formal educational organization. These training programs taught selected

young men to fly, to detect submarines, to carry a gun or to speak German in what seemed to many professional educators a surprisingly short period. If one seeks causes for the success of these programs, so far as they were successful, he is apt to conclude that one factor was that the organizers of these programs were able to define with great clarity and simplicity the program's objectives. They were able to say what knowledge, what skills, what habits of mind and muscle they wished the trainee to acquire, and they could eliminate with complete ruthlessness any material, any exercise, any point of view that did not contribute to these specific and limited ends. The organizers of these training programs were not concerned with general education or with a distant future, but with an immediate, limited and definable goal. Moreover, they were able to select their candidates freely and to weed them out without hesitation.

I should be the last to deny that there are many differences between Army or Navy or Air Force training and medical education, but I do submit that medical schools would have better organization and planning if there were clearer understanding and better agreement as to the objectives of the medical school program.

The responsibilities of medical schools, to my mind, may be summarized in six major categories:

PROVISION OF INSTRUCTION LEADING TO THE DEGREE OF DOCTOR OF MEDICINE

When the Harvard Medical School began its work one hundred and sixty-seven years ago, its faculty was mainly concerned with offering instruction to prepare men directly for practice. The faculty of today continues to accept as a primary responsibility the provision of instruction leading to the M D degree, a course that is still the basis of an informed and competent profession. As we approach a discussion of this first basic objective, the undergraduate course, we encounter the theme

*Presented at the annual meeting of the Massachusetts Medical Society, Worcester, May 24, 1949.

†Dean of the faculty of medicine and research professor of clinical medicine, Harvard University physician, Peter Bent Brigham Hospital.

port an infant born anywhere in Massachusetts to one of these hospitals within less than an hour. Most of them have, or have access to, an artificially heated carrier, which can be placed in any automobile and sent out as a "premature ambulance." Plans are now maturing for the provision, by a generous donor, of such an "ambulance" wherever a survey now in process demonstrates that one is clearly needed. Most of those in present use have a connection by which they can be converted into oxygen chambers by the attachment of a portable oxygen tank.

All the physician need do is to telephone the nearest approved hospital at once, give details and arrange a plan by which the ambulance may be sent out. This often means dispatching the infant's father or other relative in a car or taxicab. The hospital can be warming the ambulance until his arrival, and not only should send the ambulance and oxygen with him but also should provide a nurse or house-staff member to watch over infant, ambulance and oxygen on the return journey. Since we have occasionally seen infants arrive at our own hospitals in supposedly oxygenated carriers in which no one had bothered to turn on the oxygen tank, the doctor may well make sure that those accompanying the baby to the hospital know how to use their equipment. He should also see to it that a proper history, or a person able to give such a history, accompanies the infant.

A word may be added about vitamin K and stimulants. Nothing of importance will be lost if the former is not administered till the infant arrives at the nursery where he is to be cared for. Stimulants are seldom called for and, unless given by those familiar with the care of premature patients, might often better be avoided. If the infant's condition is rapidly failing and there is unavoidable delay in his admission to an approved nursery, caffeine sodium benzoate, $\frac{1}{4}$ gr (16 mg), may be given intramuscularly, and repeated once if no improvement has occurred at the end of fifteen minutes.

NOTICES

AMERICAN COLLEGE OF PHYSICIANS RESEARCH FELLOWSHIPS

The American College of Physicians announces that a limited number of fellowships in medicine will be available from July 1, 1950, to June 30, 1951. These fellowships are designed to provide an opportunity for research training either in the basic medical sciences or in the application of these sciences to clinical investigation. They are for the benefit of physicians who are in the early stages of their preparation for a teaching and investigative career in internal medicine. Assurance must be provided that the applicant will be acceptable in the laboratory or clinic of his choice and that he will be provided with the facilities necessary for the proper pursuit of his work. The stipend will be from \$2200 to \$3200.

Application forms will be supplied on request to the American College of Physicians, 4200 Pine Street, Philadelphia 4, Pennsylvania, and must be submitted in duplicate not later than October 1, 1949. Announcement of awards will be made in November, 1949.

explosive expansion of knowledge in these areas and the growth of research in universities, institutes, hospitals, Government departments and industry create a demand for competent scientists in these fields that is simply not being met

Medical schools are now facing, more clearly than before, their share of responsibility for the basic training of these indispensable people. Adequate provision for training the successors to the present generation of such scientists is a part of the duty of universities and medical schools and one of the methods for expanding total medical personnel. Harvard University attempts to meet the problems by an ingenious collaboration between the pre-clinical departments of the Medical School, on the one hand, and the Faculty of Arts and Sciences on the other—a strong and useful combination called the Division of Medical Sciences. Before the war there were some 10 men a year in training as Ph.D. candidates in this division. This year there are 50—an example of a fivefold expansion of one part of the program of medical education. If medical schools do not accept their share of responsibility for training successors to the leaders of the medical sciences, teaching will suffer and the broad and expanding program of medical research will be restricted and injured.

ADVANCEMENT OF KNOWLEDGE BY RESEARCH

The advancement of knowledge is a fundamental university objective, and a major responsibility of medical schools. These schools are in a position of peculiar advantage, standing as they do between the science departments of the university on the one hand and the great teaching hospitals on the other. The research armies of a medical school can make their attack on a wide front and have the enormous advantages of diverse talents and an integrated program. Medical schools, in my opinion (by some considered a prejudiced one), have in the long run great advantages over other forms of organization for medical research, such as research institutes and hospitals. The special advantages of medical schools as research centers include the favoring presence of students and the possibility of a broad, well based spectrum of research running from the infrared of the bedside to the ultraviolet of the basic sciences in the university. It is my conviction that research is not only an opportunity but also a duty of medical schools and that its spirit and performance should be expected of each professor (in varying kind and degree) and of every department. I am equally concerned that teaching (of varying kind and degree) should be expected of every professor and every department. The integration, the mutual stimulation of teaching and research is the most healthful exercise undertaken by individuals or departments. There is no fundamental schism between research and teaching, or between different kinds of research.

In a recent valuable report of the "Medical Curriculum Committee of the British Medical Association" (under the distinguished chairmanship of Professor Henry Cohen of the University of Liverpool) the following wise sentences occur:

Claims of precedence or rivalry between clinician and laboratory researcher are falsely based and senseless, in Medicine, one cannot exist without the other, each must contribute his quota to the ultimate objective—the promotion of health, the relief of suffering and the elimination of disease in man. The scientific outlook and the humane approach in Medicine are complementary.

Research as an essential function of medical schools needs no defense: it advances knowledge, it helps all teaching, and it is indispensable to advanced training.

No one is going to quarrel very violently with the ideas expressed that training for the M.D. degree, training for the Ph.D. degree in medical sciences and research over a wide front are primary and pressing objectives of medical schools. Controversy, uncertainty and lack of knowledge are much more apparent when we come to consider the next objective.

PROVISION OF OPPORTUNITY FOR ADVANCED TRAINING FOR PRACTICE, TEACHING AND RESEARCH

What are the varieties of advanced training that may concern medical schools? Let me illustrate by describing the situation as I see it in the Harvard Medical School at the moment. There are at least three groups of individuals to whose advanced training the medical school has some relation. First, there are about 175 students classified as research fellows. This long list includes doctors of medicine and doctors of philosophy in various medical sciences. They are learning by doing in the field of research and to some degree in the field of teaching. They participate in the work of research teams as a means of equipping themselves to do research on their own. It is from this kind of group that many of the teachers and investigators of the next generation will come. Medical schools clearly have a primary responsibility for providing opportunity to these men. It is a logical place for such work to be located because teachers and investigators in the medical sciences require experience in departments of medical sciences, and these exist, on the whole, in medical schools. It is equally important, to my mind, that the growth of investigators in clinical fields should also be centralized in medical schools because I believe that the evidence of the last twenty years indicates that the clinical investigators of this generation are not able, by themselves, to train the clinical investigators of the next generation, but that the evolution of these investigators, if they are to be effective, requires the help of medical-science departments of medical schools.

The second group is also a large one, less precisely related to the medical school, but clearly influenced

of this address, if it can be said to have one. That theme is as follows: a characteristic of twentieth-century medicine is *rapid change* in knowledge and in practice.

In David McCord's* anthology of light verse, there is a composition by Mr. Newman Levy that concerns the characteristically rapid change of modern life. It is entitled "I Wonder What Became of Rand, McNally," and the most relevant verses run thus:

Mr. Rand and Mr. McNally,
Arbiters of hill and valley,
Portraitists of sea and land,
Mr. McNally and Mr. Rand
Two sad cartographic chaps,
Sat in their office surrounded by maps
Globes and maps around the room,
And on *their* maps a look of gloom.

"Time was when this business of ours was grand,"
Said Mr. McNally to Mr. Rand,
"When our toughest job was to sit and think
Shall France be purple and Britain pink?
Shall Spain be tinted a bright cerise,
And perhaps a dash of green for Greece?"

"But that," said Rand to Mr. McNally,
"Was before Benito got rough with Halie,
When we didn't fret about changing borders,
And we just sat here receiving orders."

"Remember those days," McNally said,
"When we'd plan a map a month ahead,
And we'd know, if it came out at noon, let's say,
It was up to date the entire day?"

"Those days," said Rand, "are gone *totally*."
"You said it, brother," said Mr. McNally.

The changes of the recent past have multiplied the variety of careers in medicine. Those equipped with medical training may translate it into the practice of surgery or of psychiatry, into general practice or that of ophthalmology. They may go into research and work with methods as diverse as those of nuclear physics, of statistics and of psychoanalysis. They may go into teaching, or into hospital or medical-school administration. The basic course, then, must *be* a basic course, not aimed simply or singly at preparing men for any one of these careers, but qualified to serve as a foundation for all. It must do better than this, it must serve as a foundation for types of careers that are still unknown but that will surely evolve in the years ahead.

A suitable plan of instruction, in a changing world, is concerned with developing in students not only knowledge of facts, not only good ways of using facts, but in particular, and at all possible times, providing a basis for understanding facts. Medicine should be taught, so far as our knowledge permits, in terms of the mechanisms of the phenomena of health and disease, thinking all the time about "why" and seeking always (to borrow a phrase from that rich source of memorable phrases, Mr.

*McCord D. T. W. *What Cheer: An anthology of American and British humorous and witty verse gathered, sifted and salted*. 515 pp. New York: Coward-McCann Inc., 1945.

Winston Churchill) "the unique and inexorable sequence of cause and effect."

Teaching based on this principle is often successful and stimulating, one is tempted to think that emphasis on mechanisms and sequences is perhaps the chief merit of modern medical education. There is another point in favor of this philosophy. If one believes that a chief function of what we may agree to call undergraduate medical education is to establish a basis for the continuing self-education of graduates, then emphasis on understanding is of central importance. The war was a testing ground for men and for methods of education. Many colleagues, on the basis of their war experience, have brought forcibly to my attention two attributes of the young physicians who during the war were best able to adapt themselves to unfamiliar varieties of medical activity. Let us remember that these unfamiliar varieties of medical activity were carried on under unfamiliar and difficult circumstances and by unfamiliar methods. These attributes of professional success were, first, stability and integrity of character, and, second, a good basic understanding of disease in terms of pathology, physiology, immunology, psychobiology and the other general formulations that underlie our understanding of the interactions of man and his complex and changing environment. Such attributes permit a young man to adjust himself to the unfamiliar tasks of military medicine and permit him to adapt himself to and utilize the changes brought about by the advance of knowledge.

I conclude that a major objective of medical schools is to provide the M.D. candidate with educational opportunity planned to let him acquire an understanding of the mechanism and the natural history of man and his diseases. The degree is not a certification of fitness for practice, it is a certification of basic medical training—the decision of readiness for practice is another. In the United States the several states reserve to themselves the right to say when a physician is ready and suitable to practice his profession.

So much for this indispensable objective and duty of medical schools in training physicians for participation in the medicine of the future by the provision of instruction leading to the ancient and worthy degree of Doctor of Medicine.

PROVISION OF INSTRUCTION LEADING TO THE DEGREE OF DOCTOR OF PHILOSOPHY IN ONE OF THE MEDICAL SCIENCES

There is an over-all shortage of physicians. This assertion is the subject of general agreement although no two people are agreed about the degree of the shortage. But, however severe this shortage is, there is another shortage even more severe: that of teachers and investigators in the fields of the "medical" sciences such as physiology, biochemistry, pharmacology, pathology and bacteriology. The

We may ask ourselves, "What is the essence of his plan of graduate education?" It is, I think, quite simple. First, he assumed the responsibility for planning and carrying out the program of his own continuing education. Second, he defined his goal. He drew the specifications of the kind of life he wished to have and the kind of doctor he wished to be. Third, he systematically, patiently and industriously acquired the skills, the knowledge, the judgment based on experience that made it possible for him to be that kind of doctor. In general, that is the way I think advanced training should be managed, with a minimum of specification from schools or boards and with a maximum of individual responsibility.

PARTICIPATION IN COMMUNITY SERVICES, IN THE PROVISION OF MEDICAL CARE, PREVENTION OF DISEASE AND EDUCATION OF THE PUBLIC

The medical school as compared with other parts of universities stands in a special relation to the larger community. An important part of the teaching in the medical school is carried on by university appointees working in hospitals and by the participation of both teachers and students in the actual work of community service institutions, such as hospitals. As a part of its university function, therefore, the medical school actually takes part in the provision of community service. In the provision of such service, university personnel and university organization have certain special obligations. One is to see that the community services in which the university participates attain a quality that the university is willing to see accepted as an example of standards of performance that medical students may follow. In medical care, for example, medical-school teachers must set an example not only of technical competence but also of humanity, of the treatment of the whole person, of the utilization of community resources, of the recognition of environmental factors and of all the varieties of professional responsibility. When such an example is set, the medical school is serving the cause of education, is assisting the hospitals and is helping the community.

RECRUITMENT AND SELECTION OF MEDICAL PERSONNEL

So far we have considered the objectives of the medical school as they relate to the basic instruction of prospective physicians, leaders in the medical sciences, teachers and investigators, the responsibilities of the medical schools as centers for the creation of new knowledge and its relation to community activity. There is another responsibility that needs to be discussed and that in some ways is fundamental to all the rest. It is this: in general, medical schools are responsible for the *recruitment* and *selection* of the individuals who will make up the medical profession of the next generation. They

play the role of the guardians of the gate, of St. Peter or of Cerberus, according to one's point of view. Obviously, the quality of the group so admitted to the profession depends upon two major factors: first, what individuals apply to medical schools for admission, and, second, what individuals are selected from the applying group?

In the past, most of the thought and time of faculties of medical schools have been concerned with the matter of selection. Perhaps it is now time for the faculties, and indeed for the medical profession, to give consideration to the still broader problem of the factors that attract men to the profession of medicine and those that repel them. These recruitment factors are partly the responsibility of medical schools and partly that of the profession at large. The factors that attract men to medicine include such diverse influences as their interest in science or in human beings, the tradition of their families, the romantic attraction of the profession, the prestige of medicine and its opportunities for service, for research and for a life of dignity and community standing. The factors that repel men from medicine include the cost of education, the ever-increasing prolongation of the training and the uncertainty of the future. It is not always recognized that in a changing world the professions that have a long training period are apt to be at a disadvantage so far as recruitment is concerned because it is so difficult to prophesy what the state of the profession will be when the long training has been achieved. At any rate, a systematic study of the factors that lead men to enter or to refrain from entering medicine is an important job for someone to do in the future.

Selection is a perennial problem. No one is satisfied with the methods, and no experienced person is prepared to suggest the ideal procedure. What is sought here, since we are talking about objectives, is a student body made up of individuals who have the intellectual capacity to deal with the prodigiously complicated and a rapidly changing period of medicine, who have the integrity and moral strength that we call character, and who represent wide varieties of talent and interest so that they can play successful roles in the extraordinarily diverse parts of the medical spectrum. To end up with a superior profession requires a wide variety of superior applicants, skillful admission committees, and *freedom to select the best men*.

The recognition of intellectual superiority is easier by formal tests than judgment of character. So far, selection by formula has not been as successful as a combination of statistical material with the judgment of experienced teachers. As has been repeatedly emphasized, they are being selected for general practice, for highly technical specialties such as ophthalmology, for surgery, for psychiatry, for research in fields as diverse as nuclear physics and the unconscious mind, for teaching, for administration, for careers in the sciences underlying medi-

by many members of its faculty. This is the group receiving advanced training for practice, including house officers in the hospitals in which Harvard Medical School teaching is done, and also those who attend the so-called "courses for graduates." This is the field in which the least clarity regarding the role of the medical school exists. Obviously, medical schools cannot be responsible for all or even a large part of advanced training for practice, so that this is peculiarly an area in which definition of objectives and roles of different organizations is urgently needed.

The situation is made more of an emergency by the rapid development of specialty boards and the expansion of their requirements. To my mind, a particular danger threatens advanced training of these types. It is in danger of becoming stereotyped by over-organization, and so becoming preparation for the medicine of today or even yesterday, rather than for the medicine of tomorrow. This danger threatens M.D.'s (in training for practice, teaching and research in medicine) more than it does Ph.D.'s (in training for similar work in the medical sciences).

A point of view relating to this problem may be described in terms of the following case history.

Among the figures that stand out in the great army of men who have contributed to our knowledge of heart disease is the slender silhouette of James Hope. James Hope was born at Stockport in the county of Cheshire, England, on February 23, 1801. The grammar school at Macclesfield having given him what it could, he determined on a career in the law. Before he embarked on this course, however, he went into the Yeomanry Lancers (at the age of eighteen) and spent a year in military service, or something approaching it. At the age of nineteen he began the study of medicine at the University of Edinburgh. His medical-school career was somewhat irregular, since he left the school before the end of his final year to take an excellent hospital post that offered itself at that time. He took this job with the blessing of the faculty and returned in 1825 to present his thesis and to take his degree. At the time of his graduation, Hope was twenty-four years old, intelligent, able, ambitious and possessed in a high degree of a most valuable characteristic, the habit of effective and unremitting industry.

As a medical student he had paid particular attention to pathological anatomy and to pathological physiology, believing those subjects to be the basis of intelligent practice. He had developed a native talent for drawing to great facility in medical illustration and had already begun the collection of drawings of specimens obtained at autopsy that were to be used in his own books later on. He proposed as his own goal to be a highly competent internist, with special interest and skill in the field of cardiovascular disease, and he set out to train himself to be the kind of person he wanted to be.

First, he took a dressership at St. Bartholomew's Hospital because he was convinced by his own observations that medical people did not know enough about surgery. This was followed by a year in Paris in the exciting atmosphere of the great French clinical school. He reached Paris in 1826. Laennec had just died (of tuberculosis), but Chomel was professor of clinical medicine at La Charité, and working with him were Andral, Louis and other stimulating teachers. Hope spent a month acquiring facility in speaking and understanding French and then went to work in ward and autopsy room. He labored not only to learn and to understand but also to perfect himself in the newer technics of physical diagnosis. No doubt some of his colleagues thought his diligence wasted, since many of these technics were so new that there was no general agreement about their future importance in the practice of medicine. After this year of rich clinical experience in France, he worked systematically for another year in the hospitals of Italy, Bavaria and Holland. At twenty-seven he was, as he had set out to be, a well trained internist with a broad clinical experience and with a special competence in the field of his interest. He knew the literature, he knew the men, he knew the subject. He was skilled in the technical aspects of the field and had had some exposure to the methods of thought and the methods of procedure of experimental medicine. He began his practice. At thirty he published a treatise entitled "The Diseases of the Heart and Great Vessels" — a book that Dr. Herrick, in his short *History of Cardiology*, says, "Outclassed all other books on the subject that had then been published." Dr. Herrick goes on to say further:

Hope struck a new note in the literature of heart disease. His volume has a modern ring to it. His discussion of the anatomy and physiology of the heart, heart murmurs and other physical signs is thorough and scientific with conclusions drawn from a study of the writings of others, as well as from his own experimental and clinical observations.

Hope's book had a deserved success. He influenced the practice of medicine in England, in Continental Europe and in America. My conclusion is that in spite of his untimely death from tuberculosis at the age of forty James Hope made important contributions to our knowledge of medicine and to its translation into practice. I do not suggest that he be taken as a complete model for young men in medicine. He was able and useful, but he had defects of character that made his ultimate stature less than it might otherwise have been. He was egocentric, jealous and hypersensitive, and neither generous nor fair in controversy. But in spite of these limitations of character it seems reasonable to conclude that his plan for the advanced training of James Hope was a successful one.

We may ask ourselves, "What is the essence of his plan of graduate education?" It is, I think, quite simple. First, he assumed the responsibility for planning and carrying out the program of his own continuing education. Second, he defined his goal. He drew the specifications of the kind of life he wished to have and the kind of doctor he wished to be. Third, he systematically, patiently and industriously acquired the skills, the knowledge, the judgment based on experience that made it possible for him to be that kind of doctor. In general, that is the way I think advanced training should be managed, with a minimum of specification from schools or boards and with a maximum of individual responsibility.

PARTICIPATION IN COMMUNITY SERVICES, IN THE PROVISION OF MEDICAL CARE, PREVENTION OF DISEASE AND EDUCATION OF THE PUBLIC

The medical school as compared with other parts of universities stands in a special relation to the larger community. An important part of the teaching in the medical school is carried on by university appointees working in hospitals and by the participation of both teachers and students in the actual work of community service institutions, such as hospitals. As a part of its university function, therefore, the medical school actually takes part in the provision of community service. In the provision of such service, university personnel and university organization have certain special obligations. One is to see that the community services in which the university participates attain a quality that the university is willing to see accepted as an example of standards of performance that medical students may follow. In medical care, for example, medical-school teachers must set an example not only of technical competence but also of humanity, of the treatment of the whole person, of the utilization of community resources, of the recognition of environmental factors and of all the varieties of professional responsibility. When such an example is set, the medical school is serving the cause of education, is assisting the hospitals and is helping the community.

RECRUITMENT AND SELECTION OF MEDICAL PERSONNEL

So far we have considered the objectives of the medical school as they relate to the basic instruction of prospective physicians, leaders in the medical sciences, teachers and investigators, the responsibilities of the medical schools as centers for the creation of new knowledge and its relation to community activity. There is another responsibility that needs to be discussed and that in some ways is fundamental to all the rest. It is this: in general, medical schools are responsible for the *recruitment* and *selection* of the individuals who will make up the medical profession of the next generation. They

play the role of the guardians of the gate, of St. Peter or of Cerberus, according to one's point of view. Obviously, the quality of the group so admitted to the profession depends upon two major factors: first, what individuals apply to medical schools for admission, and, second, what individuals are selected from the applying group?

In the past, most of the thought and time of faculties of medical schools have been concerned with the matter of selection. Perhaps it is now time for the faculties, and indeed for the medical profession, to give consideration to the still broader problem of the factors that attract men to the profession of medicine and those that repel them. These recruitment factors are partly the responsibility of medical schools and partly that of the profession at large. The factors that attract men to medicine include such diverse influences as their interest in science or in human beings, the tradition of their families, the romantic attraction of the profession, the prestige of medicine and its opportunities for service, for research and for a life of dignity and community standing. The factors that repel men from medicine include the cost of education, the ever-increasing prolongation of the training and the uncertainty of the future. It is not always recognized that in a changing world the professions that have a long training period are apt to be at a disadvantage so far as recruitment is concerned because it is so difficult to prophesy what the state of the profession will be when the long training has been achieved. At any rate, a systematic study of the factors that lead men to enter or to refrain from entering medicine is an important job for someone to do in the future.

Selection is a perennial problem. No one is satisfied with the methods, and no experienced person is prepared to suggest the ideal procedure. What is sought here, since we are talking about objectives, is a student body made up of individuals who have the intellectual capacity to deal with the prodigiously complicated and a rapidly changing period of medicine, who have the integrity and moral strength that we call character, and who represent wide varieties of talent and interest so that they can play successful roles in the extraordinarily diverse parts of the medical spectrum. To end up with a superior profession requires a wide variety of superior applicants, skillful admission committees, and *freedom to select the best men*.

The recognition of intellectual superiority is easier by formal tests than judgment of character. So far, selection by formula has not been as successful as a combination of statistical material with the judgment of experienced teachers. As has been repeatedly emphasized, they are being selected for general practice, for highly technical specialties such as ophthalmology, for surgery, for psychiatry, for research in fields as diverse as nuclear physics and the unconscious mind, for teaching, for administration, for careers in the sciences underlying medi-

cine and for fields of the future even the identity of which is as yet unknown. It is a nice assignment, and it does not lend itself to solution by a narrow formula.

William James said something to the effect that there is not much difference between one man and another, but that what difference there is turns out to be very important.

In summary, then, it appears that the objectives of medical schools include the following: the provision of instruction leading to the M.D. degree, the provision of instruction leading to the Ph.D. degree in medical sciences, the prosecution of research over a wide spectrum, the provision of ad-

vanced training for practice, for research and for teaching, participation in the community service of hospitals and other institutions of medical service, the recruitment and selection of the medical profession of the future.

* * *

In attacking these objectives, schools need the help, the support, the criticism and the understanding of the medical profession. It is a great and happy privilege to be able thus to present my concepts to this important part of our profession, the Massachusetts Medical Society.

THE EFFECT OF THE RICE DIET ON THE LEVEL OF THE BLOOD PRESSURE IN ESSENTIAL HYPERTENSION*

DOROTHEA G. LOOFBOUROW, M.D.,† ANNIE L. GALBRAITH, B.S.,‡ AND ROBERT STERLING PALMER, M.D.§

BOSTON

INTEREST in the influence of diet on the course of hypertension has existed for at least half a century. In 1904, in France, Ambard and Beaujard¹ advocated the use of a low-salt diet for the treatment of hypertension. In the early 1920's in this country Allen and Sherrill² and O'Hare and Walker³ reported on the use of low-salt diets in hypertension. These workers believed that the effect was produced by restriction of the chloride ion. Addison⁴ was among the first to suggest that the sodium ion was the important element, and came to the conclusion that "One has forced on one the concept that the prevalence of arterial hypertension on this continent (North America) is in large part due to potash poor diet and an excess use of salt (sodium chloride) as a condiment and preservative of meat." In 1920 Mosenthal⁵ discussed the influence of protein foods on the blood pressure, and concluded that restriction of this dietary component had little or no beneficial effect. In 1929 Berger and Fineberg⁶ reported on 13 patients on a low-sodium diet, stating that they failed to see any unquestioned blood-pressure modification that they could attribute to sodium restriction. Interest in the dietary treatment of hypertension lagged until 1944, when Kempner⁷ reported on the treatment of kidney disease and hypertensive vascular disease with the rice diet. Since that time there has been a renewal of interest. Many workers,⁸⁻¹¹ believing that the most important factor in the rice diet was the restriction of sodium chloride, have used a very low-sodium diet, which has otherwise met the accepted standards of adequacy in other food essentials (National Research Council

standards). Kempner's rice and fruit diet has been said to combine practically all the theories that have been advanced for the dietary treatment of hypertension, being low in sodium (200 mg), low in protein (20 to 25 gm), low in fat (5 gm) and restricting fluid intake to 800 to 1000 cc.

One naturally speculates about the rationale of using such a restrictive diet as Kempner's, which violates the accepted pattern of proper nutrition. Kempner¹² says, in a recent publication, "The treatment of hypertensive vascular disease with the rice diet was suggested by observations made on the protein, fat and carbohydrate metabolism of isolated kidney cells under various pathologic conditions (cell injury and/or changes in pH, sodium bicarbonate concentration, oxygen tension, and metabolizable substrate)." Working with damaged kidney tissue, he was led to consider the kidney as an organ of metabolism¹³ as well as an excretory organ. He postulated that pathologic conditions in the kidney lead to changes¹⁴ that may be summarized as follows: certain substances that are normally removed by kidney metabolism may be increased in amount, whereas other substances produced by the kidneys may be decreased in amount. These abnormal substances, which accumulate as a result of disturbed kidney metabolism, may be presumed to be harmful, and to be partially responsible, either directly or indirectly, for the production of hypertensive vascular disease. Kempner suggests, therefore, that the ordinary mixed diet may contain constituents that increase the production of these abnormal substances. By reduction of the elements of the diet that must be metabolized by the kidneys, the production of the abnormal substances is presumably reduced. This reasoning, *a priori*, accepts the renal etiology of hypertension. It is known that Kempner⁷ first used

the rice diet in treating hypertension resulting from kidney disease. Later, he extended the use of the diet to the treatment of essential hypertension.^{12, 11}

The enthusiastic reports of the treatment of essential hypertension with the rice diet by Kempner have stimulated many workers to attempt to evaluate this therapy.¹⁶⁻¹⁸ During the last year, in the Hypertension Clinic of the Massachusetts General Hospital we have used the rice diet as a method of treatment. Our study had been in progress for about nine months at the time this material was collected so that the number of patients is not large nor is the time elapsed sufficient to form conclusive opinions regarding the influence of this treatment on the course of such a disease as hypertension. We present this primarily as a progress report. In using the rice diet on clinic patients we hoped to determine whether this method of treatment is a practical one for use with ambulatory patients observed once a week while living in their normal surroundings and eating with other members of the family who are on a regular diet, and what clinical results are obtained when the treatment is applied to such a group.

METHOD

The patients in this study were taken from our regular clinic patients. Many had been followed for a number of years and therefore had a long control period, others were relatively new to the clinic and had a shorter control period. The group included patients with essential hypertension with and without renal involvement, the majority falling into the latter category. All patients were submitted to our routine workup, which includes history, physical examination, routine blood work, urinalysis, electrocardiograms, x-ray study of the chest, examination of the fundi, renal-function tests and determination of blood sodium, chloride, cholesterol, total protein and nonprotein nitrogen.

The patients advised to try the rice diet were seen weekly while on the strict rice diet. Although this made a heavy clinic load it was deemed important to follow the patients closely to pick up any evidence of sodium depletion in patients with poor renal function. Weights were recorded on admission to the clinic. At first each patient received individual instruction from the dietitian on the following diet:

- I *Rice* Each day 1 cupful of rice, measured before cooking, is used. This yields approximately 4 cupfuls of cooked rice. Brown, polished or white rice may be used. It should be boiled or steamed without salt, milk or fat. (No butter, margarine, drippings, lard, grease or salad oil is used.)
- II. *Fruits* Fresh, raw or cooked fruits are taken. Any fruit with the exception of avocados, dates and nuts may be eaten (no tomatoes). No more than 1 banana a day is taken. Canned fruit is allowed, if no preservative has been added (all labels should be inspected, especially the fine print, which may

mention artificial flavor or color, sodium benzoate, sulfur dioxide or corn syrup). Frozen fruits may also be used.

III *Sugar* Sugar is taken as desired (white only). Glucose (dextrose) may be used — it is less sweet and better tolerated by many people. Honey is permitted, but no maple sugar, corn syrup or molasses. Fruit and sugar jams and jellies — if pure — are allowed.

IV *Fruit juices* Any fresh or canned fruit juice may be used if it contains no artificial flavor, color or preservative. Tomato juice and vegetable juice are not allowed.

V *Fluids* Fluids are limited to 3 or 4 cupfuls of fruit juices a day. After the first three or four days, no additional water should be taken.

Special Instructions The patient is instructed to eat only the foods outlined on the diet and not to drink any tonics, root beer, sodas, gingerale or other carbonated beverages, no beer, ale, wine, whiskey, coffee or tea is permitted.

Later, the patients were seen in a group by the dietitian, and their problems were discussed and new ideas in fixing rice or fruit reported. There was a food display each week aimed at interesting the patients and demonstrating new methods of preparing rice or fruit combinations, using fruits that were currently in season. This produced a group motivation that we considered important in achieving close adherence to an unpalatable diet.

Each patient was seen individually at every visit by one of the doctors, who evaluated the symptoms as well as any physical changes that had occurred. The blood pressure was taken three times at each visit: on entrance, during the interview and just before departure. Modifications in the diet were ordered by the doctors, depending on the response to treatment, or if it became apparent that the patient was growing restive under such a stringent diet, modifications were made regardless of response. An attempt was made to follow Kempner's general plan in modifying the diet by the addition of items in the following order: white potato, low-sodium, nonleguminous vegetables, tea or coffee without milk, white meat of chicken, white fish or lean meat.

Several workers^{12, 19} have pointed out the importance of careful determination of the blood chemical constituents of patients on very low-sodium diets, especially those of patients with impairment of renal function. Our plan has been to order determinations (including sodium, chloride, cholesterol, nonprotein nitrogen and total protein) before the rice diet was started, and at frequent intervals (two weeks) while the patients were on the strict rice diet. In our experience a careful clinical follow-up study serves as a good protection for the patient. In the group of patients followed, only 1 developed a low serum sodium level (127 milliequiv per liter) and clinically this was apparent before the laboratory report had been returned.

The frequent determination of twenty-four-hour urinary chloride excretion is important to determine how closely a patient is adhering to the diet. On an average diet the excretion of urinary chlorides

varies from 125 to 175 milliequiv per liter in twenty-four hours, on the strict rice diet the excretion falls to 10 milliequiv or below. By use of this determination we separated our patients into the following classes: strict adherents, moderate adherents and delinquents. All patients whose urinary chloride excretion fell to 10 milliequiv per liter or below on the diet were called strict adherents, whereas those with excretions between 10 and 50 milliequiv were called moderate adherents, and those with excretions above 50 milliequiv were called delinquents. The moderate adherents could be rightly thrown out of the study, for this group does not represent patients on the Kempner diet. They do demon-

were men and 6 were women, whereas of the moderate adherents 5 were men and 15 were women. This division apparently points up one of the difficulties met with in treating patients in their normal environment: the women have to prepare the food for the rest of the family and are therefore subjected to greater temptation to deviate from the diet.

In evaluating the clinical results of this study, at present we shall limit ourselves to objective results as manifested by change in blood pressure and change in weight. Evaluation of renal, cardiac and cerebral status will be left until a later report.

What constitutes a significant reduction in blood pressure? This has been a difficult question to

TABLE 1 *Criteria for Evaluation of Blood-Pressure Response*

AUTHOR	TREATMENT	TYPE OF CASE	NO OF CASES	PERIOD OF OBSERVATION	METHOD OF EVALUATING RESPONSE
Berger and Fineberg ⁸	Effect of different amounts of sodium chloride on hypertension	Inpatient	11	Control 10 to 14 days; treatment, 39 days	Trend of blood-pressure curve
Bryant and Blecha ⁹	Low sodium diet; forced fluids	Outpatient	100	Control period not stated; treatment, weeks to 1 yr	Blood pressure fell to 135/95; diastolic fell to 95 or below
Fishberg ¹⁰	Sympathectomy	Outpatient	119	Control months to years; treatment, 4 to 6 yr	Diastolic pressure 25 per cent below preoperative level; systolic 25 per cent below preoperative level; blood pressure fell to 130/100 or less
Flipse and Flipse ¹¹	Rice diet	Outpatient	54	Control period not stated; treatment, 3 to 30 wk	Decrease in mean arterial pressure of 20; fall of diastolic pressure to normal; increase in blood pressure more than 20/10 on modification of diet (uncontrolled)
Grollman et al. ¹²	Low sodium diet	Inpatient	6	Control, 2 wk; treatment, 57 to 129 days	Evaluation of blood pressure chart; improvement equals drop to normal
Kempner ¹³	Rice diet	Inpatient and outpatient	500	Control 2 wk; treatment, 2 to 6 mo	Improvement equals decrease of 20 in mean arterial pressure
Fanson et al. ¹⁴	Potassium sulfocyanate	Outpatient	100	Control 1 to 3 mo; treatment, months to 4 yr	Improvement equals fall of blood pressure to 150/100; sustained drop of systolic pressure of 30-50; sustained drop of diastolic pressure of 20-30
Contratto and Rogers ¹⁵	Rice diet	Outpatient	55	Control 3 yr; treatment, 6 mo	Decrease in blood pressure to 150/100; systolic drop of 50; diastolic drop of 20
Smithwick ¹⁶	Sympathectomy	Outpatient	439	Control period not stated; treatment, 1 to 3 yr	7 categories: (1-2-3—improvement, 4-5—unchanged, 6-7—failure) 1—decrease in diastolic pressure of 20 or below 90; 2—decrease in diastolic pressure of 20 but not below 90; 3—decrease in diastolic pressure of less than 20 to no change; pulse pressure narrowed; ceiling levels lowered; 4—diastolic and pulse pressure unchanged; ceiling lowered; 5—no change in blood pressure; 6—blood pressure higher; 7—deaths

strate, however, a group of patients on a restrictive diet—one that is moderately low in sodium. It seemed of interest, therefore, to follow them so as to compare the results in this group with those obtained in patients on the strict rice diet.

RESULTS

The total number of patients instructed on the rice diet in nine months was fifty-six. Our success in maintaining patients on the diet can be shown by the following figures: strict adherents, 16 (28 per cent), moderate adherents, 20 (36 per cent), and delinquents, 20 (36 per cent). Of the group who adhered strictly to the rice and fruit diet, 10

answer, and has led us to a review of the literature, where one finds many criteria for evaluating change in blood-pressure levels.^{6, 8, 10, 12, 15, 18, 20, 22} Table 1 presents a summary of the criteria for evaluating blood-pressure response by different authors. As will be seen some studies are done on hospitalized patients, whereas others are done on ambulatory patients, the number of patients varies from 6 to 500, and the length of time from twenty days to five years. In some studies the blood-pressure response is based on a few records taken at long intervals, in others it is based on many determinations taken frequently over a short time. The control period, when stated, varies from weeks to three

years. It seems important for various workers to decide on criteria to be used in the evaluation of blood-pressure response so that communication of results in treatment will be facilitated.

The method we have used in evaluating blood-pressure response is to list all pretreatment clinic

control periods, the number of weeks on the diet and weight change.

In a sense the success or failure of any method of treating hypertension can only be assessed adequately after the last patient in the group dies. Only at that time does the complete influence of

*Kempner method (systolic plus diastolic pressure divided by 2 = mean)

has been a sustained change, it is evident, but the peaks and hollows are ironed out. In tabulating our results (Table 2 and 3) we have used the method described. For comparison we have applied Kempner's¹² method of evaluating blood-pressure change to our cases. We have included in the table the

tients, or 37 per cent of those who stayed strictly on the rice diet, showed an improvement in blood pressure. When Kempner's method was applied to this group, 10 out of 16 patients, or 62 per cent, revealed an improvement in blood pressure. In the group of patients whom we termed moderate

adherers, 3 out of 20, or 15 per cent, demonstrated improvement, whereas by Kempner's criterion 9 of 20, or 45 per cent, would be considered improved. On the other hand, if a drop of blood pressure to 150 systolic, 100 diastolic, was used as a sign of improvement, as several workers have done,^{18 20 21} 4 of 16, or 25 per cent, in the strict group showed improvement whereas 4 of 20, or 20 per cent, in the moderate group showed improvement. As can be seen from this comparison the number of patients who show improvement in blood pressure on any one type of treatment is dependent on the criteria used for evaluating the improvement. When all is said and done we have no way of knowing at present whether reduction in blood pressure constitutes an improvement in the hypertensive state.

Correlation of weight reduction to change in blood pressure has long interested clinicians. No valid conclusion can be drawn from such a small group. If, however, we consider a loss of 4.5 kg, or 10 lb, as a significant weight change, 7 out of 16 strict adherers showed a significant change. Of this number 4 demonstrated a diastolic drop of 20 or more. Of 20 moderate adherers, 5 showed a significant weight change, and only 1 of the 5 showed an improvement in blood pressure.

The other criteria ordinarily used in the evaluation of improvement in the hypertensive state, such as change in electrocardiogram, heart size on x-ray study, fundal vessels and renal-function tests, have not been analyzed for this report. A rapid survey indicates that little change has taken place in the various areas as manifested by these tests.

CONCLUSIONS

The rice diet has been used in the treatment of a group of outpatients living at home in their normal environment. The method can be used with safety so long as the patients are carefully followed at frequent intervals.

A significant drop in blood pressure occurred in 6 of 16 patients, or 37 per cent, who adhered strictly to the diet, and in the group of moderate adherers a significant drop occurred in 3 of 20 patients, or 15 per cent.

ASPIRATION OF THE ELBOW JOINT IN THE TREATMENT OF FRACTURES OF THE HEAD OF THE RADIUS*

T B QUIGLEY, M D †

BOSTON

IN RECENT years there has been a revival of the principle of early active motion in the treatment of elbow fractures, first expounded by Jean Pierre David¹ in 1779 and vigorously restated a century later by Lucas-Championnière.² For fractures of the radial head in particular this concept appears to be well accepted. In general, these fractures fall into three groups: those in which the fragments are so comminuted or displaced as to require arthrotomy, those in which the fragments are displaced, motion is limited, and arthrotomy is contemplated, and those in which impaction and displacement are minimal.

For the first group, prompt excision of the radial head followed by early active motion is indicated.

literature contains several pleas for early active motion,³⁻⁵ but little note has been taken of aspiration in treatment other than the descriptions of Postlethwait,⁶ Jacobs and Kernodle¹⁰ and Buffing-

FIGURE 1 Depressed, Displaced, Wedge-Shaped Fracture of the Radial Head (Case I)

There was normal elbow motion after aspiration of 11 cc of thick, bloody fluid.

For the second and third groups, minimal immobilization results in rapid restoration of function and a low incidence of subsequent myositis ossificans traumatica.⁷

Active motion, however, although easy to prescribe, is often difficult for the patient to achieve. Relief of pain and marked increase in range of motion very often follow aspiration of the joint. The

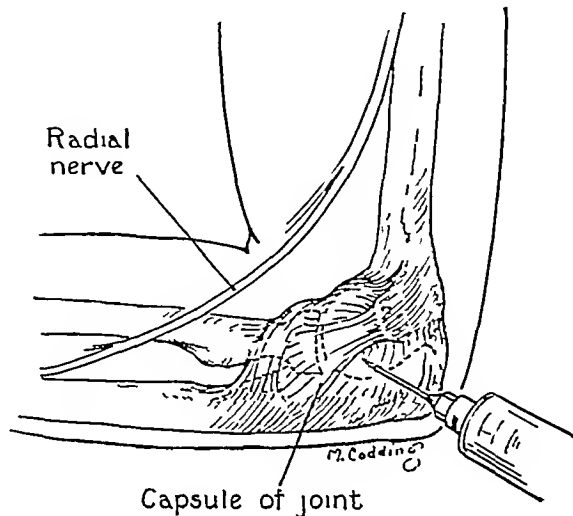

FIGURE 2 Technic of Aspiration

With the forearm pronated, after infiltration with procaine, a 16-gauge needle is introduced into the center of the triangle formed by the head of the radius, the lateral epicondyle of the humerus and the tip of the olecranon.

ton¹¹ of its use in fractures of the radial head in soldiers.

The following case is typical of the second group of fractures — those with limitation of motion and moderate displacement of the fragments.

C W, a 42-year-old housewife, was first seen 48 hours after a fall down a flight of stone steps on her outstretched left arm. Active and passive flexion and extension at the elbow were limited to the middle third of the normal range, as was rotation of the forearm. X-ray examination disclosed a depressed, displaced wedge-shaped fracture of the anterolateral aspect of the head of the radius (Fig 1).

Arthrotomy was contemplated because of the size and shape of the fragment, which, it was believed, was acting as a mechanical block to rotation. However, after aspiration of 11 cc of thick, bloody fluid, active and passive flexion, extension and rotation were normal. Active exercises were started, and 2 months later function of the two elbows was indistinguishable.

Aspiration is not carried out for at least 24 hours after the injury, lest the hemarthrosis recur. The technic is simple (Fig 2). However, no aspiration of a joint should be undertaken casually as an office procedure. The resistance of joints to infection is low, and no antibiotic can take the place of a clean operating room, meticulous skin disinfection and rubber gloves.

*From the Surgical Service, Peter Bent Brigham Hospital and the Department of Surgery, Harvard Medical School.

†Associate in surgery, Harvard Medical School; associate in surgery, Peter Bent Brigham Hospital; surgeon, Harvard Athletic Association.

With the forearm pronated to minimize the possibility of injury to the deep branch of the radial nerve,¹² and after infiltration with procaine, a 16-gauge needle is introduced into the joint through the center of the triangle formed by the head of the radius, the tip of the olecranon and the lateral

Rapid return of function after aspiration in the third group of fractures, those with minimal impaction or displacement, is illustrated by the following case

G K., a 40-year-old brakeman, tripped over a rail, striking his right elbow. When he was first seen, 4 days later,

TABLE 1 Results of Aspiration in Treatment of 7 Cases of Fracture of the Head of the Radius

PATIENT	SEX	AGE	TYPE OF FRACTURE	MOTION BEFORE ASPIRATION	AMOUNT OF FLUID ASPIRATED	RESULT
J J S	M	49	Comminuted impacted but not deformed	Patient "unable to move without pain"	15	Immediate full range of motion function normal 4 days later
W D	M	16	No displacement	Rotation normal, flexion and extension limited to 15°	5	Patient immediately able to extend and flex to 45° rotation normal function normal 2 mo later
J K	F	46	No displacement	Flexion and extension very limited" normal rotation	10	Immediate improvement function normal 2 mo later
V A	F	37	Downward depression and slight impaction of lateral aspect	"Elbow moves only between 90° and 140°" rotation, 10°	10	Immediate return to 50°-175° function normal 6 wk. later except for 10° loss of pronation
A. M. C.	F	61	No displacement	"Motion greatly limited"	15	Immediate return to 150°-80° with normal rotation normal function 3 mo. later
G K.	M	40	No displacement	"Marked limitation of motion and pain"	14	Immediate normal range of motion function normal 2 wk. later
M. W.	F	42	Wedge-shaped displacement	Flexion, extension and rotation limited to middle third of normal range	11	Immediate free range of painless motion, function normal 2 mo later

epicondyle of the humerus. Often, bloody fluid under considerable pressure is encountered. This is to be expected since the normal fluid content of the adult elbow joint is less than 1 cc,¹³ and more than 10 cc is frequently recovered. Aspiration in this group of fractures does not take the place of

flexion and extension of the elbow were limited to 30°, and rotation of the forearm to 15°. X-ray examination disclosed a fracture of the radial head with minimal displacement (Fig 3). After aspiration of 14 cc of thick, bloody fluid, the range of active motion of the elbow was normal and painless. The patient returned to work 12 days after the injury and 8 days after aspiration.

The results in 7 consecutive cases treated at the Peter Bent Brigham Hospital are summarized in Table 1.

SUMMARY

Attention is called to the usefulness of aspiration of the elbow joint in the treatment of undisplaced fractures of the radial head, and also in clarifying the indications for arthrotomy in fractures with moderate displacement.

arthrotomy and excision of the radial head when indicated. The persistence after aspiration of limitation of motion or palpable grating on passive rotation is an indication for operation. Arthrotomy should not be delayed, and the decision can almost invariably be made at the time of aspiration.

BOSTON MEDICAL LIBRARY

Report of the Librarian*

IT IS again the duty of the Librarian, as provided by the by-laws, to present to the Corporation of the Boston Medical Library his annual report — his eleventh accounting of the state of the Library since he took office in 1938. In growth, service to its readers, quality of accessions and increase in personnel, the Library had in 1948 the most profitable year in the seventy-three years since it was organized in 1875. More books and journals were used by readers in the past year than ever before — 10,000 more than in 1947, the year of largest use up to 1948. As the attendance in Holmes Hall did not exceed the average of the last decade, this use came largely through the growth of inter-library loans to non-members and, more particularly, by way of professional members — libraries in hospitals and medical schools who borrow for our own fellows and for nonfellows as well.

The total membership of the Library remained practically unchanged at a little over 1100. The increased use of the Library presumably came from the 5671 Massachusetts Medical Society members who, using our books in hospital libraries and elsewhere, solved their medicoliterary problems. It makes little difference where our books and journals are used — in hospital, laboratory or home — as long as they fill the needs of some doctor for the printed record of his contemporaries or those who have gone before. The Library has one primary aim — service to all. In supplying the needs of a growing body of physicians and scientists, the Library grows also — in size, in quality, in resources and in availability. Use is the best barometer of worthiness, on that score we can report a rising glass.

On December 31, 1948, the books and volumes of periodicals in the Library were 206,564 and, in addition, 147,144 pamphlets were catalogued and available for use. The circulation during the year was 53,518 items, the attendance 10,089. The inter-library loans to nonmembers had grown to 1798 — all figures far in excess of those for 1947 and showing a healthy increase in all departments.

THE USABLE PAST

Only by a knowledge of the usable past can one evaluate the foreseeable future. To the Librarian the past is all printed material, even the latest number of a current periodical. The immediate past is naturally the primary test, since the Library aims to provide for its fellows, the Massachusetts Medical Society members and the public all the printed records of contemporary research that are likely to be called for by clinicians and students. Secondly, we try to make available in a reasonable time other

material that we do not possess, taking advantage of our neighborhood libraries, the great repositories of Harvard University and the Massachusetts Institute of Technology, as well as many others that go, with ours, to make up the cultural heritage of Greater Boston.

In the older literature of medicine, I need not remind you, we are rich indeed. To the great works of the past we constantly add — in 1948 we acquired three unique manuscripts and eighteen books of medical interest printed before 1501. Among the incunabula are some of considerable interest, reflecting fifteenth-century medicine as it was recorded in the early days of printing with movable type. Another edition of the works of Michele Savonarola was added to the two acquired in 1947. We now lack only two of this author's publications in our incunabula holdings, having ten of the dozen issued before 1501.

ACCESSIONS

Incunabula

Two early tracts on syphilis were acquired in 1948. Johannes Widmann's *De pustulis, sive mal de franços* (Strassburg, 1497), and Gaspar Torrella's *Dialogus de dolore cum tractatu de ulceribus in pudenda* (Rome, 1500). The Library has some of the most important of the syphilis literature of the fifteenth century, including Schellig (1495), two tracts by Grünpeck (1496, 1497) and Leonicensio (1497). We lack the first editions of both of the Grünpeck books, and the tracts by Torrella, Gilino, Stäber, Montesauero and Scanaroli. Some are only known in a few copies and may never come into the market. Of the ten that were produced in facsimile by Sudhoff and Singer in 1925, the Library has three. The list, with the Klebs numbers, is shown in Table 1.

Hans Widmann, born in 1440, studied medicine in Italy but took his degree in Freiburg in 1474. After 1484 he was professor of medicine at Tübingen, where he also served as inspector of "lepers." His tract on syphilis was completed on January 20, 1497, when he sent it to Johann Nell, a physician and friend at Strassburg, where it was printed, probably in the spring of that year. Sudhoff and Singer knew of only four copies, since 1925 two more, including ours, have been recorded. The book was reprinted a few months later in Rome. Widmann called syphilis, as Schellig did, the French disease, both following the Edict of the Diet of Worms (1495), which they attended. Widmann made a differential diagnosis between leprosy and

*Read in part at the annual meeting of the Boston Medical Library March 1, 1949.

†Sudhoff K. Adapted by Singer C. *The Earliest Printed Literature on Syphilis Being Ten Tractates from the Years 1495-1498*. 332 pp. Florence, 1925.

syphilis, for he was long familiar with the former disease. He advised standing on the windward side of the syphilitic, a common practice in his time in dealing with lepers. In treatment, Widmann used mercury as had his predecessors. The Library also owns Widmann's *De pestilentia* (Tubingen, 1501) containing the reference to *malum franciae* in 1457, a date that seems quite improbable and may be a printer's error for 1495 or 1497. As Sudhoff says, "It is a matter on which we can only conjecture."

Of more importance was the work of Gaspar Torrella, who left his native city of Valencia in

Unfortunately, only three copies seem to have survived, none have reached America. A later work of Torrella, printed in Rome in 1500, attacks the subject in a lighter vein — a kind of prelude to the style of Fracastor's poem on syphilis of 1530. It is this book that was acquired by the Library in 1948.

Sixteenth-Century Imprints

Torrella's publication in 1500 brings us into the sixteenth century, an age of increasing output of medical works, for the presses were hard pushed to keep up with a growing demand for the easily transported book, movable in pocket or saddlebag, that could be used in the same text and at the same time by doctors in Cracow, Montpellier and Edinburgh. Thus, there took place a vast spreading of knowledge, not dreamed of before the days of printing. Having catalogued our fifteenth-century books in 1944 and recorded our addenda of incunabula in the *Report of the Librarian*, year by year, the Library is in the process of segregating its sixteenth-century holdings for convenience of recataloguing and adds to this new class of books as fast as funds will permit. Over sixty books printed before 1600 were acquired in 1948, including the pest ordinances of Antwerp for the years 1575, 1578, 1580 and 1586, an anti-pest tract by Cermisonus (Milan, 1512), Gesner's *Schatz* (Zurich, 1555), and the famous *Malleus maleficarum* by Sprenger and Institoris, in editions issued at Cologne (1520), Lyon (1584) and Frankfurt (1588).

Americana

In the field of Americana a few texts were added. Perhaps the most important were copies of the *Christian Watchman*, a Boston newspaper, for October 23, 30 and November 6, 1846, containing what appears to be an eye-witness account of the second ether operation at the Massachusetts General Hospital on October 17, 1846, and possibly of the first operation the day before. Medical letters include one by O. W. Holmes relating to his son's injury during the Civil War, correspondence from Zadok Howe to Moody Kent (1812-1827) and twenty-three letters from James Thacher, many to his daughter, written from Plymouth, 1784-1824.

Special Gifts

As usual the Library added many gifts from our fellows and friends. The list is a long one and the Library, as in the past, reflects the devotion of its users, whether fellows, members, hospitals or medical schools. The Harvard Medical School Library continued to send us inaugural dissertations and theses, as well as current Russian literature — classes of material that we, by mutual agreement, have arranged to keep in the Boston area. Dr. George Kelemen supplied us with Hungarian periodicals, Dr. Stephen Rushmore gave us a large part of his personal library and allowed us to purchase from

*In Boston Medical Library

Spain in the late fifteenth century to seek his fortune in Italy. Coming from a well known medical family, this energetic young doctor was welcomed in Rome by a fellow-countryman, Roderigo de Borgia. The wily Roderigo, already a wealthy cardinal, bought up enough votes in 1492 to become Pope Alexander VI, and Torrella became his body physician and the medical adviser to the papal household. Among the Borgia family and the papal court, Gaspar had, in spite of his restricted chentele, a considerable experience with syphilis. During September and October, 1497, for instance, the papal physician treated seventeen cases of the *morbo gallico*. One of his patients was Cesare Borgia, the profligate son of the Pope, who, at the age of sixteen in 1493, had been made a cardinal by his father. In Torrella's first publication, a tract of twenty-four leaves, issued in Rome in 1497, 5 typical cases are described. All were treated by mercurial ointment. The case presentations are "first hand," and this little pamphlet is the most valuable of all the early literature on syphilis. One of the case histories is almost certainly that of Cesare Borgia.

him a few of the more expensive items, much to our advantage, books and periodicals were received from the estates of Abraham Myerson, Richard F. O'Neill, Isadore E. Reid and George H. Torney, a substantial bequest was received from the estate of Walter P. Bowers, the Suffolk District Medical Society continued its support, and miscellaneous gifts were received from many others.

LIBRARY ACTIVITIES

Addresses and Meetings

The Librarian addressed the annual meeting of the Cleveland Medical Library Association on January 16, 1948, reading a paper, "A Roving Commission. The doctor calls on some of his friends," describing a sojourn with Sir William Osler in Oxford in 1916 and a visit to the home of Arnold C. Klebs at Nyon in Switzerland in 1939. On February 10 he gave the Walter Reed Lecture before the Section on the History of Medicine, Richmond Academy of Medicine, entitled "James Thacher and His Influence on American Medicine," and was made an honorary member of the Section. The Librarian also visited, during the course of the year, the Army Medical Library, the medical libraries of the University of Minnesota, the Rhode Island Medical Society, the College of Physicians of Philadelphia, the John Crerar Library, Chicago, the St. Louis Medical Society and the Welch Medical Library, Baltimore. The Librarian attended the Section on the History of Medicine at the annual meeting of the American Medical Association, held in June in Chicago, and the meeting of the Honorary Consultants to the Army Medical Library in Washington, October 21 and 22, as chairman of the Committee on the History of Medicine. He was elected president of the American Association of the History of Medicine for two years at the annual meeting in Philadelphia in May.

The Director also attended the meeting of the Honorary Consultants to the Army Medical Library in Washington in October, the meeting of the Medical Library Association in Philadelphia in May and that of the Special Libraries Association in Washington in June.

In February the Library entertained in Boston Dr. Josep Trueta, formerly of Barcelona and now of Oxford, the authority on Servetus and author of *The Spirit of Catalonia* (London, 1946), and, in April, Dr. Douglas Robb, of Auckland, New Zealand. Both visited the Library, much to our profit.

Book Reviews

About 270 new books, received from the *New England Journal of Medicine*, were reviewed by the fellows and staff of the Library in 1948, either by short notes or by longer, critical reviews (about 80). Nearly 100 reviewers perform this task as a contribution to the Library. This service, one of outstand-

ing merit, brings to the Library promptly many of the latest publications in medical literature and the new editions of older books for the benefit of our readers.

Exhibits

At various times during this year small exhibits were arranged in the Osler Exhibit Cases (donated to us by Osler from his Ingersoll Lecture honorarium of 1904) in the rotunda of the Library, largely of the chief current accession, complemented by other works in the Library. Among the books shown in 1948 were the writings of Giovanni Michele Savonarola (1384-1462), the Paduan physician. Also on exhibit were a collection of medals and tokens, illustrating medical numismatics, including the Baker Clinic diabetic medals recently presented to the Library by Dr. Joslin, and a portrait and the original article on DDT in honor of Paul Mueller, winner of the Nobel Prize in Medicine for 1948.

Conferences

A conference with nineteen of the medical librarians of Metropolitan Boston was held at the Library on October 30, 1948. The Director acted as chairman for the discussion of various library problems including library statistics, losses and their control, co-operation and the relation of the Boston Medical Library to other medical libraries, damaged material, foreign periodicals and their coverage, inter-library loans and other topics. Consideration was given to the possibility of organizing the conferences on a semi-official basis, and it was agreed that this should be done, with at least two meetings a year and at different libraries.

Publications

VARIA

A few of the books of unusual interest to medical scholars, published recently, deserve notice *Pioneer Life in Kentucky, 1785-1800*, by Daniel Drake (New York, 1948), edited from the original manuscript by Emmet Field Horine, was first issued in 1870. Dr Horine went back to Drake's original letters, now in the Cincinnati General Hospital and long out of print, as is a reprinting of 1907, only to find that previous editors had taken many liberties. The book, now edited with scholarly accuracy, is not a medical treatise, but a portrayal of farm and family life by the most eminent early nineteenth-century physician of the Central West. Another physician, George W. Corner, has performed a similar task for Benjamin Rush, editing his autobiography from the original manuscript for the American Philosophical Society *The Autobiography of Benjamin Rush His "Travels Through Life" together with his commonplace Book for 1789-1813* (Princeton, 1948) is superbly and meticulously documented by Corner, with numerous illustrations. A delight-

ful book of essays is *Wayfarers in Medicine* (London, 1947), by William Doolin, the editor of the *Journal of the Royal Academy of Medicine in Ireland*, a salty, varied series of sketches ranging from "Graeculi Esurientes" to "Osler." Among the best are "Some Old Journeyman Surgeons" and "Pathfinders in Dublin." Sharp, too, is *Rabelais* (London, 1948) by John Cowper Powys, a translation of his life story and an interpretation of his genius. Powys, in a thoughtful book, takes you "on sunny morning stops" where Rabelais meets his friends. One notes further *The Legacy of Swift A Bi-Centenary Record of St Patrick's Hospital, Dublin* (Dublin, 1948), *Dr Kirkbride and his Mental Hospital* (Philadelphia, 1947), by Earl D. Bond, *The Story of St Thomas's 1106-1947* (London, 1947), by Charles Graves, *Encyclopedia of Medical Sources* (Baltimore, 1948) by Emerson Crosby Kelly, *The Physicians of Essex County* (Salem, 1948), by Russell Leigh Jackson, *Religio Medici* (Lund, 1948), by Thomas Browne, translated into Swedish by Ernst Abramson, a provocative book, *Surgery Orthodox and Heterodox* (Oxford, 1948), by Sir William Heneage Ogilvie, and *Selected Writings of William Clowes* (London 1948), with a delightful introduction by F. N. L. Poynter, of the Wellcome Historical Medical Museum.

MEDICAL PROGRESS

NEUROPHYSIOLOGY, 1942-1948 (Concluded)*

JOHN F. FULTON, M.D.†

NEW HAVEN, CONNECTICUT

THE PYRAMIDAL SYSTEM AND THE MOTOR AREAS

The Pyramidal System

An even more profound modification has taken place in beliefs concerning the origin and nature of the pyramidal system. Current texts in neurology generally state that the pyramidal tracts take origin from the giant cells of Betz in the motor area (area 4) and from a few similarly large cells in the parietal cortex. This view is based largely upon the studies of Holmes and May,⁶¹ published in 1909, these authors having found in cases of spinal transection in man that retrograde degeneration in the cerebral cortex was limited to the cells of Betz. Lassek, in a series of 19 papers on the pyramidal tract of man and animals,[†] finds that whereas there

is an average of 34,000 Betz cells in a given hemisphere (that is, cells between 900 and 4100 sq microns in size), there are 1,000,000 fibers in a human pyramid. This discrepancy between numbers of Betz cells and fibers in the pyramid indicates that the Betz cells can contribute at most 2 or 3 per cent of the fibers in the human pyramid, and that the greater proportion must come from some other source. The Betz cells no doubt give rise to the larger fibers in the pyramid, for fibers of large diameter increase in proportion as the primate scale is ascended, and so does the size of the Betz cells.

In attempting to discover from what other parts of the cerebral cortex the pyramidal tract might arise, Woolsey and Chang⁶² have carried out the ingenious experiment of leading off electrically from the surface of the cortex while the pyramids are being stimulated antidromically at the level of the medulla. Using rabbits, cats and monkeys they find that an antidromic action potential can

*From the Department of Physiology, Yale University School of Medicine.

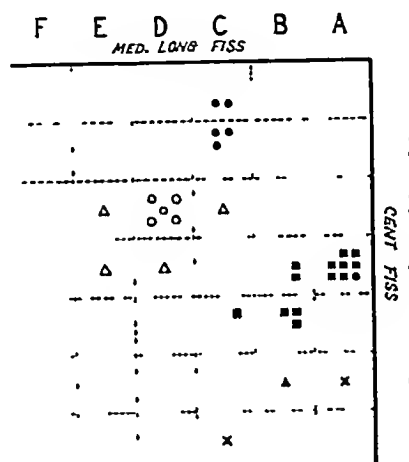

†Sterling Professor of Physiology, Yale University School of Medicine.

‡These papers are summarized in the 1948 volume of the Association for Research in Nervous and Mental Disease.⁶³

be detected over wide areas of the cortex in all three species, including fields 6, 4, 3-1-2, 5 and 7 of Brodmann. In the monkey and cat two waves can be detected—a fast one, which is most conspicuous in area 4 (and its counterpart in the cat), followed by a slow wave, which is present in all the areas just mentioned. In the cat the slow wave is much larger relatively than the fast wave, and in the rabbit only the slow wave can be detected. These findings are in harmony with the belief that the faster spike wave represents the contribution of the large fiber components, for in the rabbit there are no large fibers, and in the cat the proportion of large fibers is much smaller than that in the monkey (Lassek). It becomes necessary, therefore, to regard the pyramidal tract as taking origin from the entire precentral convolution as well as from the full extent of the parietal lobe, and it is therefore concluded that only the fast fiber components are primarily restricted to area 4.

The effects of *interruption* of the pyramidal tract at the level of the pyramid have also proved surprising in the light of earlier neurologic teaching, for the spasticity that was thought to be characteristic of an upper motor neuron lesion is completely lacking, indeed, Tower⁶⁴⁻⁶⁵ finds, both in monkey and chimpanzee, that the skeletal musculature on the affected side is flail and that the muscles themselves undergo conspicuous atrophy as a result of disuse. This result was scarcely surprising since it was known that similar flaccidity is seen after isolated lesions of area 4 in chimpanzees, such lesions, however, involve extrapyramidal, as well as pyramidal, projections. This no doubt accounts for the transient digital spasticity that Denny-Brown and Botterell^{65a} observed in monkeys after partial lesions of area 4. The flaccid character of the paresis seen by Tower makes imperative some modification of the older view, espoused by Walshe⁶⁷ and others, that all the phenomena following interruption of the corticospinal system are to be interpreted as "release phenomena." Thus, Tower writes "In the realm of motor function the condition is unquestionably one of deficient function without phenomena of release," adding that "there is no evidence of inhibitory function [in the pyramidal system]." Walshe⁶⁷ objects to this interpretation, for he contends that the Babinski plantar response must be looked upon as an example of release of a phasic nociceptive reflex from cortical control. The point is perhaps an academic one, but if Dr Walshe will accept flaccidity and atrophy as an essential part of the pure pyramidal syndrome in man and the higher primates, one will not begrudge his insistence that the Babinski reflex is to be regarded as a release phenomenon. Denny-Brown⁶⁶ characterizes Tower's classic description of the effect of pyramid section as "the final blow to the clinical conception of disorder of the pyramidal system," but Walshe considers such an obituary premature.

It may prove more difficult to bring Dr Walshe to terms on the question of whether individual muscles find representation in the motor area, or only movements. Believing that the controversy could be resolved more readily by recourse to experiment than by philosophic reflection, Chang, Ruch and Ward⁶⁸ isolated eight representative muscles in a series of monkeys, attaching each muscle to separate myographs, they then explored the responsiveness of several muscles to unipolar stimulation of various foci on the motor area. With minimal intensity of stimulation they found that certain points gave "solitary responses,"—that is, an isolated reaction of a single muscle unaccompanied by contraction of any other muscles under observation. Such a group of solitary reactions is shown in Figure 6. Not only were individual muscles rep-

resented, but in some instances small portions of a given muscle were separately stimulable.

In discussing their results, Chang and his associates write

Inspired by the dictum of Hughlings Jackson that movements rather than muscles are represented in the motor cortex other investigators have emphasized the instability of the cortical mosaic and a multiplicity and diffuseness of representation of muscles in the motor cortex. This formulation leaves out of account the fact that a somatic movement, however complex, is produced

by the contraction of muscles. As a consequence, at some level, muscles must be represented as muscles so that they can be manipulated and organized into movements.

Hines⁶⁹ is even more outspoken:

The above study indicates that in the precentral gyrus of the macaque there is a detailed pattern of representation of the skeletal muscular system and that the basic plan of this pattern can be analyzed in terms of muscles. Thus, although there is overlapping of cortical fields for peripheral cutaneous areas, individual muscles are represented maximally in specific parts of the precentral gyrus, just as areas of skin are represented maximally at particular points on the postcentral gyrus. This does not mean that a particular muscle is the only muscle represented at a specific cortical point, but that it is the one predominantly represented there.

The maps of muscle foci observed by Chang et al suggest that "the Betz cells for a particular muscle

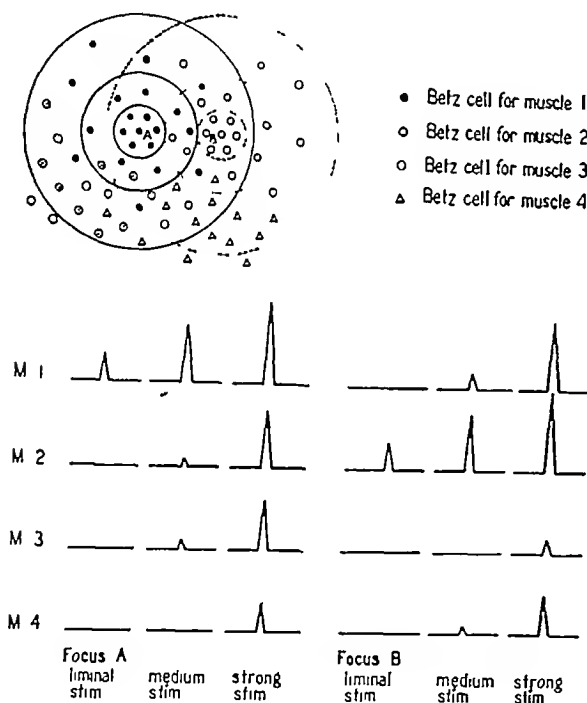

FIGURE 7 Diagrammatic Representation of the Hypothetical Distribution of Betz Cells for Individual Muscles with Cell Group for Each Muscle Having a Focal Distribution and an Overlapping Fringe

Each symbol stands for a Betz cell, and the large concentric circles represent the sphere of excitation. The expected contraction of the muscles in response to cortical stimulation at different strengths is shown by the curves drawn in the lower part of the figure, in which the magnitude of the contraction is determined by the number of Betz cells involved in the sphere of excitation. (Reproduced from Chang, Ruch and Ward⁶⁸ with the permission of the publishers)

are distributed over a contiguous area of the cortex with the highest cell concentration located at a particular focus within that area, and that the farther from that focus, the more sparsely scattered are the Betz cells devoted to that muscle." They thus envisage a considerable overlapping of the

fringes of each field of Betz cells, which is illustrated schematically in Figure 7.

Broadly considered, the pyramidal tract must be regarded, as Sherrington originally insisted in *The Integrative Action of the Nervous System*, as an internuncial pathway between the motor mechanism of skeletal muscle and the distance receptor impinging upon the higher levels of nervous function. As Walshe⁶⁷ has aptly put it, the pyramidal tract "is a sort of common path standing between the receptors and the motor mechanisms of the nervous system." This view should have the hearty concurrence of those who have performed experiments in this field.

The Motor Area

Perhaps the most notable advance in the sphere of the motor area has been Rasmussen and Penfield's⁷⁰ résumé of their experience in stimulating the precentral and postcentral convolutions during 206 operations (principally under local anesthesia).

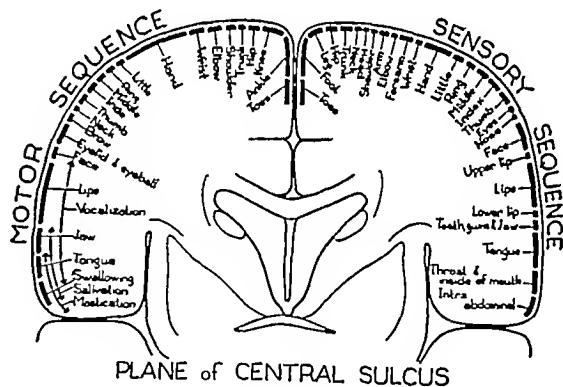

FIGURE 8 Motor and Sensory Sequence in the Human Cerebral Cortex

This is based on observations in 222 operations carried out under local anesthesia. (Reproduced from Rasmussen and Penfield⁷⁰ with the permission of the publishers)

on 186 patients and their more recent report on stimulation of the human eye fields.⁷¹ The sequence of sensory representation in the postcentral gyri had long been thought to correspond with that of the precentral motor cortex, but these observers find that the sensory projections of the head fall between trunk and arm (Fig 8). Their illuminating summary may be quoted:

1 As a result of further stimulation studies in man, certain modifications in the sensory sequence are suggested: (a) The head as a whole is represented between trunk and arm. (b) Neck sensation seems to belong between the head representation and trunk. (c) Tongue sensation has been moved to below teeth, gums and jaw, conforming to its location in the motor sequence. (d) Taste has been eliminated from the sequence of the cortical convexity since it occurs very rarely as a result of stimulation here, although somatic sensation in the tongue is the most frequent sensory response in the face area. (e) Intra-abdom-

inal sensation has been added to the lower end of the sequence, below throat. The extent of this representation, which is largely precentral, into the island of Reil has not yet been determined.

2. Sensory responses simultaneously in more than one of the area units of the face region are fairly frequent. The same is true among the units of the upper extremity. It is, however, very rare that overlap occurs between the three major regions — face, upper extremity, lower extremity. This may cast light on the fact demonstrated by Dusser de Barenne and McCulloch that each of these regions may be activated in animals by local application of strychnine without activating the adjacent major region.

3. Stimulation of the banks of the Rolandic fissure has shown that the sensory and motor responses produced there are similar in character and location to those elicited from the superficial surfaces of the pre- and postcentral gyri.

4. In the motor sequence certain minor alterations are also suggested. (a) Salivation and mastication are represented in the lower portion of the motor face area. The latter is predominantly postcentral in location and below tongue, whereas simple jaw movements are predominantly precentral in location and located above tongue. (b) Neck movements are represented between the area for finger movements and the upper margin of the face area.

5. Vocalization may be produced in man from an area between upper face and throat of both the dominant and nondominant hemispheres, either alone or with movement or sensation in the various structures about or in the mouth.

6. Conjugate eye movements toward the opposite side are produced by stimulation anterior to the precentral gyrus without seeming to be confined to a discrete architectonic area. Eye movements produced from the precentral gyrus may be conjugate to either side or upward or may be movements of convergence. Eye sensation is produced by stimulation anterior to the central fissure but not posterior.

7. Evidence is presented for the possible existence of a second sensory area for arm and leg in the cortex adjacent to the fissure of Sylvius. It seems likely also that there may exist in the same zone a second representation of movement.

Secondary motor areas. As indicated in Rasmussen and Penfield's last paragraph, there is some suggestion that secondary sensory areas exist as Adrian⁷² and Woolsey⁷³ have indicated, but that there is also evidence of the existence of a secondary motor field. Speculations in this connection have indeed been rife for some time. Thus, in 1943 Garol⁷⁴ found a second motor area in the cat lying in the inferior portion of the anterior ectosylvian gyrus, and here the representation was inverted as compared with that of the first motor region, — that is, the leg area was more lateral than the arm and head, — just as Woolsey and Fairman⁷⁵ have found for the second sensory area of the cat and monkey.⁷⁶ French, Sugar and Chusid⁷⁷ find on strychninization of the buried opercular surface that it "fires" heavily into areas 4 and 6 and also into postcentral gyri. To quote these authors further

The arrangement of connections as found by strychnine neuronography agrees with the somatotopic arrangements found on sensory and motor explorations. Anterior segments of the superior Sylvian bank communicate more actively with the inferior portions of the pre- and postcentral gyri, while the more posterior segments of the infraparietal plane are more strongly connected with the superior portions of areas 4 and 1. The face region is thus predominantly anterior, and the leg region posterior, in the superior Sylvian bank — an arrangement which agrees well with the other studies.

The functional significance of these second sensory and motor areas is thus being effectively elucidated through the use of Dusser de Barenne's invaluable new technic of strychnine neuronography.

EXTRAPYRAMIDAL FUNCTIONS

The secondary motor areas described above belong strictly to the extrapyramidal division, but they have been grouped with the corticospinal system since normally they discharge principally through the pyramids. The interaction, however, between the pyramidal outflow and that of extrapyramidal projections from the cortex and from subcortical levels, is close-knit, and they are difficult to disassociate in the intact animal. Denny-Brown,⁶⁶ in his monumental treatise on the diseases of the basal ganglions and subthalamic nuclei, is the first clinical writer to give adequate attention to the part played by the cerebral cortex in genesis of symptoms of extrapyramidal disease, although Kinnier Wilson⁷³ had pointed the way.

The underlying mechanism of the so-called extrapyramidal syndromes, such as Parkinsonism, chorea and other hyperkinetic states, has been clarified during the past five years through experimental studies carried out on primate forms. The fact that the suppressor areas of the cerebral cortex — that is, areas 2s, 4s, 8s and 24 — operate by direct connection with the striate bodies and thence via the thalamus back to the cerebral cortex indicates that one cannot regard the extrapyramidal system as separate from the cerebral cortex. The suppressor bands in the chimpanzee are shown in Figure 5.

Many years ago Kinnier Wilson⁷³ insisted that the tremor of Parkinsonism must originate in the cerebral cortex through the operation of extrapyramidal projections unsupported by the striatum and subthalamic nuclei. Bucy⁷⁹ has offered the hypothesis that since the extrapyramidal suppressor bands operate through a circuit involving the striatum, thalamus and thalamocortical projections, interruption of that circuit at any point — be it the corticostriatal path, the caudate nucleus, globus pallidus, thalamus or the thalamocortical projection — may give rise to manifestations of Parkinsonism. This hypothesis harmonizes with the known variability of pathologic lesions in Parkinsonism. It does not, however, fully account for the fact that the substantia nigra and reticular formation are generally heavily involved in advanced Parkinsonism. Moreover, Ward, McCulloch and Magoun⁸⁰ find that the syndrome of tremor and rigidity, closely akin to Parkinsonism in man, can be precipitated experimentally in monkeys by Horsley-Clarke lesions involving the reticular formation throughout its entire length. Attempts to reproduce the syndromes in monkeys and chimpanzees by lesions of the striatum have been uniformly disappointing, and Ward's results strongly suggest that the vital lesion of Parkinsonism lies in the reticular formation. One of

Kennard and Fulton's⁸¹ chimpanzees showed marked athetoid movements following a lesion restricted to the globus pallidus, which indicates that athetosis and Parkinsonism are no doubt distinguishable in terms of basic mechanisms

Comparative studies of the type just outlined lend support to the view that many of the extrapyramidal syndromes that occur in human beings are probably peculiar to the human nervous system. It has been impossible, for example, to cause anything remotely approaching chorea or athetosis in a dog or a cat. In monkeys states similar to chorea in man have been seen, and in the chimpanzee present indications are that one may be able through isolated destruction of the individual extrapyramidal nuclei to evoke many more of the clinical extrapyramidal syndromes

Applications

Relief of hyperkinetic states The therapeutic uses to which the newer knowledge of cerebral function may be put have begun to be dimly appreciated, but the wider applications are undoubtedly in their earliest developmental stages. Parkinson,⁸² in his celebrated essay on the shaking palsy, observed in 1817 that tremor of long standing disappeared after a hemiplegia, many similar instances of tremor vanishing subsequent to a stroke can be culled from the clinical literature. In 1909 Horsley⁸³ removed the arm area of a fourteen-year-old boy who had had severe unilateral athetosis for seven years, the patient's athetoid movements were completely suppressed after the ablation, and they continued so for a year (when the patient had been last examined). It is incidentally interesting that the patient suffered a severe flaccid paralysis as a result of the ablation, but this seems not to have made an enduring impression upon the neurologists who had examined the case.

With the revival of interest in functional localization in the cerebral cortex neurosurgeons, especially Bucy and Buchanan,⁸⁴ Bucy⁸⁵ and Sachs,⁸⁶ have lately begun to make cortical ablations for the relief of focal seizures (in which the results have been for the most part excellent), and also for the relief of hyperkinetic states—choreoathetosis, hemiballismus, torsion spasm and so forth. Opinion, however, has been divided regarding whether ablations of area 6 or of area 4 are the more effective. It is Bucy's contention that the involuntary movements of chorea and athetosis arise from premotor discharge via the pyramidal system. Klemme⁸⁷ shares a similar view concerning the origin of Parkinson tremor and favors premotor ablation since he believes it less debilitating from the motor standpoint. Bucy⁸⁸ has recently reported upon a striking case of unilateral weakness and athetosis that had persisted for fifteen years in a twenty-three-year-old man. After isolated ablation of area 4, tremor was completely and permanently abolished, and

although the patient suffered considerable paresis and excessive sweating in the affected extremity, the relief from his tremor proved particularly dramatic.

Suppressor areas in man It is of primary significance that Garol and Bucy,⁸⁹ in their patient from whom area 4 was ablated for the relief of tremor, were able positively to identify 4s, the suppressor band lying just rostral to the anterior margin of area 4 (Fig 9). On stimulation of this region, resting contraction of all muscles on the opposite side of the body was inhibited, the threshold for stimulation of area 4 itself was greatly increased, and the effect persisted for several minutes after stimulation. The observation is important, for it represents the first positive demonstration of the existence of a suppressor band in the human brain, the position of the band being closely similar to that of area 4s in the chimpanzee (Fig 10). This fact takes on fresh significance in the light of the recent study of Russell⁹⁰ on the relation of site of lesion to subsequent development of seizures in a series of cases of gunshot wounds of the brain.

Traumatic epilepsy Many who have had experience with gunshot injuries of the brain have noted the fact that some patients develop epileptic sequelae, whereas others—with seemingly similar wounds and with similar post-traumatic history—have failed to do so. Russell,⁹⁰ impressed with the possibility that the suppressor bands discovered by Hines⁹¹ (and brilliantly elucidated in the chimpanzee by Dusser de Barenne and McCulloch⁹²) have some causal relation to focal seizures, has plotted the site of injury in 138 cases of post-traumatic epilepsy and in 222 cases in which convulsions had not developed eighteen months to three years after wounding. The sites of wounding in the epileptic cases tended to accumulate in certain zones that correspond closely to the position of the suppressor bands as worked out in the chimpanzee. Little is known as yet concerning the actual position of the suppressor areas in man (except for the observation of Garol and Bucy⁸⁹ on area 4s), but there is every reason to suppose that they correspond to those in the chimpanzee. These important findings suggest that destruction of a suppressor band would release epileptogenic foci from inhibitory control and so precipitate seizures. Russell has put forward his findings with the greatest modesty, but many are prepared to believe that he has made a discovery of outstanding significance to neurology.

THE CEREBELLUM

The advances in knowledge of frontal-lobe function parallel those concerned with the cerebellum. Thanks to the work of Larsell⁹³ and Dow,⁹⁴ the cerebellum has emerged as a tripartite organ with discrete functional localization in three major spheres of integration: equilibration in the flocculonodular lobe, postural regulation in the anterior

lobe and regulation of phasic volitional movement in the posterior lobe (that is, in the cerebellar hemispheres) The anatomic correlates of this functional triad are also clear-cut, for the flocculonodular lobe is the only part of the cerebellum that both

hind extremity was stimulated, the primary responses appeared in the centralis. These studies were later considerably extended by Adrian,⁹⁶ who obtained the same pattern of reaction with lumbar and sacral segments having representation more anteriorly than thoracic and brachial segments

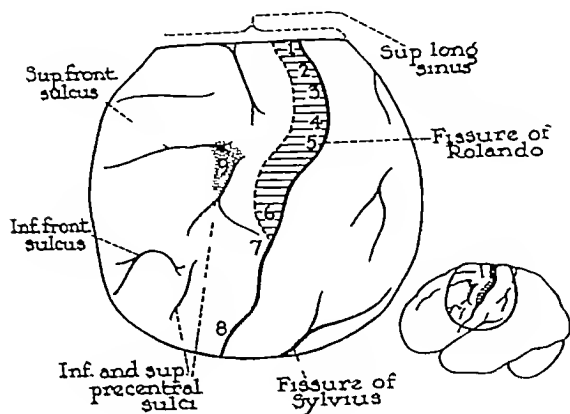

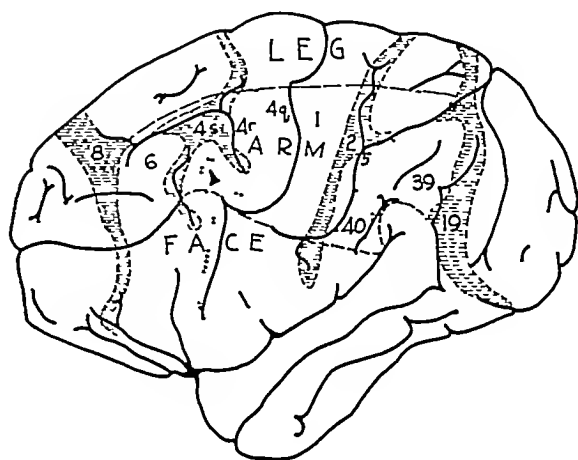

FIGURE 9 The Suppressor Area 4s in the Human Cortex

The stippled area 9 when stimulated caused generalized muscular relaxation, a rise in threshold of stimulation of points 1-8 in Area 4 and curtailment of after-discharge of area 4 response. The shaded area shows the strip of area 4 that was subsequently ablated. 1—flexion of the right hip, 2—contraction of the right quadriceps femoris muscle, 3—contraction of the right pectoralis major muscle, 4—flexion of the fingers of the right hand, 5—flexion of the right elbow and wrist, 6—movement of the neck and right shoulder, 7—movement of the right corner of the mouth and contraction of the right platysma myoides muscle, 8—movement of the lower lip on the right side, and 9—suppressor area (area 4s) (Reproduced from Bucy,⁹¹ with the permission of the publishers)

sends to and receives fibers from the vestibular nuclei. The anterior lobe receives the spinocerebellar projection and sends motor bundles to the reticular formation, red nucleus and other levels of extrapyramidal motor function, the posterior lobe receives its primary input from the frontopontocerebellar projections arising in the cerebral cortex.

Beyond these large primary divisions there has been until recently little evidence of more precise functional localization. Focal lesions, to be sure, had been made, both in the posterior and in the anterior lobe, but the resulting deficits never appeared to be sharply restricted to a given muscle group, or even to a given extremity. The only localization that was recognized was that the right half of the cerebellum presided over the homolateral musculature and the left over the musculature on its side. The first suggestion of more precise functional localization came from study of action potentials led off from the cerebellar cortex by Snider and Stowell.⁹⁵ They found, when the upper extremity was stimulated, that well developed action potentials appeared in the culmen, whereas when the

FIGURE 10 The Suppressor Areas in the Chimpanzee

Map indicates areas of sensory and adjacent cortex, distinguishable by physiologic neuronography, in *Macaca mulatta* (a) and *Pan satyrus* (b). Below are diagrams indicating maximal axonal field disclosed by repeated strychnizations in area marked Δ . Horizontal dashes indicate suppression of electrical activity, Y indicates area fired, ce refers to central sulcus, double vertical lines indicate anterior and posterior borders of sensory cortex. (Reproduced from McCulloch, [Chapter VIII] in Bucy,⁹⁵ p. 233, with the permission of the publishers)

The face, similarly, had representation more posteriorly in the posterior culmen and lobulus simplex. Adrian⁹⁷ made the interesting observation that the pig, which so largely depends upon its nose for its food supply, has a relatively enormous representation of its snout in sensory cortex.

The problem of functional localization in the anterior cerebellum has also been approached by

two other methods — namely, focal ablation and combined cortical and cerebellar stimulation. The ablation studies, which were begun by Connor⁹⁸ in 1940-41, gave unsatisfactory evidence, for although there appeared to be, in the dog at least, fairly clear evidence of functional localization, the effects were seldom sharply confined to a single extremity, and he was at first under the impression that such localization as appeared to exist was in the reverse sequence of that indicated by the electrical studies of Snider and Stowell. In an effort to obtain more satisfactory evidence of focal lesions, Soriano and Fulton⁹⁹ used the device of removing areas 4 and 6 from the cortex (monkeys) at a first operation (which gave a moderate degree of spasticity in both extremities of the opposite side). A focal lesion was then made in either the centralis or the culmen of the anterior cerebellum. When the lesion was in the centralis, the hind extremity became noticeably more rigid and more awkward than the upper extremity, when the focal lesion was restricted to the culmen, the reverse was true—that is, the upper extremity showed the most conspicuous effect.

Much more satisfactory, however, were the combined corticocerebellar-stimulation studies carried out by Nulsen and his associates¹⁰⁰. Nulsen had been influenced by the report from Hampson, Harrison and Woolsey¹⁰¹ that primary stimulation of the anterior lobe appeared to show evidence of localization similar to that disclosed by Snider and Stowell. Nulsen et al found that a cortically induced movement of a given extremity, such as the thumb, could be inhibited from a sharply defined focus on the anterior cerebellum and that a cortically induced movement of another muscle could be inhibited from another highly discrete focus. On mapping the cerebellum after this procedure, Nulsen was led to conclude that a degree of localization almost as sharp as that in the motor cortex itself exists in the anterior cerebellum and that a homunculus illustrating this generalization can be properly drawn. His summary was as follows:

Utilization of the inhibitory effect of cerebellar stimulation upon existing motor activity has permitted mapping of the anterior cerebellum as an homunculus representing individual muscles. The cerebral motor cortex or bulbar pyramid are stimulated at regular intervals and the uniform contractions of a single muscle are recorded. Simultaneous stimulation of cerebellar points is then undertaken to establish the location most effective for inhibition of response in that muscle. Such studies in the cat, dog, monkey, and chimpanzee under dial anesthesia show that the point corresponding to tail, hind-limb, fore-limb, and face musculature have an anteroposterior arrangement in lingula, centralis, culmen, and simplex lobules, respectively. Further localization in the monkey indicates that proximal muscles, as those of the upper arm, are best inhibited by ipsilateral cerebellar points near the mid-line, whereas distal muscles, such as the adductor pollicis, are best modified by lateral points in the same lobule. The homunculus for efferent effects thus obtained corresponds to that evolved by Snider and Stowell by observing the localized electrical activity of the cerebellar cortex induced by tactile stimulation.

In each animal, excepting the cat, increasing the frequency of cerebellar stimulation will result in facilitation rather than inhibition of the existing motor movement. The cerebellar homunculus for such facilitation is identical to that obtained when working with inhibition at low frequencies. The dentate nucleus (probably the dorsomedial portion) is involved in inhibition since its bilateral destruction allows only facilitation on surface stimulation, while its direct stimulation yields pure inhibition at all frequencies. Parallel evidence indicates that the fastigial nuclei transmit facilitatory impulses. Analysis of the effects of additional lesions of the brain-stem and cerebellar peduncles, combined with the oscillographic evidence of Snider, Magoun, and McCulloch, suggests that both inhibition and facilitation are ultimately mediated through the bulbar reticular formation.

Thus the same cerebellar point which receives tactile stimuli from a localized somatic area will upon electrical stimulation modify motor activity in the same region of the body. Depending upon the frequency of the stimulus, either inhibition or facilitation can be elicited from the same surface point. Evidence suggests that the pathways for the two effects then diverge to travel through different roof nuclei into the suppressor and facilitatory areas of the reticular formation. It is possible that these results of electrical stimulation may mimic the mechanisms by which the anterior cerebellum modifies the movements of an extremity in response to afferent impulses.

If the anterior cerebellum has given up some of its secrets, one can make an even more substantial claim for the flocculonodular lobe, for the war investigations of Bard et al¹⁰² have disclosed that ablation of this ancient nucleus (and of no other part of the forebrain) confers dramatic protection against motion sickness. Bard finds that dogs, whose susceptibility to vomiting when placed in a swing has been carefully appraised, continue to vomit after removal of any part or all of both cerebral hemispheres, even decerebration does not alter their susceptibility to swing sickness. The anterior and posterior lobes of the cerebellum can similarly be removed without effect, but if the nodulus is taken out in an otherwise unaltered animal, it can be swung for indefinite periods without signs of nausea and without the appearance of vomiting. The academic importance of this disclosure is, of course, considerable, whether my neurosurgical colleagues will take advantage of it in dealing with less seaworthy subjects remains an open question.

EDITH E. PARRIS, *Assistant Editor*

CASE 35231

PRESENTATION OF CASE

First admission. A sixty-five-year-old man, a newspaper editor, entered the hospital with the chief complaint of chest pain of three and a half hours' duration.

The patient had been entirely well until about ten days before admission, when he noted for the first time some substernal pain. This first attack came on after his noon meal, while he was walking, lasted two or three minutes and was characterized as a dull, aching, substernal, nonradiating pain. Since then he had about one mild similar episode each day, usually coming on after eating or walking. On the morning of admission, while working at his desk, the patient again noted the onset of a substernal and precordial pain. This increased in se-

verity over three quarters of an hour. This time the pain was of constant, severe nature in the left chest and precordium, without further radiation. The patient began to sweat and went into mild peripheral circulatory collapse. A physician admitted him to the hospital two hours after the onset.

The past history was noncontributory.

Physical examination revealed a well developed and well nourished man in mild discomfort. There were no other significant abnormalities.

The urine had a specific gravity of 1.016, with a + test for albumin, and the sediment contained 5 white cells per high-power field. The white-cell count was 20,800, with 72 per cent neutrophils. The hemoglobin was 15.1 gm. A blood sedimentation rate was 13 mm per hour. An electrocardiogram showed findings consistent with a recent anterior myocardial infarct.

The patient was given quimidine sulfate and dicumarol. The prothrombin time was maintained throughout the hospital stay at an average level of about 35 per cent of normal. The white-cell count remained distinctly elevated, with figures of 20,800, 19,400, 16,000, and at the time of discharge 12,300. The patient stayed in the hospital five weeks. His hospital course was relatively uneventful. He continued to sweat profusely at times. Three weeks after admission he had an episode of profuse sweating, with discomfort in his epigastrium, which came on after lunch, lasted about ten minutes and then disappeared. There was no real pain associated with this. There was no other change in his physical

signs, and there was no recurrence of these symptoms. He was discharged at the end of five weeks.

Final admission (two months later) After leaving the hospital, the patient continued to do well, and he gradually arrived at the state where he could be up and around his home on one floor most of the day, with short rest periods and without symptoms. About five weeks after discharge, however, he began to have some paroxysmal dyspnea and orthopnea. He was digitalized and temporarily relieved, but because of increasing dyspnea in spite of digitalization, he was readmitted to the hospital.

Physical examination showed a pale and apprehensive man with distended neck veins. There were scattered rales, dullness and diminished breath sounds at both bases. Tactile and vocal fremitus at the right base was diminished. The heart was enlarged, the sounds were slightly diminished, and there was a protodiastolic gallop. The liver edge was percussed 2 cm below the costal margin. The prostate was symmetrically enlarged. There was no peripheral edema.

The temperature was 99°F, the pulse 92, and the respirations 24. The blood pressure was 170 systolic, 90 diastolic.

There was no change in the urinary finding from the previous admission. The white-cell count was 19,000, with 84 per cent neutrophils. The hemoglobin was 13.4 gm. The nonprotein nitrogen was 27 mg per 100 cc. The chloride was 86 milliequiv, the carbon dioxide 33.7 milliequiv, and the sodium 133.9 milliequiv per liter. An electrocardiogram was consistent with a healing anterior myocardial infarct. X-ray examination of the chest showed cardiac enlargement, both to the right and to the left. There was bilateral pulmonary edema, and a moderate pleural accumulation on the right.

In spite of intensive therapy, including full digitalization, mercurial diuretics, a low sodium regime and oxygen therapy, the patient remained in congestive heart failure, with recurring episodes of pulmonary edema that were very nearly fatal for a period of almost two weeks. A venesection produced some temporary improvement. The patient was febrile, the temperature being elevated to 102°F by rectum for the first week. On the third hospital day he was started on penicillin (300,000 units a day), and the temperature returned to normal three days later. Penicillin was discontinued on the tenth day. The patient developed acute urinary retention when he was first admitted, and this necessitated placing him on constant bladder drainage. In addition to digitoxin, penicillin and aminophyllin, quinidine was added as part of the therapy because of cardiac irregularities. The abdomen was very distended and tympanitic, and the patient gradually accumulated fluid in the right chest. In the face of strenuous and heroic therapy, he gradually improved. The lungs became less congested. The pitting edema of the thighs and sacrum, which de-

veloped soon after admission, had subsided by the tenth hospital day.

The laboratory data about the tenth hospital day revealed a hemoglobin of 9.5 gm, a white-cell count of 18,000, a normal urine, a nonprotein nitrogen of 31 mg, and a serum protein of 6 gm per 100 cc, a sodium of 133.6 milliequiv, a chloride of 82 milliequiv and a carbon dioxide of 31.5 milliequiv per liter. At the end of two weeks right-sided heart failure recurred as manifested by increasing distention of his neck veins, increasing fluid in his right chest, enlargement of the liver and marked distention of the abdomen. A chest x-ray film showed no change. Because of increasing difficulty in breathing and discomfort in the right chest a thoracentesis was done, yielding 1000 cc of clear, straw-colored fluid. This procedure afforded considerable relief of symptoms.

On the nineteenth hospital day, he began complaining of epigastric fullness, discomfort and hiccups. There was abdominal distention, most marked in the epigastrium. There was no spasm or tenderness. The abdomen was tympanitic. Stomach and rectal lavage was done, relieving the abdominal discomfort somewhat. The temperature, which had been normal, began to spike to levels of 101-102°F. Coincident with this last episode he became drowsy, lethargic and occasionally disoriented. The sodium was 119.1 milliequiv, chloride 82 milliequiv, and carbon dioxide 27.1 milliequiv per liter. The nonprotein nitrogen was 32 mg per 100 cc. He was given measured quantities of sodium chloride, crysticillin and sulfadiazine. His mental condition improved, but the fever and white-cell count of 22,000 continued. A urine culture showed colon bacilli and rare beta-hemolytic streptococci. After a week on crysticillin and a week on sulfadiazine without any effect on the temperature, streptomycin was started in dosage of 2 gm a day. Six days later his temperature returned to normal and remained so until the last thirty-six hours of his admission. He maintained this status for about two weeks. The striking features at this time were apathy, weakness, persistent anemia and leukocytosis. A rounded nontender mass was palpated far laterally in the right abdomen, just above the iliac crest. Several thoracenteses were done on the right, which always yielded clear, straw-colored fluid with 53 polymorphonuclear leukocytes, 21 lymphocytes and 125 red cells per cubic millimeter. No organisms were present in a smear and none were grown out in culture. After about forty days in the hospital his circulation was much improved. His congestion was in abeyance, but he remained weak, apathetic and gaunt in appearance. There was fluid at the right base, with a widespread friction rub over most of the right chest. The latter finding was a new development. A chest x-ray film at this time revealed that there was considerable decrease in the congestive changes previously noted.

in the lung fields. There was, however, still some prominence of the peripheral vessels bilaterally, and there may have been a minute amount of residual fluid at the right base. An anteroposterior view of the upper abdomen showed the right liver edge to be rather low in position.

Shortly after this the patient began to complain of some difficulty in swallowing. This was rather persistent. It was most commonly associated with the ingestion of pills. It was described as discomfort beneath the lower third of the sternum and under the right lower ribs. This sometimes seemed to be relieved by gelusil and at other times subsided spontaneously. These symptoms were persistent enough so that after two months of hospitalization, in spite of the patient's precarious position, a gastrointestinal series was done. He was examined in the recumbent posture and with only a minimal amount of time spent because of his cardiac status. There was no gross evidence of involvement of the esophagus, stomach or duodenum. About three weeks after the onset of difficulty in swallowing the patient began having intermittent attacks of right-upper-quadrant discomfort radiating laterally. This was frequently accentuated by deep breathing. Pain was only transitory, however, and was relieved spontaneously. The patient again associated the onset of this pain with the ingestion of the pills that he was taking. A complete physical examination at this time revealed fluid in the right chest, and some coarse, moist rales at the right base. The left chest was clear and resonant. The heart sounds were not changed. The abdomen was soft and flat. The liver was palpable, as was the rounded mass in the right lateral quadrant. It was still not clear whether this mass was a part of the liver or a separate entity.

On the seventy-sixth hospital day, while sitting up in a chair in his room and within a few minutes after swallowing two pills of enteric-coated sodium chloride, the patient complained of severe, excruciating pain in the upper mid-abdomen radiating toward the right lower costal margin. This pain increased in severity. The patient became cold and sweaty. The blood pressure was 150 systolic, 90 diastolic, the pulse 90 and regular, the respirations 25, and the temperature 99°F. The neck veins were flat, and the lungs were normal except for dullness at the right base. The heart sounds were not changed. The abdomen was rigid, particularly in the upper half. Peristalsis was absent. The pain was made worse by the supine position and was relieved by sitting up. Respiratory excursion was limited by the pain. The femoral pulses were normal. The white-cell count was 31,600, with 75 per cent neutrophils. The serum amylase was 33 units. Signs of peripheral collapse became more apparent. A plain film of the abdomen in the supine and upright positions revealed no air under the diaphragm.

An exploratory laparotomy disclosed no abnormalities in the stomach, biliary tract or small or large intestine. For the first twenty-four hours the patient rallied from operation with surprising stamina. The abdominal pain was relieved. He complained of some sharp pain in the left axilla aggravated by breathing. He was alert and in good spirits. The temperature rose to 102°F, and the pulse and respirations became more rapid. Thirty-six hours later, he began to fail. The pulse became weak and thready, and the respirations increased, the temperature rose to 106°F. There were absent breath sounds and diminished resonance over the entire left chest. There were no rales. The heart sounds were of good quality, but the rhythm was grossly irregular. The blood pressure was 140 systolic, 60 diastolic. The abdomen was soft and not distended. He died about forty hours after operation.

DIFFERENTIAL DIAGNOSIS

DR EDWARD D CHURCHILL. The first admission seems to have been an episode of myocardial infarction. The history is quite typical. The patient was brought into the hospital and stayed five weeks, and the infarction was confirmed by electrocardiographic findings — in fact, localized as a recent anterior myocardial infarct. I see nothing in the first admission that is not fully accounted for by that diagnosis, which apparently was the discharge diagnosis. It might be well to note that the white-cell count is recorded as 20,800, in association with this lesion. He was able to be up and around his home for about two months, and then the dyspnea increased and was uncontrolled by digitalization. The second hospital stay was a very long one, in fact, the terminal events started on the seventy-sixth day of residence. The former diagnosis of anterior myocardial infarction was confirmed by electrocardiogram, and the lesion was classified as "healing." The heart was enlarged, both to the right and to the left. There was bilateral pulmonary edema, and pleural effusion on the right. Venesection and a low sodium regimen appear to have been indicated, and apparently the situation was assayed as congestive heart failure with recurring episodes of pulmonary edema. Some of these were serious, since it is stated that only strenuous and heroic therapy finally led to improvement. The patient showed anemia and a hemoglobin of 9.5 gm and still had an elevated white-cell count. The kidney function seems to have been satisfactory. The venous pressure was elevated, and the chest was aspirated several times.

During the second admission, increasing abdominal symptomatology was apparent. On the nineteenth day, he complained of epigastric fullness, discomfort and hiccups, with abdominal distention. The leukocytosis and fever appeared to center on a secondary infection, and colon bacilli and beta-hemolytic streptococci were cultured from the urine.

He was treated with sulfonamides and finally streptomycin, and the fever subsided and remained normal until the terminal event. This was puzzling to the medical attendants as shown by the sentence "The striking features [even when the temperature was brought down to normal] were apathy, weakness, persistent anemia and leukocytosis." Then the observation was made that a round, nontender mass could be palpated far laterally in the right abdomen, just above the iliac crest—in other words, in the region of the appendix. That completes the grouping of a series of findings that pointed to something below the diaphragm. Previously, everything was associated with myocardial insufficiency and myocardial infarction. At this point, it is noted that a few days later a widespread friction rub was heard over the right chest. That was a new development, and came despite the fact that the pulmonary congestion was diminishing. A mass in the right lower quadrant, a friction rub over the right chest and persistent leukocytosis immediately raise the question, Did this man, during a period of cardiac decompensation, insidiously develop an appendiceal abscess with extension to the subphrenic space? Perhaps the fluid in the right chest is not explainable on the basis of cardiac decompensation. It may have been inflammatory. The fluid itself, taken from the right side, was clear and straw colored but did show 53 per cent polymorphonuclear leukocytes per cubic millimeter and remained sterile. It would be perfectly consistent with an inflammatory fluid in contrast to that from passive congestion. So I have no doubt that the constellation of events caused worry and discussion, because a man of sixty-five will sometimes, right under our eyes on a ward, develop an appendiceal abscess, showing very little reaction. Certainly, that is one of the first things that a palpable mass in the right lower quadrant suggests. There are many other happenings that could have caused the fluid in the right chest in addition to cardiac failure. Pulmonary infarction would have accounted for this completely, but I take it that there was no evidence by x-ray film of pulmonary infarction, in fact, the radiologist says that the lungs looked clearer than they had for two weeks.

Then a new symptom appeared—difficulty in swallowing, particularly noticed in swallowing pills. There was also discomfort below the lower third of the sternum and under the right lower ribs. I take it that this was intermittent but persistent enough, so that despite the fact that the patient was very sick he was taken to the x-ray department for investigation. A great many reservations were made about the findings. It is stated that the patient was examined in the supine position. Obviously, he was very ill, and the roentgenologists want us to know that they did not have complete confidence in the results of the examination. Dr Wyman will comment later. The abdominal symp-

toms again come to the fore. After about three weeks with the difficulty in swallowing, there began to be right-upper-quadrant discomfort radiating laterally, not very severe, apparently, or very disturbing to the patient. Again, it was the pills that were annoying him and seemed to bring on right-upper quadrant pain. Still no explanation was found. The liver edge was down, as one would expect with cardiac failure, with peripheral congestion and high venous pressure. The rounded mass in the right lower quadrant was still palpable. Again, reservations are thrown in—the examiners were not sure whether it was liver or a separate mass, although the story does not quite hang together, the liver edge was described as palpable just below the costal margin, and the mass was at the iliac crest.

An acute episode ushered in the terminal event on the seventy-sixth hospital day. The patient was sitting up in a chair in his room when he was given some more pills (enteric-coated sodium chloride). Severe, excruciating pain was felt in the upper mid-abdomen, radiating again toward the right and along the costal margin. This pain was more severe than any he had had before, and was followed by peripheral vascular collapse. The abdomen is described as being rigid, particularly in the upper portion. Peristalsis was audible, and he was much more comfortable while sitting up than when trying to lie down. Respiratory excursions were limited by pain. Apparently, his physicians worried about embolism and carefully ascertained, as far as the femoral arteries were concerned, that the circulatory pathways were not blocked. The white-cell count was high, but this was always a fairly constant finding in this case. Peripheral collapse was not severe at the onset because he was running a blood pressure of 150 systolic, 90 diastolic, and a pulse of 90, but it increased, and he was examined for a perforated viscus by inspection for air under the diaphragm. Operation was performed, apparently in the belief that an acute abdominal crisis had occurred. Lo and behold, no disease was found at operation! It is definitely stated that there were no abnormalities in the stomach or biliary tract or in the small or large intestine. If we accept that statement at its face value, we must rule out the tentative diagnosis of appendiceal abscess. So, I see no justification in entertaining the somewhat attractive idea that this man had a smoldering appendix with subphrenic-space infection. Certainly exploration during life is nearly as accurate as exploration at autopsy, and we have to keep on the beam of the evidence as given to us. After the operation, the examiners appear to have been somewhat surprised that the patient staged a comeback and complained no longer of abdominal pain. Perhaps he had medication, or other ancillary treatment, and forgot about it, but he had other events to worry about. A sharp pain appeared in the left

axilla and was described as pleuritic. The pulse and respirations were more rapid. He then went into a tailspin of peripheral vascular collapse, the temperature rising to 106°F. There were terminal atelectasis and aspiration pneumonia, presumably, of the left lung associated with pleuritis, completely irregular cardiac rhythm and death forty hours after operation.

Dr Wyman, will you give any x-ray evidence that you have on this obscure case?

Dr STANLEY M. WYMAN: The first two films taken at the first admission show bilateral pleural effusion. The heart is large but without characteristic configuration. There is rather pronounced engorgement of the hilar and pulmonary vascular shadows. The next film, taken a month later, shows what is probably a large collection of fluid in the right pleural space and a hazy ground-glass density overlying both lung fields centrally, consistent with edema. A little more than three weeks later the lung fields have cleared very definitely, and the fluid in the right pleural space also appears to have decreased considerably. Taken on the same day is this film of the upper abdomen.

Dr CHURCHILL: This is at the time he was sent down in a search for a cause of the difficulty in swallowing?

Dr WYMAN: No, this is a month before that. This film shows the liver margin extending down close to the iliac crest.

Dr CHURCHILL: Could that have been the mass that was felt?

Dr WYMAN: I should think so, but I should think the tip of the liver would have been recognized.

Dr CHURCHILL: The examiners did not know whether it was liver or not.

Dr WYMAN: There is nothing particularly diagnostic on these films. This is the film after barium was given in an attempt to explain the difficulty in swallowing. It shows no gross abnormality in contour or position of the lower esophagus, stomach or duodenum. The next films are taken approximately a month later, and the liver shadow appears to have increased in size still further and is now overlying the upper portion of the right ileum. I do not recognize any definite bone metastases or any abnormal soft-tissue shadows. The kidney outlines are fairly well seen.

Dr DANIEL S. ELLIS: What is the shadow overlying the eighth dorsal vertebra?

Dr WYMAN: I think that is an artifact. It may well be a pill.

Dr CHURCHILL: In doing the fluoroscopy, did they get a look at the full length of the esophagus?

Dr WYMAN: I would assume so from the description. I believe the fluoroscopist probably had his best look at the esophagus. That usually is the case in a gastrointestinal series on a person as sick as this. One can see the esophagus quite well. It is more difficult to see the stomach and duodenum.

Dr CHURCHILL: But you do not see any x-ray evidence of, let us say, cancer of the esophagus obstructing the swallowing of pills?

Dr WYMAN: The only evidence is the fluoroscopist's word. There is no evidence for or against it on the film.

Dr ELLIS: How much fluid is there in the left chest?

Dr WYMAN: The film was taken with the patient lying down, and I can see no evidence except a small quantity in the costophrenic sinus. I think he had a small amount. There may be more posteriorly, which I cannot see.

Dr CHURCHILL: There is one major question we might as well try to resolve on the evidence. Did this man have intra-abdominal disease? What kind of intra-abdominal disease could be overlooked at a laparotomy forty hours before the patient died of it? It seems to me that we have to follow the record here. It is stated that there were no abnormalities in the biliary tract. Does that include the liver?

Dr ELLIS: It was an entirely negative exploration except for slight congestion and enlargement of the liver.

Dr CHURCHILL: Otherwise nothing was seen or felt in the abdomen?

Dr ELLIS: That is right.

Dr CHURCHILL: He was operated on within a few hours of the episode of collapse?

Dr ELLIS: Four hours.

Dr CHURCHILL: There is one question we should ask ourselves. Could a mesenteric thrombosis or an occlusion of the celiac axis have been present without changes visible to or palpable by the surgeon four hours after it occurred? I should think not. A lesion of the mesenteric vessels that causes death in forty hours would show some dusky or lack of pulsation in the mesenteric arteries at four hours. So it seems to me, as the evidence stands, that we must accept the physical findings of laparotomy as ruling out the acute abdominal crises that may be expected to occur with hypertensive cardiac failure. We must also rule out completely the somewhat tempting idea of appendiceal abscess, with liver or subphrenic-space abscess, because the surgeon in exploring this man would certainly run his hand up over the dome of the liver. We must also rule out perforated viscus, volvulus and other acute abdominal emergencies.

We then come to a discussion of acute and fatal episodes that might be linked with the difficulty in swallowing and cause pain, excruciating in nature, in the epigastrium. There is one very rare entity—namely, rupture of the esophagus. With rupture of the esophagus all the signs and symptoms of an acute abdominal emergency may be present, and abdominal exploration if carried out will be negative. Is it possible that when swallowing these large pills the patient tore the lower end of his esoph-

agus? Cases of rupture of the lower thoracic esophagus, as I say, are rare, but they have been diagnosed occasionally in life. It seems to me that we are left with that as the one possible solution. Was this rupture of a normal esophagus or extension of infection by trauma to an ulcer of the esophagus or perforation of cancer of the esophagus? It seems to me that we have to accept the findings of the fluoroscopist that there was no cancer of the esophagus causing obstruction to swallowing. However, he might have overlooked a small ulcer. Things happened so rapidly at the end and were so characteristic of an acute emergency that it does not seem possible to say that the patient died of another myocardial infarction. The heart sounds were of good quality, although the rhythm was grossly irregular.

The only suggestion I have to offer from the surgical point of view is that of rupture of the lower thoracic esophagus. It could have proved fatal in about forty hours and not have been disclosed at laparotomy. I will leave to Dr. Ellis whether the terminal event here could be interpreted simply as another major myocardial infarction. Obviously, the medical attendants did not think so, or they would not have called the surgeons to operate.

DR. BENJAMIN CASTLEMAN: How do you account for the chronic abdominal pain?

DR. CHURCHILL: I do not account for it.

DR. CASTLEMAN: It would have nothing to do with the final diagnosis?

DR. CHURCHILL: I would like to account for it, but with a completely negative examination of the abdomen by laparotomy a few hours before death I do not believe one has any basis to account for it.

DR. ELLIS: The protocol was as complete as we could make it, so I have very little to add. In retrospect, I think that some of the discomfort in the right chest, which we had been attributing purely to encroachment on the lung by fluid, may have been due to something else. On the other hand every time we tapped the right chest the patient was relieved of the discomfort. With regard to the cell count of the chest fluid, though leukocytes were present there were never many cells, and we had no idea that anything else was going on other than right hydrothorax, on the basis of cardiac failure. No further cell counts were done until after the third tap, which showed a negative culture.

The mass described was thought by one examiner at one time to be the liver and at another time a separate entity. The uncertainty was caused by the abdominal distention. I personally came to believe that it was a long tongue of liver extending down laterally and was a part of the liver and probably not any other mass.

As far as the terminal episode is concerned, with the negative exploration we were just as much puzzled

as Dr. Churchill. We, of course, considered the possibility, as we had done before operation, that the episode was caused by another myocardial infarct, but we ruled that out because the heart sounds remained good and the electrocardiogram the next day showed no further evidence for infarction. I believe that the terminal picture was due as much to a massive collapse of the left lung superimposed on his weakened myocardium as anything else. The temperature of 106°F pointed to a superimposed element of infection. But I doubt very much if this patient could have survived the massive collapse and everything else he had. That was the thing that tipped the picture if he did not have massive collapse I doubt if he would have died as soon as he did. I would like to ask Dr. Churchill if perforation of the esophagus could have occurred forty hours before death. If so, how does he explain the anemia, the persistent white count from the time of admission and the weight loss?

DR. TRACY B. MALLORY: Can you go any farther, Dr. Churchill?

DR. CHURCHILL: I cannot explain past events because I am accepting verbatim the completely negative findings in the abdomen. There are many unexplained features in this case. I see no group of symptoms, however, or findings that point toward any other specific diagnosis.

DR. ELLIS: I might say that we operated with a diagnosis of perforated peptic ulcer and thought that was what we were dealing with.

CLINICAL DIAGNOSES

Massive collapse, left lung
Myocardial infarct, with congestive heart failure
Dissecting aortic aneurysm?

DR. CHURCHILL'S DIAGNOSES

Perforation of thoracic esophagus, with mediastinitis and pleuritis
Old myocardial infarction
Hypertensive heart disease, with cardiac decompensation

ANATOMICAL DIAGNOSES

Ulcer of esophagus, with perforation into mediastinum and left pleural cavity
Subacute mediastinitis
Empyema, left, acute
Massive collapse, left lung
Coronary thrombosis, old
Myocardial infarct, old
Duodenal ulcer, active, penetrating

PATHOLOGICAL DISCUSSION

DR. MALLORY: I will show a lantern slide demonstrating the major finding, which Dr. Churchill

correctly predicted. There was a perforation of the esophagus, which can be seen at this point where the toothpick has been inserted through an orifice measuring 9 by 13 mm. We found nothing suggesting that there had been a diverticulum at that spot, and we do not see in the microscopical sections the evidence of peptic ulceration that one sometimes sees in esophageal perforation, so we cannot state what the etiology of the ulcer was. There was a considerable amount of purulent infiltration throughout the mediastinal tissues, which we classified as subacute. I am not able to give a very exact estimate of its duration. At the time of autopsy the ulcer communicated directly through into the left pleural cavity, and there was a very fresh empyema on the left. The mediastinitis was certainly of longer duration, so I would assume that the ulceration had occurred in two stages, an initial penetrative into the mediastinal tissues producing mediastinitis, and a second one, when the process broke through into the pleural cavity, which accounted for the terminal episode of collapse. There was an old myocardial infarct that had been correctly placed by electrocardiographic evidence and at the time of autopsy was completely fibrous and healed, with evidence of fresh extension. The left descending coronary artery showed completely occlusive organized thrombus. The mass in the right lower quadrant was an abnormal knob, which extended from the lower margin of the right lobe of the liver, simply an anomaly in the shape of the liver.

We did find one intra-abdominal condition that may have been responsible for a significant portion of the symptoms, a penetrating ulcer of the posterior wall of the duodenum backing up against the pancreas. It could certainly have been responsible for the anemia and for some of the pain. It is one of the easiest of intra-abdominal conditions to overlook at even a very careful exploratory operation.

DR ELLIS: The patient's stools were repeatedly guaiac negative.

DR JACOB LERMAN: I would like to suggest the possibility that some of the chronic abdominal pain was due to hypocalcemia and hyponatremia as is seen in Addison's disease for example.

DR MALLORY: The possibility I cannot rule out, although I think we have two adequate anatomic explanations for it.

DR CHURCHILL: I think the combination of a duodenal ulcer and an ulcer in the esophagus might have caused it. The ulcer of the duodenum was penetrating the head of the pancreas.

DR ELLIS: You do not think that the pills, the enteric-coated salt, had anything to do with perforating the esophagus, do you?

DR MALLORY: I would hate to be challenged in court on that.

CASE 35232

PRESENTATION OF CASE

First admission. A fifty-five-year-old single school-teacher was admitted to the hospital because of pain in the left flank.

One week before admission she awoke with severe pain in the left flank. The pain did not radiate and was steady. At the onset there were five loose bowel movements, but following this the bowels were normal. The bowel movements aggravated the pain. The pain remained severe for one day and then slowly diminished. She was admitted for study.

The temperature, pulse and respirations were normal. In the lower abdomen there was generalized tenderness most marked on the left. A tender mass was felt arising from the pelvis. A barium enema demonstrated multiple diverticula, most numerous in the region of the upper sigmoid, where there was marked spasm, there were streaks of barium extending outside the lumen of the bowel on its medial aspect. In the region of the gall bladder there were three ring shadows, which a Graham test proved to be in the gall bladder. The dye concentrated normally.

A gall bladder full of stones was removed. The common duct was explored and was normal. Convalescence was uneventful.

Second admission (ten years later). In the interval the patient remained on a low roughage diet and mineral oil. There was no change in bowel habit. She occasionally noticed an increased feeling of gaseousness, especially after eating, and this was often relieved by passing of gas or a bowel movement.

Five days before admission the patient was awakened by a sudden, severe pain in the left upper quadrant that spread across the abdomen. She

believed that passing gas might relieve the pain. She fainted twice and her doctor found a large mass in the left upper quadrant and severe left-costovertebral-angle tenderness. Several hours later the doctor found the mass to be smaller. There was no nausea. The pain subsided and did not recur. Bowel movements did not change during the days preceding admission and the appetite remained fair.

Physical examination of the heart and chest was negative. In the left upper quadrant there was a definite sense of increased resistance with a questionable, tender mass. There was spasm and some costovertebral-angle tenderness. Examination of the urine was negative.

The temperature, pulse and respirations were normal.

An intravenous pyelogram was reported as follows:

Preliminary films show a small patch of density adjacent to the superior aspect of the left pelvic aperture, which may represent barium outside the colon from a previous examination or is possibly still present in a diverticulum of the sigmoid. There is evidence of a mass in the left mid-abdomen, which is rather vaguely made out but appears to measure at least 10 cm. in its greatest dimension. The left psoas muscle is just visible through the density of the mass although it is not well defined. The inferior pole of the left kidney is likewise just barely visible. There is no definite evidence that the mass is associated with the kidney, although the likelihood is not entirely excluded. The opaque medium is excreted promptly by both kidneys in good concentration outlining essentially normal-appearing renal calyx, pelvis and ureters, except for a suggestion of slight displacement of the proximal left ureter medially. A barium enema shows multiple diverticula in the region of the sigmoid and a lesser number in the distal transverse and descending portion. There is evidence of encroachment by the mid-abdominal mass upon the descending colon and distal transverse colon.

A gastrointestinal series was negative except for a hiatus hernia. The body of the stomach and proximal jejunum were displaced toward the midline by the previously described mass. There was no evidence of splenic enlargement.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. WALTER E. GARREY: The first admission seems to be a clear-cut story of a flare-up of diverticulitis of the sigmoid with perforation, apparently well walled off. During the course of interpreting these abdominal films three ring shadows were demon-

strated that were evidently gallstones. Some time later (I suppose time was allowed for the diverticulitis situation to improve), an operation was performed, and a gall bladder full of stones was removed. The surgeon evidently found small stones as well as large, round ones, and he explored the common duct and found that it was normal. That was over ten years before the second admission, so I suppose the films are not available. The patient had an uneventful convalescence and got along well for ten years.

Then she came back with a different story, at the age of sixty-five. She had been advised to maintain herself on a low roughage diet and had taken mineral oil. We are not told about leukocytosis or the total blood count and smear. Both were noncontributory, I judge, and I also judge that the temperature was normal during the period that followed entry.

There was x-ray evidence of encroachment by a large abdominal mass on the descending colon and the distal transverse colon. I hope for further amplification of the word "encroachment." I want to know if Dr. Wyman can see any evidence of mucosal involvement of the bowel itself by this mass or whether it really means that the position of the mass was such that it had altered the position of the transverse and the descending colon. I would particularly like to know whether any lateral films were taken, either during barium enema or lateral oblique films during the pyelogram.

May we see the x-ray films? I do not have much of a clinical story and I cannot feel the mass, so I have to depend a good deal on what help I can get from the x-ray studies.

DR. STANLEY M. WYMAN: The plain film of the abdomen as described in the protocol shows the indistinct border of the left psoas muscle. There is a sense of increased density overlying this area, which cannot be accurately outlined. The left kidney lies definitely lower than usual, and I think that this lower pole is more medially placed than the right and certainly more medially than is commonly seen. There is also some displacement of the upper ureter as suggested in the protocol. This is the area of unusual density described on the plain film, which was thought to be barium from previous examination. Three films of the barium enema show extensive diverticulosis in the sigmoid, descending colon, and distal transverse colon. The mass

lies in this area and appears to displace the colon without involving it. This film was taken with the left side raised in oblique projection, and shows that the mass lies well posteriorly. The two films from the upper gastrointestinal series show again a mass displacing loops of jejunum medially. I think there is a hiatus hernia but nothing more that I can be sure of. Incidentally, from the previous story I believe that this shadow of barium actually is a small extravasation adjacent to the colon.

DR GARREY: The x-ray studies have been helpful. From the protocol I certainly had no very clear idea whether we were dealing with an intraperitoneal mass or a retroperitoneal mass, and if a retroperitoneal mass whether or not it was extrarenal.

I think we can begin our discussion by eliminating certain possibilities that seem unlikely. I would eliminate first of all primary renal tumor on the basis that all the renal calyces are seen, and that there is no demonstrable distortion of any renal calyx. I would think, then, that, while we cannot be absolutely sure that this mass was not associated with structures near the root of the mesentery, the lateral film here suggests that it had its origin far posteriorly, and that it probably was a retroperitoneal mass, rather than a mass in the root of the mesentery. I would have liked to see, for a retroperitoneal tumor, a little more displacement or distortion of the kidney, either by rotation or by displacement of the ureter, than is demonstrated here, but, still, there apparently was some. I would eliminate any connection between this mass and the previous diverticulitis. I think it is unlikely that this mass had resulted from a perforation posteriorly. In the first place the diverticula are usually along the other border of the bowel. We are not told that she ran a temperature or leukocytosis. When we do come down to the question of what sort of retroperitoneal, extrarenal mass this might have been, there are legions of tumors that occur in this area. Many of them probably have their origin in the structures along the urogenital ridge and may have a variable histology. They may be embryonal-cell carcinoma or various tumors or may show mixed histology. This might be a fibroma or neurogenic sarcoma or fibrosarcoma. It seems to me too laterally placed to be derived from lymph-node structures, and I doubt that it was any of the malignant lymphoma series. Could it have originated from an adrenal rest or from the adrenal gland

itself? There are large adrenocortical tumors that are found in this retroperitoneal flank area, and they do not, by any means, show endocrine stigmas on the surface of the body. However, one would expect that the kidney would be displaced downward if this were adrenocortical carcinoma, and I think that is unlikely. Was this mass tender? Why did this patient have acute pain for a while? The best hypothesis, I think, is that in some way the encroachment of this mass on the bowel with narrowing of the bowel caused some transient distention of a hollow viscus even though she did not vomit, and the exacerbation of pain that came and went was on that basis.

I will venture to say that the operating surgeon was not very sure of exactly what kind of tumor he was going to find, or whether it could be extirpated and cured. I would like to know what the preoperative diagnosis was. I take it that no bruit was heard with a stethoscope in this mass and no pulsation made out, or such a finding would have been indicated in the protocol.

In summary, I would eliminate any infectious process and would eliminate aneurysm and would come back to a solid tumor, which I believe to be a retroperitoneal rather than an intraperitoneal one. But I would simply say that the exact histology of such a mass is usually not predictable until the time of biopsy or excision, but from the general shape of this thing one might expect it to be an embryonal-cell carcinoma or one of the spindle-cell tumors, neurogenic sarcoma or fibrosarcoma. I take it that the possibility of a secondary implant from something in the pelvis is pretty well ruled out by adequate pelvic or rectal examination, and in a woman, of course, the extremely common situation of metastasis from a small tumor in the testicle is eliminated.

DR CLAUDE E. WELCH: Dr Wyman, is the shadow of the spleen discernible on the films?

DR WYMAN: I think it lies in this region, it is not remarkable.

I do believe, Dr Garrey, that the left kidney lies lower than usual.

DR GARREY: That could bring us back to primary adrenal neoplasm, but it seems to me that the kidney is not displaced very far down. It is probably lower than the one on the right. It is rotated. That would be further evidence for a retroperitoneal extrarenal lesion. I would like to revise my assump-

tion and bring in another structure as a possibility, although I think it is unlikely — namely, something in the tail of the pancreas. It seems to me that the whole shape and delineation of this thing is down farther than a pancreatic cyst or tumor in the tail of the pancreas would be, and I am accepting the x-ray statement that the shadow of the spleen could be seen to rule out cyst of the spleen. I do not believe that would be nearly so likely to displace the kidney downward, and it brings me back to whether this might be an adrenal tumor or sympathicoblastoma originating in the adrenal area. I can only say that it is a possibility.

CLINICAL DIAGNOSIS

Retroperitoneal tumor

DR GARREY'S DIAGNOSIS

Left retroperitoneal extrarenal tumor, either embryonal-cell carcinoma or neurogenic sarcoma or fibrosarcoma

ANATOMICAL DIAGNOSIS

Perirenal hematoma

PATHOLOGICAL DISCUSSION

DR HOWARD ULFELDER. As Dr Garrey so wisely predicted, we contented ourselves with a preoperative diagnosis of retroperitoneal tumor and did not believe the evidence warranted being more specific than that, although I personally thought it might arise from the pancreas. This patient was explored through a transverse incision in the left upper quadrant directly over the mass. The peritoneal cavity was free of any abnormality. The descending colon was pushed forward and ran over a retroperitoneal tumor, which was about as large as a baseball. Palpation of this tumor showed that the peritoneum was freely movable over it, and

there were a number of large vessels crossing it. It seemed to be in continuity and inseparable from the left kidney. It was my impression that we were dealing with a tumor of the lower pole of the left kidney, and therefore the incision was extended laterally and upward to remove the distal portion of the tenth rib and expose the retroperitoneal space after incision of the diaphragm. This allowed easy dissection of the tumor and kidney as one mass, the ureter was transected well below it, and it was then completely free except for the pedicle. The renal vein was normal to palpation, we transected it just distal to the left ovarian vein. The renal artery was cut, and the mass removed in one specimen and sent to Dr Mallory.

DR TRACY B MALLORY. The specimen that reached the laboratory showed a kidney embedded in a very large amount of hemorrhagic perirenal fat. The kidney was absolutely normal. The surrounding fat showed multiple dissecting planes of hemorrhage all through it and a few small foci of early fat necrosis.

The diagnosis, I think, is still somewhat questionable. In a woman of sixty-five asymptomatic rupture of a retroperitoneal vessel is a good possibility. We have on many occasions seen apparent acute abdominal emergencies from rupture of the hypogastric artery, simulating closely an attack of acute appendicitis, and I think in all probability rupture of an unidentified vessel in the perirenal tissues was the source of this hematoma. An outside possibility might be pancreatitis at the extreme tail of the pancreas. That was suggested by the small foci of fat necrosis, but there was nothing else to suggest it in either the clinical history or the anatomical findings. I think apoplexy of an unidentified perirenal artery was probably the cause of her symptoms.

THE ANNUAL MEETING

THE Massachusetts Medical Society has celebrated its one hundred and sixty-eighth consecutive annual meeting. The record may be mentioned with pardonable pride as unparalleled in this country, the New Jersey Society began its existence in 1766 but held no meetings from 1775 to 1781, when the country was otherwise engaged, and again suspended operations between 1795 and 1807. The total registration was 1454, of which 1230 were physicians.

The Council met on the evening of May 23 at the Hotel Sheraton, in Worcester, with an unusually large attendance. At this meeting three new sections were voted into existence: a section on psychiatry and neurology, one on ophthalmology and otolaryngology, and one on industrial health.

A considerable amount of business was dispatched during the course of the evening. The Executive

Committee was upheld in its disapproval of the annual registration of physicians, and a co-ordinating committee to work with the American Medical Association in publicizing the advantages of voluntary over compulsory health insurance was approved.

The fourteen proposals for improving the distribution of medical care, adopted on February 9 by the committees on Medical Economics and Public Relations, were earnestly discussed. Proposal 13, agreeing that the federal Government should "subsidize medical and nursing education, medical indigents, health and diagnostic centers, including mental, where not now adequate," was referred back to the committee for clarification. The remaining proposals were accepted with suitable modifications.

Under an amendment to the report of the Committee on Ethics and Discipline pertaining to a code of ethical conduct for physicians and institutions in their public relations, the appointment of a committee of five to draw up such a code was approved.

After debate the organization of not more than five pilot health-protection clinics in pivotal localities in the State as recommended by the Department of Public Health and the Committee on Public Health was approved.

The following officers were elected for the ensuing year: president, Dr. Arthur W. Allen, president-elect, Dr. Leland S. McKittick, vice-president, Dr. Albert A. Hornor, secretary, Dr. H. Quimby Gallupe, treasurer, Dr. Eliot Hubbard, Jr., assistant treasurer, Dr. Norman A. Welch, orator, Dr. John W. O'Meara. It is a pleasure to welcome Dr. Allen to his post and to rest secure in the knowledge of his ability to discharge its manifold functions.

The general sessions, constituting a well rounded program of clinical and scientific papers, were held in the Little Theater of the Worcester Memorial Auditorium beginning on the morning of May 24, and continuing through May 26.

The annual meeting of the Society took place also on the morning of May 24 and was highlighted by the President's report on the state of the Society, the awarding of prizes to three medical students and the annual oration.

As previously instructed by the Council, the Committee on Medical Education, on nomination by the deans of the three medical schools in the Commonwealth, had selected a fourth-year student from each school "who best exemplifies those intangible qualities which serve to designate him as the good physician." These students were Sylvan B. Baer, of Boston University School of Medicine, Henry S. Harvey, of the Harvard Medical School, and William H. Ellswood, of Tufts College Medical School. They were presented with suitably bound and illuminated autographed volumes of the George R. Minot Symposium on Hematology. It is hoped that the presentation of these detours may become an annual event.

The oration of the year, appearing as the leading article in this issue of the *Journal*, was delivered by Dr. C. Sidney Burwell, dean of Harvard Medical School, on "Some Responsibilities of Medical Education."

Among the changes in the by-laws ratified at the annual meeting was a new section providing for the creation of an advisory board to the President, consisting of the five most recent past presidents of the Society.

The Woman's Auxiliary of the Society was simultaneously holding its first annual meeting at the Worcester Woman's Club. The following officers were elected for the coming year: president, Mrs. Charles E. Ayers, of Worcester, president-elect, Mrs. Howard F. Root, of Brookline, first vice-president, Mrs. George F. Wilkins, of Brookline, second vice-president, Mrs. Roy W. Layton, of Melrose, recording secretary, Mrs. Claude E. Welch, of Belmont, corresponding secretary, Mrs. John F. Conlin, of Boston, treasurer, Mrs. Edward L. Peirson, of Salem. Mrs. Leighton Johnson, the retiring president, is to be congratulated on the progress that the Auxiliary has made during her administration.

On the morning of May 25 the Shattuck Lecture, which has already appeared in the *Journal* of May 26, was delivered by Dr. Paul D. White of Boston on the subject "La médecine du coeur." In the evening, at the annual dinner, Roscoe Pound, LL.D., university professor emeritus of Harvard University and former dean of the Harvard Law School, de-

livered an address on "The Professions in the Society of Today."

A singularly happy event on this occasion was the presentation to Dr. James C. McCann of a memorial from the Society, in recognition of the great service that he has rendered to the practice of medicine as president of Massachusetts Medical Service.

In the planning of the program and the excellent arrangement of the exhibits, great credit is due to the state and local committees of arrangements.

THE DOCTOR AND THE MEDICAL LIBRARY

THE organization of the Associates of the Yale Medical Library, extending to physicians in Connecticut borrowing privileges formerly reserved to those connected with the School of Medicine, indicates a growing awareness of the value of the medical library in medical education. All doctors in Connecticut, as well as all Yale medical alumni, have been invited to become members of the group, whose purpose is to maintain and augment the present medical collections and to extend their usefulness to the medical community at large, for expansion of the facilities and services of the Library, the Associates are required to pay a small annual subscription fee and are urged to contribute books and other material. The response to this invitation has been encouraging. Both Yale University and the officers of the Associates deserve credit for making this excellent collection available to doctors in Connecticut.

A similar association of the Boston Medical Library and the Massachusetts Medical Society has enabled physicians in Massachusetts to share the benefits of an outstanding medical collection.¹ The annual report of the Librarian, printed elsewhere in this issue of the *Journal*, points out the increased use of the facilities of the Library in 1948, apparently owing to the extension of borrowing privileges to members of the Society. In return, the allocation of a part of the dues of Society members has provided vital financial support for the Library. This additional income, although welcome, is not sufficient to enable the Library to make the repairs and alterations in its plant that are essential to maximum efficiency. The Library still lacks the \$75,000 for the erection of new stacks.²

The doctors in Connecticut and Massachusetts may well be proud of their support of these institutions whose contribution to medical education is so great. It is to be hoped that the funds essential to continued and expanded usefulness will be provided by those who benefit most from the opportunities offered: the physician who is doing research on an important project for which the records of previous work are essential, the writer of medical articles who wishes to make an adequate survey of the literature on the subject concerned, and the doctor, specialist or general practitioner, who desires to keep abreast of medical progress in his own and related fields. A small contribution from each would guarantee continuation of privileges that might be considered a generous return on a wise investment.

THERE LL ALWAYS BE AN ENGLAND

AN ANNOTATION, according to the latest ruling of Webster, is a note added by way of comment or explanation. The annotation, as featured in the *British Medical Journal* or *The Lancet*, is by way of being a minor editorial in that it sometimes reflects the editor's views. The full-dress editorial in the *British Medical Journal* or *The Lancet*, is a leading article. An annotation in certain American journals is classed as current comment. Other journals employ the same form without classification — a relatively safe maneuver.

A fascinating annotation, in *The Lancet* of January 15, 1949, considers the various aspects of the writing of a report, as discussed at a meeting of the section of epidemiology of the Royal Society of Medicine. Writing is defined by one authority participating in this discussion as a development of the art of speaking. On the type of speaker that the writer may be depends the style of his writing — if he is able to address large groups he may write for the general public, if he speaks best to an audience of one his reports should be written as though they were personal letters.

Professor A. Bradford Hill, the well known statistician, defends his own peculiar form of intellectual activity, cleaving to the table as opposed to the

graph. Conclusions, however, must be in accord with the figures. As a classic discrepancy a statute of George III is quoted "which required half the penalties paid under the Act to be given to the informer and half to the poor of the parish, but the only penalty it allowed was 14 years' transportation."

Dr. A. L. Banks, apparently a disciple of the Roman military writers, maintains that the important question to be decided is whether any report is necessary at all. If the decision is in the affirmative it should be sufficiently complete to kill the subject stone dead with one blow, and that is a lesson that some American authors who spin from a subject a dozen yarns for a dozen different journals should learn.

According to another disputant, three types of reports may be considered for three classes of readers. 'A report to a health committee should contain the facts and all the facts, a report to a senior officer should contain selected facts, and a verbal report to students should contain one fact repeated three times.'

BOSTON MEDICAL LIBRARY

INCUNABULA AND EARLY MANUSCRIPTS

During 1948 eighteen incunabula were added to the Bullard and other collections, making a total of 715 to January 1, 1949. The collection is now the largest in a medical library in the United States and is outstanding among the collections in the country. Notable additions include a unique copy of Baldovinus Sabaudiensis, *Ars memorativa* (c. 1485), Gentilis de Fulgineo, *Tractatus de balneis* (Santorso, 1473), *Somnia Danielis* (Rome, about 1482-1488), this edition not being recorded in the United States, Dominicus de Carpanis, *De nutrienda memoria*, (Naples, about 1476), Gaspar Torrella, *Dialogus de dolore cum tractu de ulceribus in pudendragra* (Rome, 1500), an early tract on syphilis, with which is bound three early sixteenth-century tracts of Torrella, Pythagoras, *Ludus* (Padua, about 1482), not recorded in the United States, and the second edition in quarto of Sprenger and Institoris, *Malleus maleficarum* (Speir, about 1491), a popular book on witchcraft issued a number of times in the fifteenth century of which the Library now has the second to fourth editions. Dr. William Norton Bullard, who gave the Library a substantial sum for the purchase of books and manuscripts issued before 1700, was greatly interested in this subject.

and presented to the Library a large collection of books on witchcraft and demonology, including a number of incunabula and early English imprints, to which there has been added the Deetjen library, with surprisingly little duplication

The Library is interested in acquiring a representative collection of medieval and early renaissance manuscripts relating to medicine and in all the learned languages of the period. During 1948, an Arabic manuscript of the fifteenth century on drugs, one in Hebrew of the fourteenth century on personal health and one in English of the fifteenth century, comprising the receipt book of an English physician, were added to this division, which now totals sixty-two items

COLLECTED WORKS

The Boston Medical Library has been interested for many years in the regularly published works of physicians and collections of reprints of individual authors and of institutions and has a very large division of this type of material, and is pleased to add to it as occasion offers

Collections of writings of one or more authors are important to libraries for reference purposes and fall into a number of classes, one of which is collections of reprints of single authors. These again may be divided into two classes, of general and special interest

Those on special subjects are in some cases very important. The Boston Medical Library has received recently the *Collected Reprints* of Dr. William G. Lennox, bound in five volumes and containing his published writings from 1919 to 1947, numbering 190 papers and monographs. Dr. Lennox is recognized as an international authority on epilepsy and allied conditions. Likewise, there are the current series of Dr. Samuel A. Levine, the noted heart specialist, 1915-1946, and that of Dr. Maxwell Finland, of the Boston City Hospital, on infectious diseases, chemotherapy and allied subjects, bound in three volumes, 1923-1945

From time to time the Boston Medical Library receives important collections, such as the papers of Benjamin A. Broca, in five volumes, published in various places in France, 1882-1924, and presented by his widow, and a series of forty-nine papers by Pio Colombini, 1892-1910, published in Italy, and presented by an Italian friend. Dr. Lynn Thorndike, the eminent classical historian, presented to the library a series of his reprints of medical interest

A notable general collection of reprints is that of Dr. William Osler, bound in seven volumes, 1870-1920, by Dr. Osler and distributed to libraries and friends by the doctor

Collected works of institutions are issued by a large number of organizations. Likewise they fall into two categories, general and special. The

general class is well represented by the *Reprints of the Rockefeller Institute for Medical Research*, currently published, and now in its one hundred and thirty-fourth volume (1947). In the special division may be noted the *Collected reprints of the grantees of the National Foundation for infantile paralysis*, volumes one to eight (1928 to 1947)

Another class is represented by the regularly published works of individual authors, a notable example is the *Opera omnia* of Jerome Cardan, published in ten large folio volumes at Lyon in 1663. It is said that Cardan was paid by the page for his writings, and this accounts in some way for his large output. Likewise, there is the *Opera* of Galen, issued at Venice in two large folio volumes in 1490. It is a scarce work, four copies being listed in Stullwell's census of *Incunabula in American Libraries*, New York, 1940. There are copies in Boston, New Haven and Washington, and there was one in a dealer's stock in Philadelphia. The copy in the Boston Medical Library is in mint condition, untouched by the miniaturist, illuminator or rubricator. The definitive edition, by Kuhn, was not published until 1821-1833 at Leipzig. Likewise, the scholarly edition of Hippocrates by Littré, in ten volumes, was not published until 1839-1861 in Paris

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

GONORRHEA AND SYPHILIS — STANDARDS OF DIAGNOSIS, TREATMENT AND FOLLOW-UP STUDY

With the advice and assistance of the Advisory Committee to the Division of Venereal Diseases, the Massachusetts Department of Public Health has adopted standards for the diagnosis, treatment and follow-up study of patients with gonorrhea and syphilis who are seen in the state-co-operating venereal-disease clinics

On the basis of the changing terminology as applied to venereal diseases and particularly to syphilis, the following nomenclature has been adopted

I GONORRHEA

- 1 Acute — with or without complications
- 2 Chronic — involving the urethra (anterior and posterior), prostate, seminal vesicles, epididymis, vulva, cervix, pelvic contents, Bartholin's gland, joint, eye, meninges and other structures

II SYPHILIS

- 1 Primary — only if chancre is present.
- 2 Secondary — only if secondary manifestations are present and include recurrent secondary syphilis
- 3 Early latent — the presence of a symptomless infection characterized by a repeatedly positive standard blood test for syphilis with negative spinal-fluid serologic findings and with a history of a primary lesion within four years, or in the absence of history of initial lesion when the patient is less than thirty years of age.

4. Late latent — the presence of a symptomless infection characterized by a repeatedly positive standard blood test for syphilis with negative spinal-fluid serologic findings and with a history of a primary lesion for four years or more, or in the absence of history of initial lesion, when the patient is thirty years of age or more

5. Late syphilis

- A Mucocutaneous
- B Osseous
- C Visceral
- D Neurologic

(a) Asymptomatic

(1) Early — abnormality in the spinal fluid within four years after the primary infection in the absence of all symptoms and signs

(2) Late — abnormality in the spinal fluid four years or more after the primary infection in the absence of all symptoms and signs

- (b) Acute meningitis
- (c) Chronic meningovascular
- (d) Vascular
- (e) Tabes
- (f) Paresis
- (g) Taboparesis
- (h) Gumma
- (i) Primary optic atrophy
- (j) Other types

6. Congenital syphilis

A. Early — congenital syphilis in a child less than two years of age

B. Late — congenital syphilis in a child two years of age or more.

III CHANCROID

IV GRANULOMA INGUINALE

- 1 Exuberant
- 2 Ulcerative
- 3 Cicatricial
- 4 Other

V LYMPHOGRANULOMA VENEREUM

- 1 Anorectal
- 2 Genital
- 3 Inguinal
- 4 Urethral
- 5 Other

GONORRHEA

In general, a diagnosis of gonorrhea is made on history of exposure, clinical signs and symptoms, and positive smears and cultures

A complement-fixation test or skin tests for gonorrhea are not recommended

Smears

The laboratory diagnosis of acute gonorrhea in male patients may safely be made in the majority of cases on the basis of a positive smear, the method is less accurate in acute gonorrhea in the female. In chronic gonorrhea in both male and female, the smear method alone is unreliable, and the cultural method should be used in addition

Cultures

The cultural method of diagnosis should consist of growing of the gonococcus on a standard medium (Mueller's starch agar, Difco's proteose No. 3, chocolate agar, Peizer's medium, Thayer's medium and so forth), performance of oxidase test, and sugar fermentation reactions

The taking of cultural specimens requires the careful attention of the physician. The ideal

method is to obtain a specimen and streak it immediately on a solid medium. If this cannot be done, the inoculum should be dispersed in the transport medium and mailed to a central laboratory. The results with this latter method — other conditions being equal — varies directly with the interval between the taking of the specimen and its being placed on the cultural medium. If there is a delay of forty-eight hours before plating, indirect cultural methods are for all practical purposes worthless.

A smear should accompany every specimen that is to be cultured.

The Inoculum

In the male, the urethral discharge may be used as an inoculum. The prostatic and seminal vesicle strippings may also be used. However, urinary-sediment culture is the method of choice in the absence of urethral discharge in male patients. The first morning urine should be used.

In female patients, cervical cultures are preferred. A nonlubricated cervical speculum should be used for visualization of the cervix. The cervical mucus is removed with a dry applicator, and the cervix firmly squeezed with the blades of either a bivalve speculum or a pair of forceps. A sterile, dry applicator is then passed into the cervical canal, rubbed firmly against its walls and immediately streaked on the solid cultural medium or placed in the transport medium. Cultures should also be taken from the urethra after it has been stripped or from the orifices of Bartholin's gland if that structure is involved.

Follow-up Study

Each treated case of gonorrhea should be followed by smears and cultures until at least two smears and cultures taken at weekly intervals are negative. The patient should be asked to return on the third day after treatment, and smears and cultures should be taken at this time. Thereafter, they should be taken at weekly intervals. It is agreed that a standard serologic test for syphilis should be done when the patient initially reports to the clinic for diagnostic examination, one week after treatment, and thereafter at monthly intervals until four months have elapsed from the date of the last exposure, or until two consecutive blood tests taken at least a week apart are negative (whichever is later).

Contacts

If a history of a definite onset exists, the patient should be interviewed for all contacts within two weeks prior to the onset of symptoms and all contacts subsequent thereto.

If there is an indefinite history of onset or if symptoms are denied, the patient should be questioned for all contacts within the past month.

and presented to the Library a large collection of books on witchcraft and demonology, including a number of incunabula and early English imprints, to which there has been added the Deetjen library, with surprisingly little duplication

The Library is interested in acquiring a representative collection of medieval and early renaissance manuscripts relating to medicine and in all the learned languages of the period. During 1948, an Arabic manuscript of the fifteenth century on drugs, one in Hebrew of the fourteenth century on personal health and one in English of the fifteenth century, comprising the receipt book of an English physician, were added to this division, which now totals sixty-two items

COLLECTED WORKS

The Boston Medical Library has been interested for many years in the regularly published works of physicians and collections of reprints of individual authors and of institutions and has a very large division of this type of material, and is pleased to add to it as occasion offers

Collections of writings of one or more authors are important to libraries for reference purposes and fall into a number of classes, one of which is collections of reprints of single authors. These again may be divided into two classes, of general and special interest

Those on special subjects are in some cases very important. The Boston Medical Library has received recently the *Collected Reprints* of Dr William G Lennox, bound in five volumes and containing his published writings from 1919 to 1947, numbering 190 papers and monographs. Dr Lennox is recognized as an international authority on epilepsy and allied conditions. Likewise, there are the current series of Dr Samuel A Levine, the noted heart specialist, 1915-1946, and that of Dr Maxwell Finland, of the Boston City Hospital, on infectious diseases, chemotherapy and allied subjects, bound in three volumes, 1923-1945

From time to time the Boston Medical Library receives important collections, such as the papers of Benjamin A Broca, in five volumes, published in various places in France, 1882-1924, and presented by his widow, and a series of forty-nine papers by Pio Colombini, 1892-1910, published in Italy, and presented by an Italian friend. Dr Lynn Thorndike, the eminent classical historian, presented to the library a series of his reprints of medical interest

A notable general collection of reprints is that of Dr William Osler, bound in seven volumes, 1870-1920, by Dr Osler and distributed to libraries and friends by the doctor

Collected works of institutions are issued by a large number of organizations. Likewise they fall into two categories, general and special. The

general class is well represented by the *Reprints of the Rockefeller Institute for Medical Research*, currently published, and now in its one hundred and thirty-fourth volume (1947). In the special division may be noted the *Collected reprints of the grantees of the National Foundation for infantile paralysis*, volumes one to eight (1928 to 1947)

Another class is represented by the regularly published works of individual authors, a notable example is the *Opera omnia* of Jerome Cardan, published in ten large folio volumes at Lyon in 1663. It is said that Cardan was paid by the page for his writings, and this accounts in some way for his large output. Likewise, there is the *Opera* of Galen, issued at Venice in two large folio volumes in 1490. It is a scarce work, four copies being listed in Stillwell's census of *Incunabula in American Libraries*, New York, 1940. There are copies in Boston, New Haven and Washington, and there was one in a dealer's stock in Philadelphia. The copy in the Boston Medical Library is in mint condition, untouched by the miniaturist, illuminator or rubricator. The definitive edition, by Kuhn, was not published until 1821-1833 at Leipzig. Likewise, the scholarly edition of Hippocrates by Littré, in ten volumes, was not published until 1839-1861 in Paris

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

GONORRHEA AND SYPHILIS — STANDARDS OF DIAGNOSIS, TREATMENT AND FOLLOW-UP STUDY

With the advice and assistance of the Advisory Committee to the Division of Venereal Diseases, the Massachusetts Department of Public Health has adopted standards for the diagnosis, treatment and follow-up study of patients with gonorrhea and syphilis who are seen in the state-co-operating venereal-disease clinics

On the basis of the changing terminology as applied to venereal diseases and particularly to syphilis, the following nomenclature has been adopted

I GONORRHEA

- 1 Acute — with or without complications
- 2 Chronic — involving the urethra (anterior and posterior), prostate, seminal vesicles, epididymis, vulva, cervix, pelvic contents, Bartholin's gland, joint, eye, meninges and other structures

II SYPHILIS

- 1 Primary — only if chancre is present
- 2 Secondary — only if secondary manifestations are present and include recurrent secondary syphilis
- 3 Early latent — the presence of a symptomless infection characterized by a repeatedly positive standard blood test for syphilis with negative spinal-fluid serologic findings and with a history of a primary lesion within four years, or in the absence of history of initial lesion when the patient is less than thirty years of age.

during pregnancy for syphilis may still have a positive standard serologic test for syphilis at term, and the problem of deciding whether or not congenital syphilis has been contracted will have to be decided if the baby has a positive serologic test at birth. It is proposed therefore that when such a situation arises in which the mother and the newborn infant have positive blood tests quantitative serologic tests be done on both mother and child and titers established, a repeat blood test be done on the third day and thereafter at weekly intervals up to one month to determine the serologic pattern of the child (the mother should be tested at weekly intervals for one month), and, after the first month, the baby be tested at two-week intervals up to the end of the third month. The mother should be followed as any other treated case of syphilis.

If this is a reagin transfer, the blood test should revert to negativity, usually by the second month and definitely by the third month. If the baby's blood test is positive at the end of three months, a diagnosis of syphilis either congenital or acquired should be entertained.

If the baby's serologic pattern is one of decreasing titers proceeding to negativity and if the serologic titers have always been lower or at the most equal to the month's reagin titer, the child may be considered nonsyphilitic at the end of three months provided it has negative blood serologic tests.

However, if the baby's reagin titer is significantly higher than the mother's, even though the baby's blood may temporarily revert to negativity, the baby if infected will show at some time before the twelfth week and usually by the eighth week increasing blood titers. The rise in titers is frequently accompanied by the onset of symptoms.

Whenever a patient has been treated for acquired syphilis during pregnancy and on birth the infant shows no evidence of congenital syphilis and a negative blood serologic test, the follow-up study of the infant should continue at two-week intervals for the first month and thereafter at monthly intervals until a minimum of three months' observation has been completed. If the test is still negative at the end of the three months, it is recommended that the infant be examined on the sixth, ninth and twelfth months.

The presence or absence of congenital syphilis, therefore, in a patient who is seen by the physician regularly should normally be established by the end of the third month. However, unusual conditions may necessitate a longer period of study.

Blood from the umbilical cord should not be used as a diagnostic criteria for congenital syphilis.

Whole-body x-ray films of the newborn infant should be taken on or about the fifteenth day.

The treatment of primary, secondary, latent syphilis and syphilis in pregnancy is as follows:

DRUG	DOSAGE PER INJECTION	TOTAL INJECTIONS
Inpatient		
Aqueous penicillin G	80,000 units every three hours	60 (4,800,000 units)
Alternative Schedule)		
Aqueous penicillin G	80,000 units every three hours	60 (4,800,000 units)
Bismuth	0.2 gm. every other day intramuscularly	5 (1 gm.)
Alternative Schedule)		
Aqueous penicillin G	80,000 units every three hours	60 (4,800,000 units)
Bismuth	0.2 gm. every other day intramuscularly	5 (1 gm.)
Mapharsen	0.04 to 0.06 gm. intravenously weekly	10 (0.4 to 0.6 gm.)
Ambulatory or office		
Procaine penicillin G in oil with 2 per cent aluminum monostearate	600,000 units in a single injection daily	10 (6,000,000 units)
Alternative Schedule)		
Procaine penicillin G in oil with 2 per cent aluminum monostearate	600,000 units in a single injection daily	8 (4,800,000 units)
Bismuth	0.2 gm. every other day intramuscularly	5 (1 gm.)
Mapharsen	0.04 to 0.06 gm. intravenously weekly	10 (0.4 to 0.6 gm.)

As an alternative schedule, the standard Army treatment, twenty-six-week arsenobismuth series may be given:

WEEK OF TREATMENT	INJECTIONS OF ARSENOXIDE*	INJECTIONS OF BISMUTH†
1	2 weekly	1 weekly
2	2 weekly	1 weekly
3	2 weekly	1 weekly
4	2 weekly	1 weekly
5	2 weekly	1 weekly
6	2 weekly	
7	2 weekly	
8	2 weekly	
9	2 weekly	
10	2 weekly	
11		1 weekly
12		1 weekly
13	Omit arsenoxide	1 weekly
14		1 weekly
15		1 weekly
16		1 weekly
17	2 weekly	
18	2 weekly	
19	2 weekly	
20	2 weekly	
21	2 weekly	
22	2 weekly	1 weekly
23	2 weekly	1 weekly
24	2 weekly	1 weekly
25	2 weekly	1 weekly
26	2 weekly	1 weekly
Totals	40	16

*Each injection consists of 0.04 to 0.06 gm. intravenously of arsens dichlorophenarsine hydrochloride or mapharsen may be used.
†Each injection consists of 0.2 gm. intramuscularly

All contacts of gonorrhea should be reported directly to the Massachusetts Department of Public Health on the forms provided for this purpose

Treatment

Uncomplicated gonorrhea The treatment consists of 300,000 units of procaine penicillin in peanut oil with 2 per cent aluminum monostearate given intramuscularly in a single injection

Failure to respond When uncomplicated gonorrhea has been treated as above but the discharge has persisted for three days or more, or if the smear and culture is still positive for the gonococcus, the patient should be treated with 600,000 units of procaine penicillin in oil with 2 per cent aluminum monostearate in a single injection intramuscularly

Complicated gonorrhea The therapy should include 300,000 units of procaine penicillin in oil with 2 per cent aluminum monostearate daily for at least three days. The length of treatment will depend on the clinician's judgment

Patients sensitive to the oil Patients who may be sensitive to the oil may be treated with an aqueous solution of crystalline penicillin G as follows: 50,000 units of penicillin intramuscularly, 50,000 units at the end of the first hour, and 100,000 units at the end of the second hour¹

Alternative schedule An aqueous solution of 300,000 units of procaine penicillin may be given intramuscularly in a single injection

Patients sensitive to penicillin Patients sensitive to penicillin should be treated with sulfathiazole or streptomycin. Sulfathiazole should be given in 1-gm doses by mouth every four hours for four doses each day. Treatment should be continued for a period of five days

Streptomycin may be given in doses of 40,000 units every four hours for three doses or in a single injection of 300,000 units (that is, 0.3 gm) in saline solution intramuscularly

Patients who are strongly suspected of having been exposed also to syphilis should be treated for their gonorrhea with sulfathiazole and not with penicillin to prevent masking of a possible syphilitic infection

Mixed infections Patients with gonorrhea and chancroid or those with gonorrhea and granuloma inguinale may be treated for both infections with streptomycin

Vulvovaginitis This condition should be treated with the drugs enumerated above. Estrogens should not be used in the treatment of gonorrheal vulvovaginitis

SYPHILIS

The diagnosis of syphilis should be made as early as possible since a favorable outcome depends on how long the patient has had the disease before treatment

Diagnostic Methods

A darkfield examination should be performed routinely on all genital lesions, particularly of the ulcerative type, and all suspicious secondary eruptions, the examination may be immediate or delayed. The immediate darkfield examination is the method of choice and is the only type recommended for general use. The success or failure of any darkfield examination depends considerably on the material to be examined. Therefore, to obtain a specimen for this important test, the base of the chancre should be grasped firmly and the surface cleaned with a wet saline sponge. Under moderate pressure, clear serum should be allowed to ooze forth. It may be necessary to abrade the surface of the chancre with dry gauze. A small amount of bleeding may result, and the blood should be wiped off with a dry sponge until clear serum appears. While the serum is being examined, the patient should receive a standard blood test for syphilis

No genital lesion should be treated locally or otherwise until repeated darkfield examinations have been performed. Under no circumstances should an anti-septic be applied locally

Physiologic saline dressings alone should be used pending darkfield examinations

A single darkfield examination alone, if negative, is of no significance. It should be repeated again and again

Latent Syphilis

Every patient should be carefully questioned for any signs or symptoms of acquired or congenital syphilis. Any condition that may give a false-positive blood test must be ruled out. The diagnosis of latent syphilis should not be made until a lumbar puncture has been performed. Therefore, all patients presenting themselves to the clinic with a positive standard serologic test should have a repeat blood test followed by a lumbar puncture. Lumbar punctures may be done in the outpatient department. The spinal fluid should be examined for cell count, globulin estimation, total protein and complement-fixation tests

The Wassermann laboratory will perform, on request, on all positive spinal fluids quantitative serologic tests, globulin estimations and total protein determinations. Cell counts should be performed by the physician directly after the specimen has been taken. The normal cell count is 1 to 4 per cubic millimeter. The normal protein is 35 to 40 mg per 100 cc. It must be remembered that a negative spinal-fluid serologic test does not necessarily rule out neurosyphilis

Congenital Syphilis

The use of quantitative serologic tests attains its greatest value in assisting the physician in making a diagnosis of congenital syphilis. A mother treated

MISCELLANY

NOTE

Dr Franz Goldmann, associate professor of medical care at the Harvard School of Public Health, has been granted leave of absence from June through November, 1949, to serve as consultant to the Public Health Branch of the Civil Administration Division, Office of Military Government for Germany, under a project jointly sponsored by the Rockefeller Foundation and the American authority

CORRESPONDENCE

BRITISH DOCTOR LOOKS AT MEDICINE

To the Editor The following excerpt from a letter written by a former exchange medical student from England should prove of interest to the readers of the *Journal*

I hope you will forgive me if I seem terribly political but I thought I would mention a few of my feelings about

the Health Scheme since I think you may be interested I think I can honestly say that this move in England has started people thinking in many other countries besides our own I take one of the American medical journals, and each week I read with interest the comments that appear in the editorials upon the topic of nationalized and socialized medicine Incidentally, one of the best analyses of the subject I have read recently was in the *New England Journal of Medicine* Anyone would be very hard put to disagree with the basic principles of the scheme — namely, to try to provide medical care of reasonable standard to all people and to see that no one should be denied medical care because of poverty But I think many people will disagree with the methods adopted to bring this about. Quite frankly, I feel that the British medical profession is to blame to a large degree There do not appear to be the leaders of the caliber that is needed, and all through the negotiations I feel that the vast majority of the profession has been betrayed by the leaders One saw this particularly in the hospitals The seniors of the rank of "specialist" pleaded with the profession to withstand the demands of the Government, and then they themselves were the first ones to seek favor with the ministers and to secure the best positions In many ways the change was inevitable The cost of upkeep of a modern hospital, for instance, is a very considerable sum, and the voluntary institutions were falling into more and more debt With the present setup the Government is the main force controlling the expenditure of the service, and hence with this there is a distinct tendency for the policies of medicine to be dictated from a series of White Hall desks Check has been kept of everything, and so the number of forms that have to be completed is something quite phenomenal, particularly by the poor general practitioner, who has now become a sorting clerk He can devote only about three minutes at the very most to each patient and so if he suspects that there is a serious illness present he has to refer the patient to the hospital and thus lose any real medical work or else he spends the three minutes with the patient completing forms to provide him with free spectacles or extra milk or even a free wig Many people think this is a grand thing and trail along to the doctor to get something for nothing, little realizing that they are actually paying quite a lot for these "free" services I am afraid that British medicine is going to slide a long way behind the standards of other countries, for there is just no stimulus at all to provide a good standard Perhaps if there should be attempts to socialize American medicine you will see that the initiative comes from the doctors and not from the administrators

I am afraid that this has been a rather jumbled account but perhaps you can make a little sense out of it.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender Books that appear to be of particular interest will be reviewed as space permits Additional information in regard to all listed books will be gladly furnished on request

Fractures and Dislocations For Practitioners By Edwin O Geckeler, M D, fellow of the American College of Surgeons, the American Academy of Orthopaedic Surgeons and the American Association for the Surgery of Trauma and diplomate of the American Board of Orthopaedic Surgery Fourth edition 8°, cloth 371 pp, 344 illustrations Baltimore Williams and Wilkins Company, 1948 \$5 00

The first edition of this short textbook for students and general practitioners was published in 1937 Dr Geckeler has revised this fourth edition to bring it up to date since the third edition was issued in 1943 New methods of treatment have been included, and the experiences gained during the last war have been incorporated in the text A good index concludes the volume The illustrations and publishing are excellent The author recommends the methods that he considers the simplest and most reliable The book should prove useful to the persons for whom it was written

The treatment schedules for various forms of syphilis are as follows

DRUG	DOSAGE PER INJECTION	TOTAL INJECTIONS
Early congenital syphilis		
Aqueous penicillin G	100,000 units per pound of body weight divided into 60-100 doses every 3 hours	—
Late congenital syphilis		
Treatment is the same as in acquired syphilis		
Interstitial keratitis — penicillin as in early syphilis accompanied by fever, unless contraindicated		
Late mucocutaneous manifestations		
Treatment is the same as in early syphilis		
Other late manifestations except neurosyphilis		
Patient prepared with bismuth therapy, 0.2 gm weekly for ten doses, followed by penicillin		
Aqueous penicillin G	80,000 units every 3 hours q 3 ^o for 60 doses	
Procaine penicillin G in oil and so forth	600,000 units daily for 10 days	
Neurosyphilis — asymptomatic, acute meningovascular, gumma		
Aqueous penicillin G	50,000 units every 3 hours	120 (6,000,000 units)
<i>(Alternative Schedule)</i>		
Aqueous penicillin G	100,000 units every 6 hours	60 (6,000,000 units)
Tabes, paresis, taboparesis, primary optic atrophy, congenital neurosyphilis and syphilitic nerve deafness		
Aqueous penicillin G	50,000 units every 3 hours	120 minimum (6,000,000 units)
Clinical or serologic relapse, or both (other than neurorelapse)		
Double penicillin dosage		
Standard Army treatment		
Neurorelapse and failure to improve		
Penicillin treatment repeated, accompanied by fever therapy unless contraindicated		

Treatment of Arsenical Reactions

BAL (2,3-dimercaptopropanol) in oil,² containing 20 per cent benzyl benzoate, is indicated in the treatment of hemorrhagic encephalitis due to arsenotherapy, arsenical dermatitis, and possibly postarsenical jaundice, but not homologous serum jaundice following parenteral therapy. It is useful as an adjunct in the treatment of agranulocytosis due to arsenic, but other measures, principally massive doses of penicillin, must also be employed.

The toxicity of BAL appears to be less in patients suffering from arsenic poisoning, but doses of 300 mg (5 mg per kilogram of body weight) may produce nausea, vomiting and headache, a burning sensation of the lips, mouth, throat and eyes, generalized muscular aches, with burning and tingling of the extremities, and a sense of constriction in the chest. The symptoms usually subside in thirty to ninety minutes.

Dosage In the treatment of arsenic poisoning, 3 mg per kilogram of body weight should be given intramuscularly as follows every four hours for the first two days, four injections on the third day,

and injections twice daily thereafter for ten days, or until complete recovery. In milder cases the dose may be reduced to 2.5 mg per kilogram of body weight.

FOLLOW-UP STUDY OF TREATED SYPHILIS

All patients treated for syphilis should have a two-year follow-up study. All syphilis except late syphilis should be followed at monthly intervals for one year, and at quarterly intervals during the second year. Each patient should receive a lumbar puncture between the sixth and the twelfth month after treatment. Late syphilis, because of individual variations and individual problems, should be followed at the discretion of the physician — that is, in uncomplicated neurosyphilis a follow-up study at intervals of three to six months may be used.

CONTACTS

Patients with primary syphilis should be questioned for contacts within three months prior to the onset of symptoms and subsequent thereto.

Patients with secondary syphilis should be questioned for contacts within six months prior to the appearance of the secondary manifestations and subsequent thereto.

Patients with early latent syphilis should be questioned for contacts within a one-year period. All marital and familial contacts should be checked as indicated.

For patients with late syphilis, marital and familial contacts should be examined.

With congenital syphilis, the parents and available siblings should be examined.

The problem will arise of patients who while on ambulatory treatment miss one or more day's treatment with procaine penicillin. If such a patient should lapse for only twenty-four hours, the rest of the procaine penicillin schedule should be continued. But if the patient should lapse for forty-eight hours or more, the procaine penicillin series should be begun over again.

SUMMARY

With the able assistance of the Advisory Committee to the Division of Venereal Diseases, the Massachusetts Department of Public Health has adopted standards for the diagnosis, treatment and follow-up study of patients with gonorrhea and syphilis for use in the co-operating venereal-disease clinics.

The members of this Advisory Committee are the present chiefs or the recently retired heads of the venereal-disease co-operating clinics. They therefore reflect the most authoritative opinion in the field of venereal diseases in Massachusetts.

The name of each committee member and the clinic he represents are as follows

AURICULAR FIBRILLATION IN NORMAL HEARTS*

HUGH H. HANSON, M.D.,† AND DAVID I. RUTLEDGE, M.D.‡

BOSTON

AURICULAR fibrillation is not always associated with organic heart disease, and its presence may be the only sign attracting the examiner's attention to the heart. All cases of auricular fibrillation are fairly readily separated into two significant clinical groups — a minor group occurring in anatomically normal hearts and a major group occurring in damaged and diseased hearts. Emphasis should be placed on auricular fibrillation occurring in normal hearts because of its excellent prognosis, since this arrhythmia is most frequently observed in gravely damaged and decompensated hearts in which the prognosis is rather ominous.

Auricular fibrillation occurring in normal hearts has been variously termed "benign," "idiopathic," "auricular fibrillation of undetermined origin" and "auricular fibrillation in the absence of, or as the only manifestation of, cardiac disease." Although this array of terms may be somewhat confusing, they are all synonymous.

In 1911 Mackenzie¹ reported cases of auricular fibrillation in which no evidence of cardiac disease could be detected, and in 1913 Gossage and Hicks² demonstrated conclusively that such a condition existed.

MATERIAL

The material for this report consists of a review and follow-up study of all the cases of auricular fibrillation occurring in normal hearts that were seen at the clinic during the past two decades. The basis of selection was as follows: the presence of auricular fibrillation was confirmed by at least one electrocardiogram, taken at the clinic or elsewhere. If the patient had experienced two or more attacks lasting less than seven days and characterized by a sudden onset and termination, the fibrillation was considered paroxysmal, and if the condition existed longer than seven days it was considered established. After the presence of auricular fibrillation was confirmed, the following criteria were used to rule out cardiac disease: a history excluding rheumatic fever or allied disorders, hypertension, hyper-

thyroidism and coronary arteriosclerosis, a physical examination excluding cardiac enlargement, thrills, organic murmurs, hypertension and evidence of hyperthyroidism, a roentgenogram of the chest excluding abnormalities of cardiac size and configuration, an electrocardiogram excluding such abnormalities as marked axis deviation, significant T-wave changes and auriculoventricular or bundle-branch block, and laboratory studies excluding positive serologic tests, severe anemia, diabetes mellitus and an elevated basal metabolism.

A series of 651 cases of auricular fibrillation was reviewed, and only 30 cases (4.6 per cent) were found to have occurred in normal hearts. Of these, 10 (33.3 per cent) were established, and 20 (66.6 per cent) were paroxysmal (Table 1). Numerous cases of transient auricular fibrillation in apparently normal hearts were noted, but were not included in this report because the conditions under which they occurred inferentially excluded a normal myocardium. This point is elaborated below in the discussion of pathology.

INCIDENCE

That auricular fibrillation rarely occurs in congenital anomalies of the heart, syphilitic heart disease and bacterial endocarditis is well known. It may be present in any form of heart disease, but is most frequently observed in rheumatic (especially mitral stenosis) and hypertensive heart disease, hyperthyroidism and coronary arteriosclerosis; these four conditions account for approximately 89 per cent of all patients observed with this arrhythmia.³⁻⁵

Parkinson et al.⁶ found 85 per cent of their cases of paroxysmal auricular fibrillation associated with signs of cardiac disease. It is generally agreed by those familiar with the subject⁷⁻¹⁰ that approximately 6.5 per cent of all auricular fibrillation occurs in normal hearts, the arrhythmia being established in about a third of the cases and paroxysmal in the remainder. Auricular fibrillation is most frequently observed from the fourth through the sixth decade of life, reaching a peak incidence in the fifth decade, and it occurs most frequently in men. In the group reported here most of the established cases (70 per cent) were detected or occurred

Medical Research in France During the War (1939-1945) By Jean Hamburger, professeur agrégé à la Faculté de Médecine, Médecin des Hôpitaux de Paris, and Professeur Pasteur Vallery-Radot, member de l'Institut. 8°, paper, 306 pp., with illustrations Paris Éditions Médicales Flammarion, 1947

This work comprises a number of articles on a variety of medical subjects written by French physicians and translated into English for the English-speaking world. It embodies the results of medical research carried on by French physicians during the German occupation in World War II. The idea for the book came to Professor Vallery-Radot during a trip to the United States a few weeks after France was liberated, and he collaborated with Dr. Hamburger in assembling the collection of reports. The book is well published and should be in all medical libraries.

Venous Thrombosis and Pulmonary Embolism By Harold Neuhoof, M.D., clinical professor of surgery, Columbia University College of Physicians and Surgeons, and consulting surgeon, Mount Sinai, Montefiore, Beth El and Hackensack, New Jersey, hospitals. 4°, cloth, 159 pp., New York Grune and Stratton, 1948. \$4.50

This monograph is based on an intensive study of the subject for the purpose of working out a plan for the surgical management of pulmonary embolism. The text is divided into two parts: a discussion of the subject in its varying aspects, including the anticoagulant therapy with dicumarol and heparin, and a consideration of massive pulmonary embolism, based in part on a study of 88 fatal cases, and of etiology, diagnosis, prophylaxis and therapy (including embolectomy), and the mechanism of death. The author is convinced that the best results in these cases can be obtained by a special hospital team selected for the purpose. A bibliography and an index conclude the text. The monograph is well published and is recommended for all medical libraries and should prove valuable to physicians and surgeons interested in the subject.

Fielding H. Garrison: A biography By Solomon R. Kagan, M.D. 8°, cloth, 104 pp., with 8 illustrations. Boston Medico-Historical Press, 1948. \$4.00

This volume constitutes a supplement to the *Life and Letters of Fielding H. Garrison*, published by Dr. Kagan in 1938. It presents additional biographic material on the early life of Dr. Garrison and his family and his service with the Army Medical Library, in the Philippines and at Welch Medical Library in Baltimore. The text is embellished with a large number of letters. An adequate index concludes the volume. The book is well published and should be in all medical-history collections.

Essentials of Pathology By Lawrence W. Smith, M.D., and Edwin S. Gault, M.D., associate professor of pathology and bacteriology, Temple University School of Medicine. With a foreword by the late James Ewing, M.D., Memorial Hospital, New York City. Third edition. 4°, cloth, 764 pp., with 740 illustrations. Philadelphia: Blakiston Company, 1948. \$12.00

The first edition of this book was published in 1938. In this edition it has been revised and augmented with new material, and the text has been completely reset. Changes have been made in all the chapters, and some have been entirely rewritten. A large number of illustrative case histories have been inserted throughout the text. Likewise, the illustrations have been checked, some changes made, and sixty-one new figures added. A bibliography, arranged by chapters, and a good index conclude the volume. The type, printing and plate work are excellent. The book has been written primarily for students.

Dr. Robert A. Bolduc announces the opening of his office for the practice of general surgery at 180 Lincoln Street, Worcester.

MASSACHUSETTS PUBLIC HEALTH CONFERENCE AND NEW ENGLAND HEALTH INSTITUTE

The third annual meeting of the Massachusetts Public Health Conference and the New England Health Institute will be held at the University of Massachusetts, Amherst, from June 15-17.

INTERN PSYCHIATRIC AND SURGICAL RESIDENCIES

The United States Civil Service Commission has announced a medical-officer examination for rotating intern psychiatric resident and surgical resident positions in St. Elizabeths Hospital, Washington, D. C. The salaries for rotating interns are \$2200 for the first year and \$2400 for the second year, the salaries for psychiatric resident range from \$2400 to \$4100 a year, and those for surgical resident, from \$3400 to \$4150.

To qualify, applicants for the rotating intern positions must be third-year or fourth-year students in an approved medical school. Applicants for psychiatric resident and surgical resident positions must be graduates of a medical school with the degree of doctor of medicine, and must have completed a full year in an approved rotating internship. In addition to these requirements, applicants for appointment as surgical resident must have completed three full years as residents-in-training in surgery in an approved residency. No written test is required for this examination. The maximum age limit of thirty-five years is waived for persons entitled to veteran preference.

Further information and application forms may be obtained at most first-class and second-class post offices, from civil service regional offices or from the U. S. Civil Service Commission, Washington 25, D. C. Applications will be accepted by the Commission's Washington office until further notice.

CIVILIAN DOCTORS FOR PANAMA CANAL ZONE

Permanent appointments for physicians in the Civil Service now exist in the Panama Canal Medical Service. Owing to the high appeal of the health and living conditions in this tropical country, the number of appointments to be made is limited, and early applications are suggested, by the Panama Canal Office, from physicians who desire the opportunity for training and experience in tropical medicine under standard American living conditions.

Starting professional salaries are \$5599 and \$6540 a year, with free transportation to the Canal Zone provided for physicians, their families and household goods. In addition, doctors who receive appointments get two months paid vacation (including time lost by illness) and reduced fares on Panama Line passenger vessels.

Requirements for professional medical positions starting at \$5599 are graduation from an approved medical school, license to practice medicine in a state, ability to pass a standard physical examination, and completion of one year's internship in a hospital approved by the American Medical Association.

Requirements for professional medical positions starting at \$6540 are the same except that a minimum of three years of post-internship experience is required.

The Panama Canal Health Department operates several hospitals and a number of well equipped dispensaries offering excellent professional opportunities. The Health Department also maintains constant vigilance over the health conditions of the Canal Zone and the adjacent cities of Colon and Panama City.

Interested physicians should address their applications to the Chief of Office, The Panama Canal, Washington 25, D. C., or to the United States Civil Service Commission, Washington 25, D. C.

Dr. Hyman Alford announces the opening of his office for the practice of pediatrics at 1775 Beacon Street, Brookline.

unrestricted existence well into their fifth decade of life without evidence of heart disease. Case 9 is of exceptional interest, the patient maintains that his pulse has always been irregular, and that all the males in his family have a similar pulse

he had auricular fibrillation. He is now seventy-nine years old and has experienced forty-four years of confirmed auricular fibrillation without symptoms, cardiac limitation or the use of drugs. His father and brother both of whom had had auricular fibril-

TABLE 1 (Continued)

CASE No	EFFECT	SUBSEQUENT	AGE	COMMENT
1	None	Excellent health (pulse)		Patient asymptomatic in 1947 auricular fibrillation present
2	Established auricular fibrillation	Patient remained normal	Age 80	No evidence of heart disease in 1942
3	Established auricular fibrillation	Patient asymptomatic	Heart disease	Pulse 70-80 no dementia
4	Decrease in rate	Patient asymptomatic	Heart disease	In 1945 blood pressure 100/70 electrocardiogram showed auricular fibrillation x-ray film normal
5	Decrease in rate	Mild congestive heart failure excellent response to treatment	Age after 21 yr	Evidence of coronary sclerosis in 1945 blood pressure 140/70
6		Patient asymptomatic developed mild congestive heart failure after 44 yr and then died	Heart failure	In 1945 hypertensive heart disease (blood pressure 140/90) evidence of coronary sclerosis
7*		In 1947 latent congestive heart failure developed	Heart failure	In 1945 coronary sclerosis patient asymptomatic
8	Extensive slowing of rate drugs discontinued	Heart normal pulse 70	No dementia	In 1945 heart normal patient asymptomatic
9		Patient asymptomatic for 44 yr in 1945 congestive heart failure developed evidence of coronary sclerosis		All males in paternal family have irregular pulse
10*		Pulse 80-90 no dementia blood pressure 100/70		Heart normal
11	Cessation of attacks	Normal heart		In 1945 attacks less frequent
12	No effect conversion	No further attacks		Paroxysmal auricular fibrillation for 10 yr conversion sinus rhythm heart normal
13	Decrease in attacks	Heart normal after 20 yr of fibrillation		
14		Patient died of stroke in 1946		Congestive heart failure never developed
15		Coronary occlusion in 1941 after 35 yr of fibrillation		In 1945 no angina patient working hard and in excellent health fibrillation still present
16		No follow-up heart normal		Patient Canadian doctor
17	None conversion	Last follow-up 2 yr after conversion no more fibrillation		Complete cessation of attacks
18	Attacks abolished	Last follow-up 1945 no attacks no attacks heart normal		
19	No effect	Patient last seen 2 yr after evaluation heart normal fibrillation still present		
20	Attacks stopped	In 1944 carcinoma of rectum developed Miles resection performed		In 1945 no evidence of heart disease fibrillation still present
21	Attacks stopped	In 1945 blood pressure 160/100 heart normal		In 1944 fibrillation still present heart still normal
22		Attacks short and infrequent no symptoms		In 1947 heart normal fibrillation still present
23		Patient not interested in heart		No follow-up study
24	0.2 gm. daily prevents attacks	Patient has taken quinidine for 13 yr attacks occur if drug discontinued		In 1945 heart normal patient taking quinidine (brother with paroxysmal auricular fibrillation and normal heart)
25		In 1945 no more attacks		
26	Attacks ceased	1 yr after cessation of drug no attacks heart normal		
27		Fibrillation continued		Heart normal after 5 yr no problem
28	Attacks decreased	No treatment now attacks spontaneously less frequent		In 1945 heart normal 1 attack every 6 mo
29	Attacks abolished	No more attacks		
30	None Attacks abolished	Heart normal no more attacks		Fibrillation present 4 yr without symptoms

"This irregular pulse is a family legend passed on from father to son and is indicative of long life." The patient under discussion never visited a physician until thirty-four years of age, when he was told that

lution," had led a similar existence, dying at eighty-two and seventy-eight years of age, respectively, from "hardening of the arteries." This legend is very interesting, even in the absence of confirmation

in the fourth decade of life, and the paroxysmal (± 5 per cent) in the fifth. All the established cases and 55 per cent of the paroxysmal occurred in men.

Goldbloom and Segall¹¹ reported auricular fibrillation in an infant of 3 months whose heart was

Wolff¹² reported 5 cases of familial auricular fibrillation occurring in normal hearts, and stressed its benignancy so long as the ventricular rate remains slow and embolism does not occur. His patients were all athletic, enjoyed the "lesser evils" of life

TABLE 1 *Clinical Data in Cases of Auricular Fibrillation Occurring in Normal Hearts*

CASE No.	SEX	AGE WHEN CONDITION WAS DETECTED	DURATION	ASSOCIATED DISEASE	REASON FOR CLINIC VISIT	THERAPY
<i>Established auricular fibrillation</i>						
1	M	36	17	None	Evaluation	Quinidine
2	M	39	19 (paroxysmal auricular fibrillation) 6 (established auricular fibrillation)	Chronic anxiety	Irritable colon	Digitalis
3	M	35	0.8 (paroxysmal auricular fibrillation) 11 (established auricular fibrillation)	Anxiety	Evaluation	Digitalis
4	M	51	10	Anxiety	Evaluation	Digitalis
5	M	31	15 (paroxysmal auricular fibrillation) 6 (established auricular fibrillation)	None	Evaluation	Digitalis periodic
6	M	19	46	None	Evaluation	None
7*	M	38	26	None	Latent congestive heart failure	None
8	M	30	12	Peptic ulcer, inguinal hernia	Peptic ulcer	Digitalis
9	M	34	45	Arteriosclerosis	Mild congestive heart failure	None
10*	M	50	11	Carcinoma of stomach	Cancer	None
<i>Paroxysmal auricular fibrillation</i>						
11	F	26	22	None	Evaluation	Quinidine
12	M	43	10	Umbilical hernia	Evaluation	Quinidine, quinidine and digitalis
13	F	30	20	Irritable colon	Irritable colon	Digitalis
14	M	41	26	Cholecystitis with stones	Evaluation	None
15	M	35	35	Nasal polyps	Evaluation	None
16	M	45	8	Chronic sinusitis	Evaluation	None
17	F	42	10	None	Evaluation	Digitalis, Quinidine
18	M	48	12	Irritable colon	Irritable colon	Quinidine
19	F	51	2	Anxiety	Evaluation	Digitalis
20	F	42	22	Uterine polyps	Uterine polyps	Digitalis
21	M	53	27	Inguinal hernia	Hernia	Quinidine
22	F	38	7	Chronic nervous exhaustion	Evaluation	None
23	F	37	Years	Carcinoma of nose	Carcinoma	None
24	M	24	18	None	Evaluation	Quinidine
25	M	45	2	Anxiety (chronic)	Evaluation	None
26	F	21	3	Anxiety (chronic)	Evaluation	Quinidine
27	F	46	5	Menopause, arthritis	Evaluation	None
28	M	43	14	None	Evaluation	Digitalis, Quinidine
29	M	45	Unknown	Irritable colon	Irritable colon	Quinidine
30	M	32	5	None	Dyspnea	Digitalis, Quinidine

*Diagnosis made at insurance examination. Diagnosis made by local physician in all other cases except one which was discovered at clinic.

otherwise normal. Spontaneous conversion to sinus rhythm occurred at one year of age, and a ten-year follow-up study failed to reveal any evidence of cardiac disease.

and lived unrestricted without the necessity of drugs. In this series, Case 24 is an example of familial paroxysmal auricular fibrillation, and both the patient and his brother have enjoyed an active,

tors associated with attacks, but this is rare. Syncope has also been reported but is uncommon.

The one characteristic sign of auricular fibrillation in a normal heart is the slow ventricular rate with a negligible pulse deficit in the absence of digitalis therapy. In the established group of cases reported here, all had a ventricular rate between 60 and 90 per minute with an absent or negligible pulse deficit. The absence of a pulse deficit was commented upon by the examining physician in 50 per cent of the cases. The patients with paroxysmal attacks, during attacks, had a ventricular rate between 70 and 110 per minute in 90 per cent of the cases. Since most of these ventricular rates were taken from electrocardiograms obtained during attacks, the difference between apical and radial rates is unknown.

COURSE AND COMPLICATIONS

Patients with established auricular fibrillation may remain asymptomatic indefinitely. In 2 of the cases reported here it persisted over forty-four years before cardiac symptoms developed. Once established, the arrhythmia tends to remain permanently. An occasional case, however, reverts to sinus rhythm, spontaneously or under the influence of quinidine, after years of uninterrupted fibrillation.

Patients with paroxysmal auricular fibrillation may continue to experience attacks along a fairly regular course, or the attacks may become less frequent and of shorter duration, or cease—spontaneously or under drug therapy. Attacks may assume a progressive nature, becoming more frequent and of longer duration, and the arrhythmia becomes established. In such a course, digitalis is almost sure to result in established auricular fibrillation with symptomatic relief. In the cases reported here, 1 became established spontaneously and 2 by digitalis therapy, 10 cases were favorably influenced by drug therapy, paroxysms became less frequent in occurrence and of shorter duration in 1 spontaneously, and 9 continued along their usual course. Only 10 per cent of the paroxysmal cases usually become established.⁶

The duration and frequency of paroxysms are totally unpredictable. Brill^{21, 22} found that 90 per cent lasted less than seven days. In the cases reported here 90 per cent of the paroxysms lasted less than twenty-four hours, and 60 per cent less than four hours.

Complications from auricular fibrillation per se are rare, however, if the ventricular rate becomes rapid with a marked pulse deficit, anginal or syncope attacks may occur, and if this persists, congestive heart failure may supervene. Why the ventricular rate becomes rapid is unknown, but the resultant cardiac inefficiency proceeds to latent or manifest failure. This is a completely reversible type of heart failure and after decompensation

responds to the accepted forms of therapy, subsequent quinidization may effect conversion to sinus rhythm, resulting in a completely normal heart and preventing recurrence.^{6, 21, 22}

In addition to the previously mentioned complications that are peculiar to this condition, the patients, if they survive long enough, are subject to the malignant lesions, degenerative diseases and overwhelming infections of senility. Like all persons with normal hearts, many of them develop manifestations of coronary arteriosclerosis, coronary occlusion and hypertensive heart disease in later life. However, some die after years of auricular fibrillation, without clinical or pathological evidence of myocardial disease.

In this group of 30 patients, 20 have been adequately followed, and 65 per cent of these still show no evidence of heart disease. In those of advanced years, evidence of coronary arteriosclerosis has developed in 4 patients, 1 of whom has experienced an infarct, hypertensive and coronary arteriosclerotic heart disease has developed in 1, and hypertension in 2—1 died from a stroke. In 4 of these 7 patients some degree of congestive heart failure has occurred. The average age when failure made its appearance was sixty-four and a half years, and the average duration of confirmed fibrillation prior to failure was thirty-four years. It is interesting that in only 7 of these 20 patients has evidence of heart disease developed, and in these, manifestations occurred only after years of asymptomatic fibrillation and after they were approaching senility. Three patients have carcinoma, in these cases the heart remains normal.

DIAGNOSIS

There is usually little difficulty in determining the presence of auricular fibrillation on routine physical examination, but in all cases it should be confirmed by an electrocardiogram. Organic heart disease must be ruled out by the history, physical examination, roentgenogram, urine and blood studies and electrocardiogram. The criteria used in this study should be complied with before the diagnosis of auricular fibrillation in a normal heart is established.

Auricular tachycardia, auricular flutter and frequent extrasystoles may cause confusion on physical examination, but fortunately the electrocardiogram makes up for clinical inadequacies by vividly portraying the varying intervals between R waves and the absence of P waves.

In making this diagnosis one must beware of the young obese male, the diabetic patient and all persons in the sixth decade of life, for coronary arteriosclerotic heart disease may be concealed in these cases. Auricular fibrillation is frequently a manifestation of hyperthyroidism, and the nervous patient with a palpable thyroid gland cannot be dismissed without a thorough investigation. Rheu-

PATHOLOGY

That auricular fibrillation occurs in normal hearts has been proved repeatedly at post-mortem examination.^{8 10 11} Auricular fibrillation is a disturbance of auricular impulse formation and conduction that is a physiologic phenomenon and not a pathologic one. This was admirably demonstrated by Yater¹³ and summarized in his conclusion: "There is no pathologic change in the heart characteristic of auricular fibrillation." The pathology is mentioned here only to emphasize its absence.

The previously mentioned transient type of auricular fibrillation occurring in severe infections (typhoid, diphtheria, pneumonia, pleural effusions and fevers) following prolonged hypoxic surgical procedures (on the brain, chest and abdomen) and in various toxic states (diabetic coma, drug intoxication, inhalation of noxious gases and deep anesthesia) was purposely excluded from this report because the etiologic agent is obvious and pathologists are all too familiar with the myocardial edema, degeneration and inflammation associated with such conditions.

ETIOLOGY

Since an anatomic lesion has been excluded as the basis of auricular fibrillation one must explore the realm of physiology for an explanation. Friedlander and Levine⁷ advocated the theory of a "trigger mechanism" in which hypothalamic impulses transmitted via the vagus nerve produce the arrhythmia. Once the reflex is in motion it tends to become fixed, resulting in established auricular fibrillation unless some interference interrupts the circus movement. Other investigators working on the etiology of auricular fibrillation have presented evidence incriminating reflex vagal activity,¹⁴ increased intra-auricular distention¹⁵ and a combination of vagal tone and an exciting agent such as acetyl-beta-methyl-choline.¹⁶ However, these theories were presented to explain auricular fibrillation occurring in the presence of cardiac disease and are hardly applicable to that under discussion. Auricular fibrillation is frequently produced in animals for purposes of study by intravenous mechoyl or electrical stimulation of the myocardium.

Attacks of paroxysmal auricular fibrillation may be precipitated by nervous factors, and usually a combination of several are present. The arrhythmia is frequently observed in emotionally labile persons, and in mental workers who are subjected to stress. Many of the patients reported here were emotionally unstable and suffered from anxiety, nervous indigestion, fatigue and nervous exhaustion. Undoubtedly, reflex autonomic activity plays a role, but its exact relation remains unknown. Attacks of paroxysmal auricular fibrillation were associated with a psychogenic or functional element in 70 per cent of the cases studied. 30 per cent of

patients experienced attacks precipitated by anxiety, 25 per cent by indigestion, and 10 per cent by exhaustion and fatigue, and 5 per cent blamed alcohol and tobacco. Paroxysms occurred in response to any one of several psychogenic stimuli in some patients, and in a few the stimuli seemed to be additive in effect. No precipitating factor or known etiologic influence could be elicited in the cases of established auricular fibrillation.

PHYSIOLOGY

Auricular fibrillation is manifest by a totally disorganized multitude of fibrillary twitchings in the auricular muscle that convert it into a quivering mass of myocardium. The circus theory of auricular fibrillation is most widely accepted at the present time. Smith, Walker and Alt¹⁷ adequately demonstrated that in auricular fibrillation with a pulse rate below 100 and a negligible pulse deficit the cardiac output is normal, and that it diminishes as the pulse deficit increases. They also found that conversion of controlled auricular fibrillation to sinus rhythm did not increase the cardiac output. These findings were true of normal hearts and damaged hearts, in the absence of valvular lesions. By direct intra-auricular measurements, Stewart, Crawford and Gilchrist¹⁸ showed that auricular fibrillation with a nearly regular rhythm did not diminish the rate of blood flow. Buchbinder and Sugarman¹⁹ demonstrated, by direct measurements, that the arterial blood pressure is constant in cases of auricular fibrillation with a nearly regular rhythm. Hence, in normal or controlled auricular fibrillation, the cardiac output and the rate of blood flow are not diminished and the blood pressure is constant, ensuring adequate tissue oxygenation and normal tissue metabolism. Since auricular fibrillation in normal hearts is characterized by its slow ventricular rate and negligible or absent pulse deficit, it appears to be an efficient physiologic mechanism.

SYMPTOMATOLOGY

The symptomatology of this arrhythmia varies from an unawareness of its presence to partial incapacitation in the anxious and introspective. The group of cases reviewed here revealed that 80 per cent of the patients with established auricular fibrillation were unaware of its presence and asymptomatic, whereas the 20 per cent who experienced preceding paroxysmal attacks noted only palpitation and this symptom disappeared with establishment. It is remarkable that none of these patients were "heart conscious." Although 95 per cent of the patients with paroxysmal attacks experienced palpitation, the remaining 5 per cent were unaware of its presence until enlightened by the family physician. Other complaints associated with paroxysms were faintness, giddiness, exhaustion, slight dyspnea and anxiety. Wolff²⁰ reported angina pec-

intake, morphine, oxygen and mercurial diuretics as indicated and digitalized to control the ventricular rate and decrease the pulse deficit. After compensation is regained the arrhythmia may be converted to sinus rhythm by quinidine therapy, with gratifying and lasting results. Quinidine should not be used before compensation is restored because conversion may result in an uncontrollable tachycardia or embolism. When the manifestations of a complicating cardiac disease appear, the treatment is that of the underlying disease.

The young patient with auricular fibrillation and a normal heart is the ideal subject for quinidine therapy, however, one must weigh the benefits to be gained against the potential danger to the patient. Here the only real risk of quinidine therapy is that of sudden death from respiratory paralysis, ventricular fibrillation or cardiac arrest, and this has an incidence of about 1.8 per cent.²⁶ Because of its inherent risks, therapy should never be advocated for the sake of treatment. Sokolow²⁷ has advocated the use of quinidine routinely in patients with early auricular fibrillation and a normal heart, to prevent subsequent embolism, however, it is doubtful if such prophylaxis is justified. If quinidine therapy is to be instituted, the patient should receive two test doses of 0.09 to 0.2 gm four hours apart, and if no untoward symptoms occur the dose should be increased by 0.2 gm every four hours until conversion is effected or mild toxic symptoms such as nausea, tinnitus and diarrhea develop. After conversion is effected the patient should be placed on a maintenance dose of 0.2 gm three or four times a day for a brief period, and this gradually worked down to a minimal maintenance dose, which is frequently as low as 0.09 gm three times a day. This maintenance dose may be continued indefinitely if toxic symptoms do not appear.

In the group of patients reported here 36.6 per cent received no treatment, quinidine converted 16.6 per cent and diminished attacks in 10 per cent, digitalis established the preceding paroxysmal fibrillation in 6.6 per cent and diminished attacks in 6.6 per cent, and combined digitalis and quinidine produced conversion in 3.5 per cent. Digitalis had no effect on 20 per cent of the cases, and quinidine on 25 per cent of the cases in which they were used. One patient in this group has been on a maintenance dose of quinidine for fifteen years, and attacks still occur when the drug is discontinued.

SUMMARY

Auricular fibrillation, established and paroxysmal, does occur in normal hearts and accounts for approximately 6.5 per cent of all cases of this arrhythmia observed. It occurs most frequently in men and may make its appearance at any age. The patient usually experiences no symptoms, or is aware only of palpitation. The only unusual cardiac finding is slow auricular fibrillation with an absent or

negligible pulse deficit. This type of auricular fibrillation is physiologically reasonably efficient, maintaining an adequate cardiac output, a normal rate of blood flow and a constant arterial pressure. The etiology is unknown, but increased autonomic tone appears to play a part. Complications are rare, and the arrhythmia may persist for years without evidence of cardiac disease. The prognosis is that of the underlying myocardium, and the arrhythmia itself appears to be without significance. Treatment is not indicated unless complications develop, and the therapy is that of the complication.

matic heart disease may also be associated with auricular fibrillation of long standing, and one must make a careful search for valvular murmurs, remembering that the presystolic accentuation of mitral stenosis often disappears in the presence of auricular fibrillation. When murmurs are present they must be carefully evaluated. The roentgenographic shadow must be carefully scrutinized for a prominent conus, and a fluoroscopic examination of the chest made to rule out a distended left auricle. A history of previous hypertension must be sought, and the axis deviation of the electrocardiogram taken into consideration.

In the group reported here, 33 per cent of the cases were discovered at the clinic, 66 per cent were discovered at routine life-insurance examinations, and 90.1 per cent were diagnosed by the family physician. It is interesting that 60 per cent of these patients came to the clinic for an evaluation of their cardiac status subsequent to the discovery of the arrhythmia, and 40 per cent came for unrelated conditions.

PROGNOSIS

The ultimate prognosis of auricular fibrillation occurring in normal hearts is dependent upon the maintained integrity of the myocardium, and is independent of the arrhythmia. The myocardium is subject to all the stresses, inflammations and degenerative changes of life, and if these occur, the prognosis becomes that of the underlying disease. When the arrhythmia makes its appearance after the fifth decade, the patient must be followed closely for myocardial disease, which may become manifest at any subsequent time.

Clinicians are well aware of the tendency for thrombus formation and subsequent embolism in auricular fibrillation, however, their statistics are compiled from cases of organic heart disease in which the distended auricles, slowed circulation of congestive heart failure and mural thrombi of previous infarction furnish ideal conditions for such accidents. Since auricular fibrillation occurring in normal hearts eliminates the stagnant auricular circulation and mural thrombi necessary for embolism, it is doubtful if such an accident ever occurs in this condition prior to the appearance of a complicating myocardial disease.

Numerous cardiologists have commented upon the excellent prognosis²³ and benignancy of this condition and state that the incidence of cardiovascular complications, occurring only after years of fibrillation in elderly persons, and the mortality rate are that of the general population.^{10, 24} They also believe that the condition is much more common than is generally recognized.²³ The benignancy of auricular fibrillation alone is exemplified by the observation that in a follow-up study of ten years or more among thyrocardiac patients who had been operated on for hyperthyroidism, the survival rate in those with established auricular fibrillation was

no less than that in those with normal rhythm.²⁵ Master and Eichert²⁵ stressed the temporary incapacity resulting from this condition in military personnel, however, it is doubtful if this would occur in civilian life, except in a confirmed neurotic. The excellent prognosis of auricular fibrillation occurring in normal hearts is in marked contrast to that occurring in diseased hearts, in which the expectancy of life is two and a half to seven years.

None of the group of patients reported here ever suffered incapacity for work or recreation because of auricular fibrillation itself, and several underwent as many as three major surgical procedures without cardiovascular complications of any type.

THERAPY

All these patients should receive an adequate explanation of their condition and should be reassured that it is benign. If precipitating factors can be determined in the paroxysmal type, an attempt should be made to remove them, and the patient advised to get more rest, relaxation and diversion of interests — with or without the aid of mild sedatives.

In dealing with these patients it should be remembered that the health of the majority of them will not depend on any form of drug therapy.²⁴ In slow, established auricular fibrillation with a negligible pulse deficit the cardiac dynamics are physiologically normal, and nothing is to be gained by conversion to sinus rhythm. The usual case of paroxysmal auricular fibrillation with infrequent attacks of short duration is definitely not benefited by therapy. However, if attacks are progressive and associated with disabling symptoms, therapy is indicated. As a therapeutic guide, attention should be focused upon the ventricular rate, for when this becomes rapid with a marked pulse deficit, cardiac efficiency is diminished, compensation is threatened and therapy is indicated. A rapid ventricular rate, and not the presence of auricular fibrillation, is the indication for drug therapy.

Two drugs, quinidine and digitalis, are widely used in the treatment of auricular fibrillation. Quinidine is the drug of choice for converting fibrillation to sinus rhythm because of its depressive action on vagal tone, cardiac muscle and junctional tissue conduction, and it will effect conversion in 65 to 75 per cent of the cases in which it is used. Digitalis and its glycosides are largely reserved for slowing the ventricular rate in congestive failure by virtue of their ability to increase vagal tone, the refractory period of auricular muscle and the time for conduction in junctional tissue. Paroxysmal auricular fibrillation of a progressive or disabling nature may be readily controlled by quinidinization to maintain sinus integrity or digitalization to establish the arrhythmia. If congestive heart failure supervenes, the patient should be placed at bed rest, given an acid-ash, salt-free diet, a normal fluid

intake, morphine, oxygen and mercurial diuretics as indicated and digitalized to control the ventricular rate and decrease the pulse deficit. After compensation is regained the arrhythmia may be converted to sinus rhythm by quinidine therapy, with gratifying and lasting results. Quinidine should not be used before compensation is restored because conversion may result in an uncontrollable tachycardia or embolism. When the manifestations of a complicating cardiac disease appear, the treatment is that of the underlying disease.

The young patient with auricular fibrillation and a normal heart is the ideal subject for quinidine therapy, however, one must weigh the benefits to be gained against the potential danger to the patient. Here the only real risk of quinidine therapy is that of sudden death from respiratory paralysis, ventricular fibrillation or cardiac arrest, and this has an incidence of about 1.8 per cent.²⁶ Because of its inherent risks, therapy should never be advocated for the sake of treatment. Sokolow²⁷ has advocated the use of quinidine routinely in patients with early auricular fibrillation and a normal heart, to prevent subsequent embolism, however, it is doubtful if such prophylaxis is justified. If quinidine therapy is to be instituted, the patient should receive two test doses of 0.09 to 0.2 gm four hours apart, and if no untoward symptoms occur the dose should be increased by 0.2 gm every four hours until conversion is effected or mild toxic symptoms such as nausea, tinnitus and diarrhea develop. After conversion is effected the patient should be placed on a maintenance dose of 0.2 gm three or four times a day for a brief period, and this gradually worked down to a minimal maintenance dose, which is frequently as low as 0.09 gm three times a day. This maintenance dose may be continued indefinitely if toxic symptoms do not appear.

In the group of patients reported here 36.6 per cent received no treatment, quinidine converted 16.6 per cent and diminished attacks in 10 per cent, digitalis established the preceding paroxysmal fibrillation in 6.6 per cent and diminished attacks in 6.6 per cent, and combined digitalis and quinidine produced conversion in 3.5 per cent. Digitalis had no effect on 20 per cent of the cases, and quinidine on 25 per cent of the cases in which they were used. One patient in this group has been on a maintenance dose of quinidine for fifteen years, and attacks still occur when the drug is discontinued.

SUMMARY

Auricular fibrillation, established and paroxysmal, does occur in normal hearts and accounts for approximately 6.5 per cent of all cases of this arrhythmia observed. It occurs most frequently in men and may make its appearance at any age. The patient usually experiences no symptoms, or is aware only of palpitation. The only unusual cardiac finding is slow auricular fibrillation with an absent or

negligible pulse deficit. This type of auricular fibrillation is physiologically reasonably efficient, maintaining an adequate cardiac output, a normal rate of blood flow and a constant arterial pressure. The etiology is unknown, but increased autonomic tone appears to play a part. Complications are rare, and the arrhythmia may persist for years without evidence of cardiac disease. The prognosis is that of the underlying myocardium, and the arrhythmia itself appears to be without significance. Treatment is not indicated unless complications develop, and the therapy is that of the complication.

THE SCHICK STATUS OF 18,000 YOUNG ADULT MALES*

JANE WORCESTER, DR P H,† AND F S CHEEVER, M D ‡

BOSTON

THE incidence of diphtheria in the United States as a whole declined from 1924 to 1945. However, in 1945 there were 18,606 cases of the disease—a larger number than had been reported since 1939. The various sections of the country did not share alike in this increase. Table 1, which presents the cases during the period 1939–1947, shows that in New England, for example, the number of cases reported in 1946 was approximately three times that reported in 1943. In the Mountain

makes it of interest to present the results of a Schick survey among some 18,000 naval recruits carried out during the period October, 1941, to January, 1942, instigated by and performed under the direction of Captain LeRoy D Fothergill, MC, USNR. Since these men were drawn from all over the United States, it was believed that an analysis of their immunity status (as determined by the Schick test) by geographic area might throw some light on the causes of these phenomena. In the

states, on the other hand, the reported cases varied relatively little. The average annual case rates, also shown in the table, varied considerably from region to region during this period. The rates tended to be low in the northern sections and high in the southern and western. The relative increase in morbidity has been greatest in the areas showing lower annual case rates.

This increase in the number of cases has caused a certain amount of alarm, although it has not been proved that it represents anything more than the usual cyclical behavior of the disease. Another disturbing event has been a change in the age distribution in certain areas, with a greater proportion of cases occurring in the older age groups.¹ In Massachusetts, for example, during the period 1942–1944, 43 per cent of the cases were in patients over ten years of age, whereas during the period 1932–1934 only 37 per cent of patients were over ten years of age. The aging of the population seems to have been insufficient to account for the shift in the age distribution of the cases.

The increased incidence of the disease in certain areas coupled with the shift in age distribution

preliminary report of this survey by Cheever,² exigencies of space made a discussion of these points impossible.

The recruits, the great majority of whom were white, received their Schick tests promptly after their induction into naval service. Consequently, the results of the tests reflect civilian rather than military experience with diphtheria. As previously described,² the Schick test was carried out by injection intradermally into one forearm of 0.1 cc of a standard diphtheria toxin so diluted that 0.1 cc contained 1/50 MLD. A Moloney test was performed at the same time by the injection of 0.1 cc of a 1:100 dilution of diphtheria toxoid into the other forearm by the intradermal route. The tests were read at the end of forty-eight hours and again at the end of one hundred and twenty hours. Data collected at the time of the test included name, age, place of birth, place of residence before and after the age of ten years, any history of an attack of diphtheria in the subject or in members of his immediate family and finally any history of active or passive immunization against diphtheria. Similar results were obtained when the material was tabulated according to place of birth, place of residence before age ten or place of residence after age ten. Therefore, only one of the residence classifications will be used here—namely, place of resi-

group nineteen to twenty-three Only 15 per cent were over twenty-four years of age

Inspection of Table 2 shows that the variation between the different sections of the country in the percentage of positive reactors is very large The South Atlantic and East and West South Central states have the lowest incidence of susceptible recruits—15, 13 and 16 per cent respectively The percentages of positive reactors in the other regions are considerably higher They vary from 39 per cent in the Middle Atlantic states to 50 per cent in the West North Central area The correlation between the percentages of the population susceptible to diphtheria in this young adult group and the morbidity rates for the total population during the period 1939-1947 (Table 1) is not close The New England and Middle Atlantic regions combine low morbidity with high susceptibility, whereas the South shows a low susceptibility combined with a high morbidity In the West, both the morbidity rates and the susceptibility seem to be high Presumably, these statements should not be interpreted in terms of the natural history of the disease without knowledge of the immunization programs in the various sections

The differences between the percentages of positive reactors in urban and in rural areas can be seen in Table 2 The migrating group has been omitted from discussion, since the percentage of positive

in the rural and urban areas of the different sections in terms of the presence of clinical disease, no entirely satisfactory explanation for the varying incidence of the disease itself is forthcoming Doull,³ writing in 1928, commented on the fact that diphtheria acts differently in the North and the South He found that deaths from diphtheria occurred at a relatively earlier age in the southern than in the northern states He also showed that in the 26 northern states with which he was working (1917-1924) deaths occurred at an earlier age in the more highly urbanized states The same statement could not be made of the southern states, which were on the whole rural but had a relatively high proportion of deaths from diphtheria in the younger age groups Doull concluded that infection was more widespread and consequently that frank cases of the disease not only were more common in the South than in the North but also showed a greater predilection for the younger age groups in the former area He made no comparison between diphtheria death rates in urban and rural areas of the same states Analysis of the death rates for the year 1922 shows that in the South the rural areas of the states had higher death rates than the urban, whereas in the North the reverse was true These death rates refer only to the white population Collins⁴ has demonstrated that during the years 1940-1941 diphtheria mortality rates were considerably higher

be little that can be said in general about these trends. The percentages of positive reactors are increasing more rapidly in rural areas where the percentages of positive reactors exceed those in the corresponding urban areas, although the trends in neither the urban nor the rural areas show any relation to the corresponding percentages of positive reactors. The trends are not sufficiently well determined to show that in regions where the percentages of immune persons are high the percentages themselves decline less rapidly with age, presumably

It was stated above that the immunization histories in this survey are believed to be unreliable. Table 6 gives the percentages of recruits who claimed to have been actively immunized against diphtheria in the urban and rural areas of the nine regions. The numbers upon which these figures are based were given in Table 2. The percentages appear to be very low. Also included in Table 6 is the average number of years since active immunization for recruits who claimed to have been immunized. Comparison of the percentages of

in the rural areas of the South than in the urban areas. However, in the remainder of the country the differences between the mortality rates in the urban and rural areas were small and inconsistent.

Material from which comparisons of morbidity rates in the urban and rural areas of the different regions may be made is hard to find. It is possible to compute from the Navy survey the percentages of recruits giving a history of clinical diphtheria

nizing infection than those living in the outlying districts. He found that the percentages of Schick-negative white children varied directly with the size of family and that families tended to be larger in the rural districts. However, the 1930 census of population, from which statistics on median family size are readily available, shows that rural families in all sections of the country tend to be larger than urban, although the differences are greatest in the South.

It appears that the percentages of immune persons (negative and false positive) found in the urban and rural areas in 1942 in this young adult group follow more or less closely the distribution of clinically recognized cases of the disease during the period when they were growing up. It must be remembered that, as yet, no mention has been made of the proportion immunized in the different regions, but unfortunately, as shown below, the immunization histories in this survey were not reliable.

Cheever,² in his preliminary report on this material, showed that in the entire group of recruits the percentage of positive reactors varied with age. It was 27 per cent at age seventeen and increased gradually to 45 per cent at age twenty-six. Apparently, a slow loss of immunity occurs with increasing age. There is some interest in ascertaining if this increase in the percentage of positive reactors proceeds in the same way in the urban and rural areas of the different regions. For this purpose, the nine regions of Table 2 have been combined into four, and for simplicity the migrating group has been omitted since the percentages of positively

This percentage, which reflects approximately twenty years' experience with the disease, was found to be 3.7 for the entire group of recruits. Table 3 gives the number of cases and the percentages in the urban and rural areas of the different regions. Inspection of the table shows that the percentages are consistently greater in the urban than in the rural areas. It should be stated that the number of cases upon which the percentages are based is

small and that the observations are subject to the limitations of memory.

Collins⁴ gives diphtheria morbidity rates for the year 1935-1936 among residents of large and small cities surveyed by geographic section. He has shown that in these surveyed areas the diphtheria case rates were rather consistently higher in the towns and small cities than in metropolitan places in both the North and the South.

Chason,⁵ in 1936, discussed diphtheria immunity in rural Alabama. He stated that children living in the centers of the towns were less liable to immu-

reacting recruits in this group generally fall between those in the urban and those in the rural group at each age. Table 4 gives the number of recruits tested and the percentage of positive reactors at each age in the urban and rural areas of the four large regions. The percentages of susceptible persons are also shown in Figure 1. The differences between the percentages in the urban and in the rural areas at each age conform in general with the totals given in Table 2. Inspection of Figure 1 shows that the percentage of positive reactors increases with age in the urban and rural areas in each region, or, in

that the morbidity rates refer to the total population, whereas the information on immunization and the Schick status is based on young adults. It has been the purpose here to present certain

theria morbidity. Although the incidence of clinically recognized diphtheria in the different areas of the country is not high, the low level of immunity as evidenced by the high percentage of

*Navy survey (1942)

information regarding the Schick status of young adult males in different regions of the United States. On the basis of the Navy survey of 1942, this group of the population was found to be 13 to 16 per cent Schick positive in the South and 39 to 50 per cent Schick positive in the rest of the country. The percentage of positive reactors has increased with age in all parts of the country. Comment has been made upon the urban-rural distribution of the Schick-positive reactors. The young adult population of the rural areas of the North and West was found to be more susceptible than that of the urban areas, and in the South the reverse was true.

The available evidence suggests that whatever role active immunization may have played in reducing diphtheria morbidity it has had little demonstrable direct effect upon the immunity status of the general population as reflected by the results of this Schick survey. In both the North and the South the present Schick status appears to be directly related to the amount of clinical disease experienced in the last ten years. No such relation can be demonstrated in the Mountain and Pacific states, where the percentage of Schick-negative reactors is low in spite of a relatively high diph-

Schick-positive reactors among young men is not a cause for complacency.

This survey was carried out by the following officers under the direction of Captain L. D. Fothergill, MC, USNR: Captain R. W. Babione, MC, USN; Commander E. M. Bingham, MC, USNR; Commander F. A. Butler, MC, USN; Commander F. S. Cheever, MC, USNR; Commander J. N. DeLamater, MC, USN; Commander R. A. Mount, MC, USN; Commander O. F. Munch, MC, USNR; Lieutenant Commander L. R. Schoolman, MC, USNR; and Lieutenant A. B. Smith, HC, USN. Commander L. A. Barnes, MSC, USN, and Lieutenant (jg) Margaret Allen, WR, USNR, helped prepare the data for punch-card analysis.

The actual survey and the preliminary statistical analysis were carried out while Dr. Cheever was stationed at the Naval Medical School, National Naval Medical Center, Bethesda, Maryland, as a member of the Department of Epidemiology.

Memory seems to be playing an important part in these percentages

In a house-to-house canvass⁶ in 1935-36 of 200,000 families in 28 cities of 100,000 population or more, located in nineteen states, information was obtained about immunization against diphtheria, among other things Table 7 gives some of the history on immunization from this survey The first column of the table gives the regions into which the 28 cities were placed In braces are given the corresponding regions of the Navy survey, unfortunately, the correspondence is not exact The second and third columns give the respective percentages in the groups fifteen to nineteen and ten to fourteen years of age of people who had been immunized before 1935 The annual rate of immunization per

that during the period 1935-1941 considerably more active immunization was carried out among children and young adults in the southern and western states than in the northern ones It is unfortunate that the history of immunization from the 1942 survey is not sufficiently accurate so that it may be discussed in conjunction with the Schick-test material, which does not suffer from the same limitations

If the results of the 1935 survey are accepted as being more representative of the facts, collation of the information in Tables 1, 2 and 7 shows that no hard and fast statements can be made about the relations between the amount of immunization, the state of immunity as shown by the Schick test and the morbidity in the different sections of the country The northern region in general appears

THE SEQUELAE OF EASTERN EQUINE ENCEPHALOMYELITIS

JOHN C AYRES, M D,* AND ROY F FEEMSTER, M D, D R P H†

BOSTON

WHEN cases of eastern equine encephalomyelitis occurred among human beings in Massachusetts in 1938, it was noted that profound damage to the central nervous system led to marked sequelae. To determine whether these changes are permanent and progressive or whether improvement can be expected, all the survivors who could be located were reinvestigated. The purpose of this paper is to report the present condition of these survivors.

Since several years have elapsed since the outbreak, a few facts regarding it are given for the information of those not familiar with the previous papers.

REVIEW OF OUTBREAK

Epidemiology

In July, 1938, equine encephalomyelitis was recognized in horses in southeastern Massachusetts, 269 deaths being reported in about ten weeks.

The disease first appeared in the upper basin of the Taunton River, which drains through nearby Rhode Island, and spread to contiguous areas, particularly northeast. Approximately 70 per cent of the deaths among horses occurred in a 30-mile square extending from the mouth of the Taunton River in the south to Boston on the north, and from the boundary of Rhode Island eastward to the coast of Massachusetts. Rhode Island to the west reported 55 cases among horses, and Connecticut, 29.

Inasmuch as the rainfall in southeastern Massachusetts and Rhode Island during the summer and early autumn was unusually heavy, mosquitoes were very prevalent in these areas. Furthermore, since the prevailing winds in this area are from the southwest, the tendency of the outbreak to spread in a northeasterly direction was attributed to the fact that infection-bearing mosquitoes were carried by these prevailing winds. The movement of infected horses and the flight of infected birds may have also played a role in the spread of the outbreak.

Almost simultaneously, a very fatal type of human encephalitis appeared in the same area, largely limited to children. The median date of reported deaths in horses occurred two weeks in advance of the median date of onset for cases in human beings. Although the prevalence of the disease was much greater among horses than among human beings, the rise and fall of the outbreak in these groups were similar. There was a slow increase for four weeks, rapidly reaching the peak

in two more, and then a much slower subsidence, the last case being reported sixteen weeks after the beginning of the outbreak.

The Massachusetts Department of Public Health investigated 44 cases of suspected equine encephalomyelitis.¹ From 9 of the patients, the eastern virus was isolated, and in 10 others, neutralizing antibodies for the same virus were found in the blood.^{2, 3} Eight more cases were diagnosed on the basis of the clinical picture and characteristic brain lesions at autopsy.^{4, 5} A diagnosis of equine encephalomyelitis was considered justified in 7 additional fatal cases because of characteristic clinical findings even though autopsies were not performed nor blood obtained for tests for neutralizing antibodies. Some patients had died before the etiologic agent had been suspected. Although 10 other cases were suspected, investigation revealed the diagnosis of equine encephalomyelitis to be unwarranted. About 70 per cent of the afflicted children were under ten years of age, the sex distribution being approximately equal. The mortality among the 34 patients was 74 per cent.

Clinical Picture

The clinical manifestations of the infection differed from other encephalitides in the greater severity of the symptoms and the high fatality. In infants the onset was sudden, but in older children and adults there were a few days of indisposition preceding active signs of encephalitis. The first complaints of older persons were commonly frontal headache and dizziness. The actual symptoms of encephalitis were almost invariably abrupt and characterized by fever, irritability, drowsiness, cyanosis and convulsions. The course of the disease was characterized by continued tremors or muscular twitchings, rigidity of the neck was constant, and a tense anterior fontanel was noted in infants, in whom a peculiar edema also developed about the eyes and in the upper extremities. A marked cyanosis was usually present, as was deep coma. The temperature was high, from 102 to 104°F, and when recovery occurred the temperature dropped by lysis over four or five days. Neutralizing antibodies appeared in the serum usually within six to eight days, and the blood showed a well marked response of neutrophilic cells. The cerebrospinal fluid was under increased pressure containing 200 to 2000 cells of which 60 to 90 per cent were neutrophils.

Surviving the acute stage, patients experienced coma and more or less rigidity of muscles for many days. Slow apparent return to normal was observed

*Epidemiologist, Division of Communicable Diseases, Massachusetts Department of Public Health.

†Director, Division of Communicable Diseases, Massachusetts Department of Public Health.

in a few cases, paralyzes, mental changes and other residual symptoms being more frequent. Death was commonly due to encephalitis but with some terminal evidence of myocardial insufficiency or pulmonary involvement.

Pathology

The pathological changes associated with the disease in man consisted of a profound, acute, disseminated and focal encephalomyelitis characterized by intense vascular engorgement, perivascular and parenchymatous cellular infiltration and extreme

or deterioration, with 2 requiring permanent hospitalization, 1 has chronic epilepsy with mental deficiency and hysterical behavior, in 1 neurologic symptoms, with some emotional instability, have developed, and 1 has made an apparently complete recovery so far as can be ascertained (Table 1). We have unfortunately been unable to trace 1 patient (T O C). Three months after the acute episode, he showed no signs or symptoms of physical or mental impairment. Therefore, to our knowledge, 1 out of 34 patients has made an apparently complete recovery with no sequelae manifested

TABLE 1 Nine-Year Follow-up Study of Patients in 1938 Epidemic

T O C.	4 mo	M	None (at 3 mo).	Contact lost.	

degenerative changes in the nerve cells. The gross pathological manifestations were not specific.

FOLLOW-UP STUDY

Gettings,⁶ in 1941, reported his findings in following up all 9 surviving patients of the 1938 epidemic in whose blood neutralizing antibodies for the eastern variety of virus were found. In all cases except one, this follow-up study was made approximately one year after onset. All but 3 had disabling sequelae. Six showed evidence of cerebral degeneration, with mental retardation. Three patients continued to suffer from hemiparesis, 3 from complete or partial aphasia, and 1 from emotional instability.

In carrying out a nine-year follow-up study in these patients, we have found that 2 have died (deaths attributable directly to sequelae of encephalitis), 3 have hemiplegia and mental deficiency

up to this time, and another had no known defects early in convalescence when contact was lost. The mortality rate has been increased to approximately 90 per cent, with a complete recovery rate of only 3 per cent.

One can assume from this that any damage to the central nervous system during the acute phase is severe and permanent. As time goes on this damage does not improve but rather seemingly increases as more is demanded intellectually, emotionally and physically of the patients. It becomes evident that eastern equine encephalomyelitis not only is highly fatal but also carries a very poor mental and physical prognosis.

SUMMARY

The 1938 outbreak of eastern equine encephalomyelitis in southeastern Massachusetts is reviewed

Thirty-four persons were infected, 70 per cent being under ten years of age, 9 survived, and 6 had permanent sequelae after one year. One of the 9 survivors cannot be located, 2 of the 8 other survivors have died, 4 are hemiplegic, mentally deficient and emotionally unstable, 1 is mentally deficient, epileptic and hysterically inclined, 1 has a "slight Friedreich's foot" and is a habit problem, only 1 has made an apparently complete recovery.

HEPATITIS, EXFOLIATIVE DERMATITIS AND ABNORMAL BONE MARROW OCCURRING DURING TRIDIONE THERAPY*

Report of a Case with Recovery

SAMUEL E. LEARD, M.D.,† WILLIAM E. R. GREER, M.D.,‡ AND I. CHARLES KAUFMAN, M.D.§

BOSTON

SINCE 1944, when Everett and Richards¹ described the anticonvulsive action of tridione (3, 5, 5-trimethyloxazolidine-2, 4-dione), the drug has been used in human beings to control epileptic attacks, especially petit mal seizures. Varying toxic reactions have been described, but to our knowledge this is the first case in which hepatic dysfunction, severe exfoliative dermatitis and leukemoid bone-marrow changes have been reported in the same patient.

The first report on the clinical use of the drug made very little mention of toxic reactions or unpleasant side effects. In 1945 Lennox² noted that in the majority of adolescent or adult patients, but rarely in young children, there was an unusual sensitivity of the eyes to bright sunlight. In a later report on the use of the drug in 222 patients, varying toxic manifestations were noted³, 122 patients showed photophobia, 32 reported a rash, either

headache, 4 noted insomnia, poor appetite and nervousness, 3 had dizziness, pain in the eyes and nosebleeds, 2 complained of sleepiness, double vision and "poor circulation", and 1 had sneezing, hiccuping and aplastic anemia. Six per cent of 127 patients showed a decrease of polymorphonuclear leukocytes below 1600. Twenty-five per cent had an eosinophil count of 6 to 25 per cent, a complete hematologic report on these cases having been presented by Davis and Lennox⁴ in 1947. However, these side effects appeared to be of minor importance considering the beneficial effects in treatment of petit mal epilepsy, and the drug was sometimes rather loosely administered without due precaution. Butler⁵ and Perlstein and Andelman⁶ noted essentially the same relatively unimportant side reactions in later reports.

In May, 1948, Barnett, Simons and Wells⁷ described for the first time the nephrotic syndrome

bumin and elevated cholesterol reappeared on two different occasions while she was taking tridione. With the withdrawal of the drug, the blood chemical findings and nephrotic signs disappeared after several months. White⁸ reported a somewhat similar case of nephrosis occurring in a seven-year-old boy who was treated with tridione.

Aplastic anemia and agranulocytosis have both been observed by several authors. Harrison et al⁹ reported a fatal case of aplastic anemia in 1946. Mackay and Gottstein¹⁰ described aplastic anemia and agranulocytosis from tridione. A case of fatal agranulocytosis in Great Britain¹¹ was reported in January, 1948. Carnicelli and Tedeschi,¹² in March, 1948, discussed a fatal case of acute pancytopenia following tridione treatment in a nineteen-year-old girl, including the post-mortem findings.

In the case reported below, toxic hepatitis, a leukemoid reaction in the sternal marrow and severe exfoliative dermatitis occurred in an elderly man after the use of tridione, with recovery of the patient. It is possible that the reactions were on the basis of an allergic reaction to the drug rather than a true direct organ toxicity. It is probable that if tridione had a direct hepatotoxic action this would have become evident in animal experiments, and cases of human toxic hepatitis would be much more frequent.¹³

CASE REPORT

A 69-year-old divorced, epileptic salesman was admitted to the hospital on May 9, 1948, with a chief complaint of generalized skin rash of 5 days' duration.

The family history revealed that his mother had had epileptic attacks starting at the age of forty years. In the past year he had had nocturia, which was diagnosed as being caused by hypertrophy of the prostate. During the past few years he had had slight shortness of breath and also occasional ankle edema. In the past year he had become forgetful and lacked power of concentration.

At the age of 8 years the onset of minor and major seizures had occurred. The attacks always began with an epigastric sensation, which traveled up to his head and sometimes ended there or went on to a major seizure with unconsciousness. Convulsions were never described, but he often noticed that his tongue had been bitten and also found evidence of involuntary urination and defecation on recovery. He had had only the epigastric aura (without unconsciousness) for

a generalized pruritic rash occurred and tridione was stopped. Two days later hiccuping, dark urine and anorexia began.

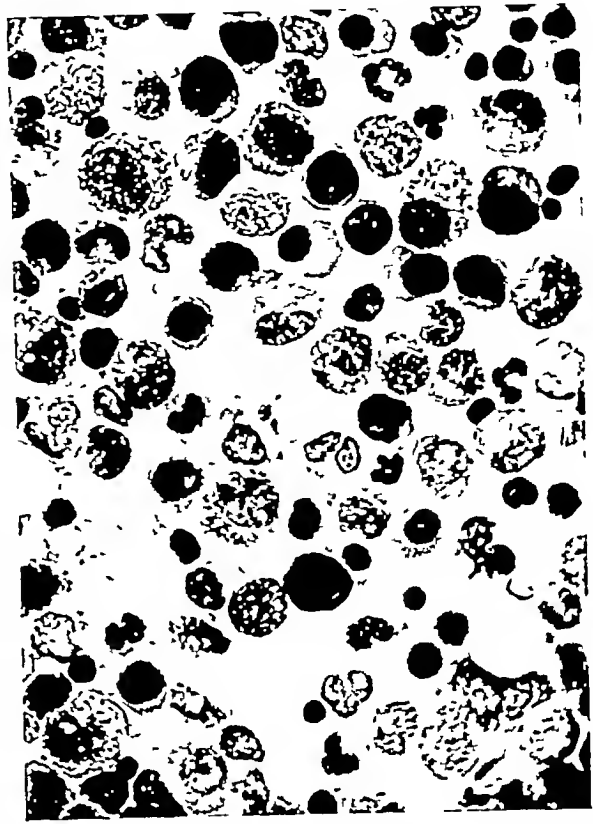

FIGURE 1 Aspiration Biopsy of the Sternal Marrow Performed on March 29 (Wright-Giemsa Stain x 800)

The marrow is markedly hypercellular, the hyperplasia including cells of both the erythrocytic and the myeloid series. There is a disproportionate increase in the more immature elements of the granulocyte series, myelocytes and metamyelocytes representing approximately 65 per cent of all leukocytes present. Plasmacytes and megakaryocytes are present in normal concentrations. Erythropoiesis appears to be active, and the progress of maturation normal in this series.

Physical examination revealed a generalized hemorrhagic, erythematous, blotchy, macular, confluent eruption involving the palms of the hands, soles of the feet, scalp, mucous mem-

12 to 15 years prior to admission, having taken phenobarbital, 32 mg in the morning and 65 mg in the evening. Six or seven weeks before admission he had seen a new doctor, who told him to take tridione, three (0.3-gm.) capsules a day in place of phenobarbital. About 1 month before admission, he reduced the dosage to two capsules daily. Two weeks before admission, greenish-yellow vision, which was improved by green-tinted glasses, developed. Five days before admission

branes and lower extremities. There were numerous cervical and submaxillary small lymph nodes, and one 2-cm. node in the right axilla that was freely movable. The scleras were icteric. The pupils were not remarkable. The conjunctivas were injected. The retina showed no hemorrhages or exudates. The nasal mucosa was injected. The lips were slightly edematous and tender to palpation. The breath was fetid. A partial upper denture was present. The throat and mucous

membranes were injected. The tongue was dry and coated. No distention of the jugular veins was apparent. The chest was clear to percussion and auscultation. The left border of cardiac dullness was 8.5 cm from the midsternal line in the 5th interspace. There was normal sinus rhythm. The liver was palpable and slightly tender, and the edge was felt 7 cm below the right costal margin on inspiration. The spleen was palpable 3 cm below the left costal margin. Peristalsis was normal. A right reducible inguinal hernia was present. The prostate was moderately enlarged. Neuro-

presented evidence of markedly increased hyperplasia in the granulocytic series, and an abnormal degree of immaturity in that series, eosinophilia was likewise marked. The findings seemed consistent with those of myelogenous leukemia or severe leukemoid reaction, the latter indirectly being the correct interpretation in view of the findings obtained on the most recent examination, which must be regarded as within normal limits.

The nonprotein nitrogen was 23 to 40 mg per 100 cc. The total protein was 5.45 gm per 100 cc, with an albumin of 3.26 and a globulin of 2.19 gm. Prior to discharge the total protein was 7.02 gm per 100 cc, with an albumin of 3.26 gm. The serum bilirubin on admission was 3.2 mg per 100 cc direct, 4.3 mg total, and remained elevated for 3 weeks. At discharge it was 0.24 mg per 100 cc direct and 0.96 mg total. The alkaline phosphatase, which was 11.76 Bodansky units initially, rose to 14.13 Bodansky units and fell to 4.89 Bodansky units by the 3rd week. Thymol turbidity was 0. Cephalin flocculation was +++. The serum amylase was 16 units and later 8 units per 100 cc. Lumbar puncture showed an initial spinal-fluid pressure equivalent to 170 mm of water, the dynamics free, and the fluid clear and colorless, there were 43 red blood cells and 0 white blood cells per cubic mil-

FIGURE 2 Sternal Marrow on May 13 (x 400)

Cellularity of the marrow has decreased to a degree approaching normal, although the relative proportions of the more immature myeloid elements are essentially unchanged.

logic examination was negative except for absent patellar and Achilles-tendon reflexes bilaterally.

The temperature was 100.2°F (by rectum), the pulse 88, and the respiratory rate 18, the blood pressure was 125/75.

The urine showed a specific gravity of 1.006 to 1.022 and gave a +++ to ++++ test for bile. The urobilinogen was 1.16 on many occasions. Slight traces of albumin were noted in the sediment on several occasions. Bile was present for the first 6 days. Blood studies showed a sedimentation rate of 12 mm per hour on admission, which rose to 47 mm in the 3rd week and then fell to 30 mm prior to discharge. The hematocrit was 49 per cent on admission and 34 per cent on discharge. The blood Hinton reaction was negative. The hemoglobin was 15.5 gm on admission and 11.9 gm on discharge. The reticulocyte count was 0.7 per cent, and the platelet count 173,000 and 144,000. The white-cell count, which was 10,500 on admission, rose to 12,200 after 3 weeks, and was 9,400 on discharge. On the day following admission, the differential count was 48 per cent neutrophils, 24 per cent lymphocytes, 26 per cent eosinophils and 1 per cent basophils. The eosinophilia remained high for the first 2 1/2 weeks and then fell to within normal limits. More detailed studies of the peripheral blood are presented in Table 1.

Bone-marrow examinations were performed* on May 13 and 24 and July 28 (Fig. 1, 2 and 3), the first two of which

*Bone marrow studies and examinations of the peripheral blood were performed by Dr. Charles Emerson Robert Dawson Evans Memorial Massachusetts Memorial Hospitals.

limeter, and the total protein was 40.76 mg, and the sugar 78 mg per 100 cc, and the chloride 119 milliequiv. per liter. Heterophil-antibody agglutination was negative. The stools were guaiac negative.

X-ray study of the chest revealed the heart to be normal in size, shape and position. The aorta was slightly elongated and tortuous. Both lung fields showed diffuse fibrosis and emphysema. X-ray examination of the abdomen on May 12 demonstrated a normal amount of gas in the bowel. Both kidneys were of normal size, shape and position. The out-

lines of the psoas muscles were clear. An x-ray film of the skull revealed no fracture.

The clinical course is demonstrated in Figure 4. The patient was treated with a high-carbohydrate, high-protein, high-vitamin diet with supplementary vitamin B preparations. The temperature during the first day was 100 to 100.4°, and by the 3rd day it fell to 99.0° and thereafter was normal. The pulse was never above 92. The patient was given 150,000 units of penicillin daily from the 6th to the 17th day. During the first 2 days he was lethargic, and hiccups were almost continuous. Hiccups stopped after the 5th day, and beginning clinical improvement was noted. The rash remained hemorrhagic for the first 5 days and then slowly faded. Desquamation started on the 5th day and gradually extended over the entire body. By the 13th day the liver had decreased

and careful clinical observation), tridione remains the most effective treatment currently available for petit mal epilepsy.* This opinion is supported by the experience of Dr William G Lennox, who has treated large numbers of children with tridione, has taken necessary precautions and has encountered little serious toxicity.

The case presented above indicates that tridione is potentially toxic to the liver also, and may stimulate the bone marrow as well as depress it. It sug-

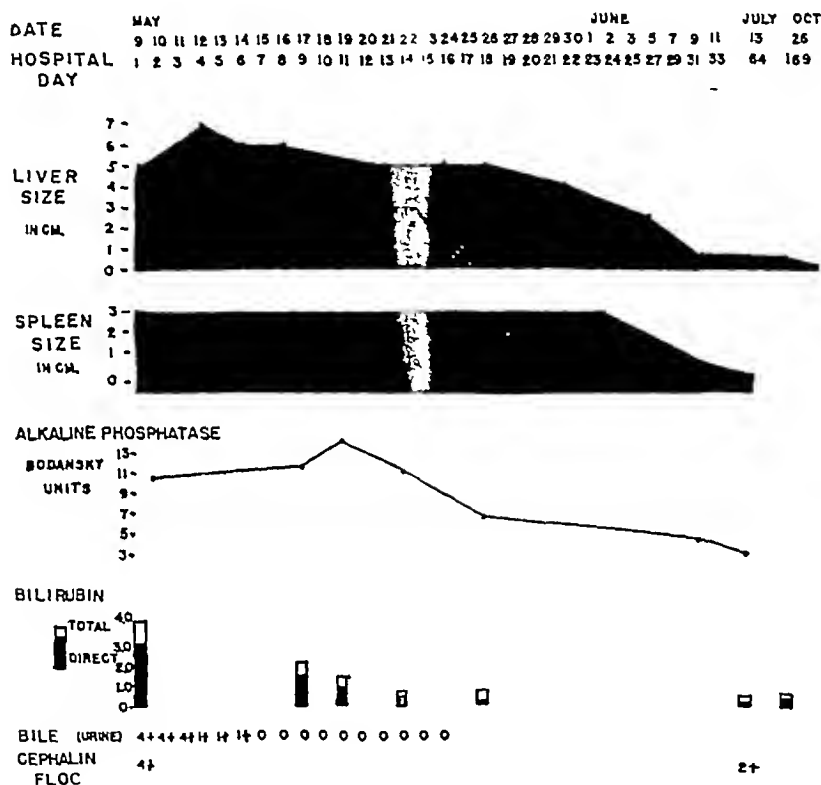

FIGURE 4 Clinical Course

in size, the edge being felt 1 cm to 4 cm below the costal margin. After the 32nd hospital day the spleen was never palpable. The enlargement of the cervical and axillary lymph nodes gradually subsided so that at the time of discharge they were insignificant. The patient was discharged on June 11, improved. Follow-up study revealed that liver function, as well as his general condition, had gradually improved.

DISCUSSION

Tridione, a comparatively new anticonvulsant drug, has been found to be an effective agent in the treatment of petit mal seizures. It has not been shown to be effective in other forms of epilepsy. It has been demonstrated further to be potentially toxic to skin, bone marrow, and kidneys. If this is anticipated and the proper precautions taken (frequent peripheral-blood and urine examinations

gests also the extreme need for careful diagnosis before tridione is used, since it appears to be effective only in petit mal attacks, whereas this patient had sensory (epigastric) seizures. Petit mal epilepsy is characterized by an onset of unconsciousness, brief in duration, *without* aura, at times with akinetic or myoclonic features. An attack, no matter how brief, that begins with any aura other than unconsciousness is not petit mal¹⁴. This case indicates further that tridione should not be used unless careful supervision is maintained throughout.

The toxic hepatitis in this patient responded very well to the usual treatment of hepatitis—

*Paradione (3,5-dimethyl-5-ethylloxazolidine-2,4-dione), a new experimental derivative of uridione has been found in the early experience of one of us (I. C. K.) to be at least as effective as uridione and considerably less toxic.

epidemiologic data at the end of the 1933 epidemic, Leake et al.² reported that either mosquitoes were involved as vectors, or the infection was spread by contact. Mosquito transmission in the laboratory was attempted at that time but failed.² Since the original outbreak in St. Louis, other encephalitis epidemics have been recognized as predominantly due to this virus,^{3, 4} and there have been mixed St. Louis and western equine outbreaks.^{5, 10} Interesting to note with this is that horse infections, both of clinical and of inapparent nature, have been produced by the inoculation of the St. Louis virus.¹¹⁻¹³ Antibodies to the St. Louis virus have been found in the serums of normal persons and of those convalescent from encephalitis in many parts of the United States and even in Africa.^{3-10, 14-17} Antibodies have also been demonstrated in the serum of horses and of numerous other vertebrates, both domestic and wild.^{8, 9, 12, 16, 18-21} Blattner and Heys² reported the occurrence of 10 to 16 cases each year in the St. Louis area during the nonepidemic years 1939-1944, with a total of 88 cases during the seven-year period, and postulated the presence of an endemic focus.

In recent years, various investigators working both in the field and in the laboratory have established the mosquito as the vector. Hammon, Reeves et al. isolated the St. Louis virus from eight pools of naturally infected *Culex tarsalis* mosquitoes from the Yakima Valley, Washington, 3 in 1941,²² 4 in 1942,²³ and 1 in 1944.²⁴ Also, a strain was isolated from *C. pipiens* (Linnaeus) caught in Washington in 1942,²⁴ and a strain was isolated in 1944²⁴ from *Aedes dorsalis* (Meigen) caught in Kern County, California. The latter was the first isolation of the St. Louis virus from any source in California even though serologic evidence of the presence of the virus had been repeatedly obtained.^{5, 10, 25} Although no tests of the vector ability of *A. dorsalis* had been made in the laboratory, transmission had been demonstrated by four other species: *A. lateralis* (Meigen), *A. taeniorhynchus* (Wied), *A. vexans* (Meigen) and *A. nigro-maculis* (Ludlow).²⁶ A Japanese report in 1940²⁷ recorded the transmission of the St. Louis virus by *C. tritaeniorhynchus* (Giles) and *A. albopictus* (Skuse), in addition to the previously reported *C. pipiens* (var. *pallens* Coq).

Studies on the feeding habits of the suspected mosquito vectors in Washington,²⁸ Nebraska²⁹ and California³⁰ confirmed the fact that the two *Culex* mosquitoes found infected fed predominantly on fowl. Detailed studies³¹ on inoculated chickens in 1945 showed that a very high dilution of St. Louis virus, representing only a 50 per cent end-point dose for a mouse by the intracerebral route, when inoculated subcutaneously gave rise regularly to virus in blood in a titer greater than that inoculated, usually for two or three days. No mammal tested up to that time had proved to be as good a potential source of mosquito infection.

In spite of this apparently satisfactory and well established concept of the mosquito-fowl-mosquito cycle, the epidemiology of this disease seemed to be incomplete, for the chicken and other birds tested showed no evidence of serving as chronic or latent carriers of the virus. Hibernating *C. tarsalis* and *C. pipiens* collected during winters in Washington²² and California³⁰ had not been found infected even though 5429 mosquitoes were tested. Furthermore, eggs and progeny of infected *C. tarsalis* and *C. pipiens* were tested only to yield no evidence of transovarian passage of the virus. Therefore, knowledge of the true reservoir and the location of the virus during the winter and during seasons of no apparent infection was still quite vague.

It had been postulated that the true reservoir for the virus was either a vertebrate or an arthropod. A wide variety of vertebrates inoculated by the dermal routes failed to yield results suggesting a true reservoir. Blattner and Heys,²² in 1944, however found that *Dermapentor variabilis* (Say) was capable of transmitting the infection and of passing it on to its progeny, thereby suggesting a potential reservoir. However, no naturally infected ticks have been found, nor have any of the stages of *D. variabilis* been found upon fowl. In 1945, Smith, Blattner and Heys³² isolated the St. Louis virus on three different occasions from chicken mites (*Dermanyssus gallinae*, De Geer). Working on the hypothesis that mites and ticks belong to the same order of arthropods and are known to transmit other pathogenic agents transovarially, these investigators demonstrated in 1947 the transovarian transfer of infection by mites infected with the virus.³³ Furthermore, the virus was isolated from chickens exposed to infected mites, and fresh mites feeding on infected chickens became infected.

It is now generally accepted that the St. Louis virus is frequently transmitted to man by mosquitoes that have become infected, in most cases by feeding on recently infected fowl. However, the true reservoir or winter carry-over mechanism has still not been definitely ascertained. Other ectoparasites of birds, such as ticks and mites, may be the unknown factor.

AMERICAN EQUINE ENCEPHALITIDES

In Horses

For many years in Europe a mild form of equine encephalomyelitis of horses has been known as Borna disease. The causative agent was demonstrated to be a filterable virus in 1924.³⁴ Similar symptoms have been observed among horses for a number of years in the United States. The Kansas-Nebraska horse plague of 1912 was probably a related disease. However, the first recognized American epizootic of horses similar to this condition occurred in the San Joaquin Valley of California in 1930 when the identity of the disease was established by Meyer, Haring and Howitt,³⁵ who isolated

namely, bed rest and high-carbohydrate and high-protein diet, together with added vitamin supplements, especially of the vitamin B complex. Early recognition and vigorous treatment of any of the toxic complications of tridione may save the life of the patient.

SUMMARY

The case of a sixty-nine-year-old man who exhibited toxic hepatitis, a leukemoid bone-marrow reaction and a severe exfoliative dermatitis after tridione therapy is reported. A review of the literature concerning the adverse reactions to the drug is presented. Suggestions concerning the use of tridione are made.

MEDICAL PROGRESS

PUBLIC-HEALTH ASPECTS OF THE VIRUS ENCEPHALITIDES

JOHN C. AYRES, M.D.,* AND ROY F. FEEMSTER, M.D., DR.P.H.†

BOSTON

VIRUS encephalitides are best discussed in three groups: virus encephalitides caused by familiar viruses not ordinarily encephalitogenic, suspected, primary virus infections, and primary virus infections.

Virus encephalitides can be caused by ordinarily nonencephalitogenic viruses, which are those of herpes simplex, measles, lymphogranuloma venereum, mumps and infectious mononucleosis (probably due to a virus). Although secondary or post-infectious encephalitis has not as yet been shown to be caused by a virus, the illness occurs within a few days to a few weeks after various virus infections, such as measles, mumps, influenza, chicken pox, vaccinia, smallpox and infectious hepatitis and after vaccination against smallpox and rabies.

Suspected primary virus encephalitides are newly discovered, and their role is significant because antibodies have been found in the blood of man, and the viruses are neurotropic in laboratory animals. Clear-cut clinical infections of the encephalitic type are yet to be seen. The viruses are West Nile, Bwamba fever, Semlike forest, Bunyamwera and Hammon-Reeves, California. The first two have been recovered from the blood of man, and the remainder from mosquitoes only. Other sus-

pected primary virus encephalitides are von Economo's disease and acute disseminated encephalomyelitis although their virus etiology has not as yet been established.

The primary virus encephalitides are the St. Louis type of encephalitis, eastern equine encephalomyelitis, western equine encephalomyelitis, Venezuelan equine encephalomyelitis, Japanese B encephalitis, Russian Far East (tick-borne, spring-summer) encephalitis, acute hemorrhagic meningoencephalomyelitis (leukoencephalitis), lymphocytic choriomeningitis, pseudolymphocytic choriomeningitis, swineherd's disease, louping ill, acute encephalitis due to rabies and the Sabin B virus. The first six are known as the summer, or epidemic, encephalitides, the remainder are endemic virus encephalitides.

The epidemic encephalitides are a greater public-health problem than most of the others. They tend to be more numerous and present difficult problems in control, because the reservoir of the virus is usually a lower animal and the viruses are spread to man by arthropod vectors. This paper is limited to a discussion of these six virus infections.

ST. LOUIS ENCEPHALITIS

The St. Louis epidemic of 1933¹ was up to that time the largest localized encephalitis epidemic recognized in North America. In summing up the

*Epidemiologist, Division of Communicable Diseases, Massachusetts Department of Public Health.

†Director, Division of Communicable Diseases, Massachusetts Department of Public Health.

virus of eastern equine encephalomyelitis Hammon et al isolated the western type from free living *C. tarsalis* five times in 1942^{23, 26} and forty-one times in 1943²⁴ from collections made in the Yakima Valley, Washington, twenty-eight times from the San Joaquin Valley, California, in 1943²⁰ and once from eastern Nebraska in 1943²⁹ Kitzelman and Grundman⁷⁰ recovered the western type virus in 1940 from a cone-nosed bug (*Triatoma sanguisuga*, Le Conte) in Kansas Sulkin, in 1945,⁷¹ reported the recovery of the western virus from the chicken mite, *Dermanyssus gallinae*, and Reeves et al, in 1947,⁷² recovered the western type from wild bird mites (*Liponyssus sylviarum*) in California Syverton and Berry^{73, 74} have been able to transmit the western virus by ticks (*Dermacentor andersoni*)

Significant findings have directed attention toward fowl, both wild and domestic, as representing the most common intermediate host in the cycle of infection.⁷⁵ Repeated isolations of both eastern and western strains of virus from various species prove that they may experience a specific infection usually of a mild or subclinical nature.^{69, 70, 76-82} Overwhelming evidence of incriminating fowl as the major inapparent reservoir has been advanced by the large-scale serum surveys of Howitt,^{5, 53} Howitt and van Herick,^{21, 54} and also Hammon and his associates.³¹ The serologic evidence suggests strongly that, in Washington and California, infection rates with western equine encephalomyelitis are higher in birds than in mammals. In these areas, the chick has frequently been found to possess antibodies, and since it can easily be infected experimentally, it is thought to be one of the principal sources of mosquito infection if not a true reservoir or latent carrier. However, in Nebraska no antibodies were detected in any of the chickens or pheasants tested. In Texas only 8.5 per cent of the domestic fowl were positive for western equine antibodies.²¹ Cox, Jellison and Hughes⁵⁰ found an infected deer in North Dakota in 1941, and McNutt and Packer⁵⁵ an infected hog.

Recovery of viruses from species of mosquitoes habitually feeding on avian hosts has established the significance of the mosquito-fowl-mosquito cycle of infection, man or horse representing merely the accidental host. However, insect vectors and also the reservoirs of infection may differ from one section of the country to another. Furthermore, as with St. Louis encephalitis, the winter carry-over mechanism has still to be definitely ascertained, although the isolation of the western type of virus from mites capable of transovarian transmission may be the answer.

VENEZUELAN EQUINE ENCEPHALOMYELITIS

Kubes and Rios⁵⁶ and Beck and Wyckoff⁵⁷ isolated a virus from cases of equine encephalomyelitis from Venezuela in 1938. The infection had been recognized also in Colombia,^{58, 59} Ecuador⁷⁵ and

Trinidad.^{90, 91} Several early reports reviewed by Gallia and Kubes⁹² suggest that cases may have occurred in man in the epidemic areas. In 1943, 2 fatal cases, with subsequent isolation of the Venezuelan virus from brain tissue, were recorded.^{91, 93} One of the cases preceded⁹¹ and the other occurred during⁹³ an epizootic among horses and mules in Trinidad, B. W. I. In 1942 mild infections developed in 2 laboratory workers in New York⁹⁴ and in 1943, 3 laboratory workers in Rio de Janeiro had a similar illness.⁹⁵ Gallia and Kubes,⁹² examining the sera of 10 laboratory workers at the Institute of Veterinary Research in Caracas, Venezuela, found high titers of neutralizing antibody against the virus in 10 of 10 persons, only 1 of the 10 having typical symptoms.

Epidemiologically, mosquitoes have been incriminated in the natural equine infections with this virus,⁹⁶ and several potential vectors have been demonstrated.^{96, 97} Gilvard found *Mansonia titlans* (Walker) infected in Trinidad and demonstrated experimental transmission with the same species.⁹⁶ Spread probably occurred from Ecuador to Trinidad, and it is easy to conceive of its spread by ship or plane or by island hopping to the Gulf Coast of the United States, where *Mansonia titlans* is already present.

In the New York and Brazilian reports,^{94, 95} the virus was isolated from the blood of 7 of the 10 laboratory cases (5 on the second day of illness, 1 on the third, and 1 on the fifth). Virus was also isolated from the nose or throat washings in 2 cases (both on the second day of illness). Koprowski and Cox,⁹⁸ in 1947, reported 4 cases of laboratory infection, in 2 of which there had been no direct contact with the virus prior to infection. Furthermore, the virus was isolated from the circulating blood in 3 cases and from the throat washings in 1.

JAPANESE "B" ENCEPHALITIS

The name Japanese "B" encephalitis was originally used to distinguish it from the von Economo type, which the Japanese called type "A." The former is an epidemiologically and clinically distinct type of epidemic encephalitis that frequently occurred in Japan in the late summer. It has probably occurred in epidemic form in Japan proper since the beginning of this century, or quite possibly even thirty years previously. However, not until the great epidemic of 1924, involving over 6000 persons with 3797 reported deaths, did it attract much attention. Since then, annual epidemics have been recorded, sometimes from numerous regions. Between 1924 and 1937, from Japan alone, 21,355 cases with 12,159 deaths were reported.⁹⁹ Case mortality rates have ranged from 42 to 74 per cent, but have averaged about 60 per cent. Epidemics or sporadic cases have also been reported from Formosa,⁹⁹ the southern Ryukyu Islands,⁹⁹ eastern China^{100, 101} and the eastern part of the

a filterable virus from the brain of 2 horses that had died from the disease. The virus was found to be immunologically different from that of Borna disease and became known as the western variety of the equine encephalitis virus.

During the early 1930's, the disease extended rapidly eastward, recorded cases reaching the peak numbers of 173,589 in 1937 and 184,062 in 1938.¹⁷ In 1939 the western type of virus was found as far east as Kentucky, and in 1940, it was identified in Alabama,¹⁸ and in 1941, in Michigan.¹⁹ Up to 1944 the western type of virus had been identified in 19 states.^{18, 19}

In 1935 a highly fatal form of encephalomyelitis appeared in several states along the Atlantic Coast, particularly New Jersey and Virginia. The virus from these equine cases was found to be different immunologically from the previously isolated western strain²⁰ and was therefore designated as the eastern type of virus. In 1940 it was identified in Alabama,²¹ in 1941, in Texas,²² in 1942, in Michigan,²³ and in 1944, in Louisiana and Missouri.²⁴ Up to 1944 the states from which eastern virus had been identified totaled 15. Thus, it became apparent that the eastern virus was no longer confined to the eastern seaboard but had spread to involve the Gulf Coast states, Michigan and Missouri. Furthermore, both eastern and western types have

In Man

Karl Meyer,²⁵ in 1932, was the first to suspect that an unusual encephalitis contracted by men working with infected horses might be due to the virus of equine encephalomyelitis. Examination of the brain of a ranch hand who died of the disease showed pathologic lesions similar to those observed in horses, however, this clinical impression was not proved by isolation of the virus or by the presence of neutralizing antibodies in the serum of the infected persons.

In August, 1938, an epidemic of considerable proportions occurred among horses in southeastern Massachusetts. At about the same time a very fatal type of encephalitis among infants and children made its appearance in the area. From a child dying in the Children's Hospital of Boston, Fothergill and his associates²⁶ isolated a virus that was identified by cross-protection tests as the virus of eastern equine encephalomyelitis. This was confirmed for the same case and 4 others by Webster and Wright,²⁷ who used the complement-fixation test. In patients who recovered Fothergill confirmed the diagnosis by neutralization tests. During the same month Howitt²⁸ isolated the virus of the western type from the brain of a twenty-month-old child dying in California. Furthermore, the blood of several persons in California who had recovered from encephalomyelitis was shown to contain neutralizing antibodies for the western virus. Thus, it was established that both known American types of equine encephalomyelitis could infect man.

Since then, the Manitoba (Canada),²⁹⁻³¹ Minnesota and Dakota epidemics of 1941,^{32, 33} and the annual outbreaks in the Yakima Valley^{34, 35} and in Kern and Fresno counties in California^{36, 37} have attested to the ever-increasing importance of this disease. The 1941 epidemic in and around North Dakota was the largest ever recorded, with 1080 cases and 90 deaths.³⁸ In Manitoba that same year, 509 cases were recognized.³⁹ In all the areas mentioned above, the western virus was found to be the causative agent. During 1941 in Texas an epidemic of the eastern type occurred, during which repeated isolations of the virus were made from horses,^{40, 41, 42} and a number of probable human cases were later revealed by mass serologic studies.^{43, 44, 45}

Transmission

In 1933, Kelser⁴⁶ first proved that the virus of equine encephalomyelitis could be transmitted by the mosquito *A. trypeti*. In the succeeding few years, several workers⁴⁷⁻⁵⁰ confirmed the work of Kelser definitely incriminating the Aedes as potential carriers of both eastern and western types of equine encephalomyelitis. Davis,⁵¹ in 1941, reported on the ability of five species of Aedes mosquitoes native to Massachusetts to transmit the

been identified in Michigan, Texas and Alabama (Table 1).

The countries adjoining the United States have had the same immunologic types of virus that are known to occur in this country. The western virus has prevailed in Canada, except for a limited number of sporadic cases due to the eastern virus in Ontario.^{52, 53} The western virus has been identified in Argentina,^{54, 55} whereas the eastern virus has been reported from Mexico,⁵⁶ Panama,⁵⁷ Brazil^{58, 59} and Cuba.⁶⁰

virus of eastern equine encephalomyelitis Hammon et al isolated the western type from free living *C. tarsalis* five times in 1942^{23, 26} and forty-one times in 1943²⁴ from collections made in the Yakima Valley, Washington, twenty-eight times from the San Joaquin Valley, California, in 1943³⁰ and once from eastern Nebraska in 1943²⁹ Kitzelman and Grundman⁷⁰ recovered the western type virus in 1940 from a cone-nosed bug (*Triatoma sanguisuga*, Le Conte) in Kansas Sulkin, in 1945,⁷¹ reported the recovery of the western virus from the chicken mite, *Dermanyssus gallinae*, and Reeves et al, in 1947,⁷² recovered the western type from wild bird mites (*Liponyssus sylviarum*) in California Svvertson and Berry^{73, 74} have been able to transmit the western virus by ticks (*Dermacentor andersoni*)

Significant findings have directed attention toward fowl, both wild and domestic, as representing the most common intermediate host in the cycle of infection.⁷⁵ Repeated isolations of both eastern and western strains of virus from various species prove that they may experience a specific infection usually of a mild or subclinical nature.^{69, 70, 76-82} Overwhelming evidence of incriminating fowl as the major inapparent reservoir has been advanced by the large-scale serum surveys of Howitt,^{5, 33} Howitt and van Herick,^{21, 34} and also Hammon and his associates.³¹ The serologic evidence suggests strongly that, in Washington and California, infection rates with western equine encephalomyelitis are higher in birds than in mammals. In these areas, the chick has frequently been found to possess antibodies, and since it can easily be infected experimentally, it is thought to be one of the principal sources of mosquito infection if not a true reservoir or latent carrier. However, in Nebraska no antibodies were detected in any of the chickens or pheasants tested. In Texas only 8.5 per cent of the domestic fowl were positive for western equine antibodies.³¹ Cox, Jellison and Hughes⁵⁰ found an infected deer in North Dakota in 1941, and McNutt and Packer³⁵ an infected hog.

Recovery of viruses from species of mosquitoes habitually feeding on avian hosts has established the significance of the mosquito-fowl-mosquito cycle of infection, man or horse representing merely the accidental host. However, insect vectors and also the reservoirs of infection may differ from one section of the country to another. Furthermore, as with St. Louis encephalitis, the winter carry-over mechanism has still to be definitely ascertained, although the isolation of the western type of virus from mites capable of transovarian transmission may be the answer.

VENEZUELAN EQUINE ENCEPHALOMYELITIS

Kubes and Rios³⁶ and Beck and Wyckoff³⁷ isolated a virus from cases of equine encephalomyelitis from Venezuela in 1938. The infection had been recognized also in Colombia,^{38, 39} Ecuador⁷⁵ and

Trinidad.^{90, 91} Several early reports reviewed by Gallia and Kubes⁹² suggest that cases may have occurred in man in the epidemic areas. In 1943, 2 fatal cases, with subsequent isolation of the Venezuelan virus from brain tissue, were recorded.^{91, 93} One of the cases preceded⁹¹ and the other occurred during⁹³ an epizootic among horses and mules in Trinidad, B. W. I. In 1942 mild infections developed in 2 laboratory workers in New York⁹⁴ and in 1943, 3 laboratory workers in Rio de Janeiro had a similar illness.⁹⁵ Gallia and Kubes,⁹² examining the sera of 4 laboratory workers at the Institute of Veterinary Research in Caracas, Venezuela, found high titers of neutralizing antibody against the virus in 10 of 16 persons, only 1 of the 10 having typical symptoms.

Epidemiologically, mosquitoes have been incriminated in the natural equine infections with this virus,⁹⁶ and several potential vectors have been demonstrated.^{96, 97} Gilvard found *Mansonia titilans* (Walker) infected in Trinidad and demonstrated experimental transmission with the same species.⁹⁶ Spread probably occurred from Ecuador to Trinidad, and it is easy to conceive of its spread by ship or plane or by island hopping to the Gulf Coast of the United States, where *Mansonia titilans* is already present.

In the New York and Brazilian reports,^{91, 95} the virus was isolated from the blood of 7 of the 10 laboratory cases (5 on the second day of illness, 1 on the third, and 1 on the fifth). Virus was also isolated from the nose or throat washings in 2 cases (both on the second day of illness). Koprowski and Cox,⁹⁸ in 1947, reported 4 cases of laboratory infection, in 2 of which there had been no direct contact with the virus prior to infection. Furthermore, the virus was isolated from the circulating blood in 3 cases and from the throat washings in 1.

JAPANESE "B" ENCEPHALITIS

The name Japanese "B" encephalitis was originally used to distinguish it from the von Economo type, which the Japanese called type "A." The former is an epidemiologically and clinically distinct type of epidemic encephalitis that frequently occurred in Japan in the late summer. It has probably occurred in epidemic form in Japan proper since the beginning of this century, or quite possibly even thirty years previously. However, not until the great epidemic of 1924, involving over 6000 persons with 3797 reported deaths, did it attract much attention. Since then, annual epidemics have been recorded, sometimes from numerous regions. Between 1924 and 1937, from Japan alone, 21,355 cases with 12,159 deaths were reported.⁹⁹ Case mortality rates have ranged from 42 to 74 per cent, but have averaged about 60 per cent. Epidemics or sporadic cases have also been reported from Formosa,⁹⁹ the southern Ryukyu Islands,⁹⁹ eastern China^{100, 101} and the eastern part of the

Soviet Union¹⁰² Smithburn and Jacobs¹⁷ stated that, as a result of serologic tests, "the St. Louis and Japanese 'B' viruses have been active over broad expanses of territory in Central Africa," and Sabin¹⁰³ in 1943 reported a number of positive serologic tests for Japanese "B" virus in the Cincinnati area.

In the summer of 1945, an epidemic of encephalitis occurred among the native population on Okinawa and the adjacent islands¹⁰⁴ and was diagnosed as being of the Japanese "B" type by the complement-fixation test¹⁰⁵. A total of 127 cases was found. However, it was believed that this number may have represented only 15 to 30 per cent of the total¹⁰⁶ because special conditions precluded discovery of all cases. At the same time, there were 38 cases of suspected virus infection of the nervous system among the American military personnel¹⁰⁷. A definite clinical diagnosis of encephalitis was probably justified in only 12 of the cases, but a specific serologic diagnosis was established only in 9 and a diagnosis by other methods in 2 fatal cases.

This outbreak gave an excellent opportunity for the study of the epidemiology of the Japanese "B" encephalitis. Following the pattern of the work done on St. Louis and Western Equine Encephalitis, a search for vertebrate hosts infected with Japanese "B" virus was made. Horses, a cow and 3 goats were found to have neutralizing antibodies,¹⁰⁷⁻¹⁰⁸ but none of the chickens taken from the epidemic area showed evidence of infection. Furthermore, either few or no mites could be found on these or other chickens in the encephalitis zones.

Japanese¹⁰⁹ and Russian¹¹⁰ investigators have reported the isolation of Japanese "B" encephalitis virus from *C. tritaeniorhynchus* and *C. pipiens* (var. *palleus*) mosquitoes caught in nature. These mosquitoes as well as *A. togoi*, *A. albopictus* and *A. japonicus*¹¹¹⁻¹¹² were demonstrated experimentally to be potential vectors. Reeves and Hammon,¹¹² in 1946, further showed the ability of six species (*C. quinquefasciatus*, *C. tarsalis*, *A. dorsalis*, *A. nigromaculis*, *Culiseta incidens* and *C. inornata*) of the California mosquitoes to transmit the Japanese "B" virus to animals and have demonstrated the presence of the virus in the blood of inoculated chickens.¹¹³ Domestic animals have also been infected experimentally.¹¹⁴ Fear has been expressed that, once introduced into any areas where the American types of encephalitis now propagate, the Japanese "B" encephalitis might become a "greater plague than any we have at present."

Before and during the Okinawa epidemic of 1945, *C. quinquefasciatus* was in abundance and most readily found¹⁰⁷, however, tests on three pools did not yield any virus, nor were any chickens, which are known to be bitten by this mosquito in the United States, found infected. It was postulated, therefore, that some other mosquito, biting larger domestic animals and human beings, was a vector

on Okinawa. The real reservoir of the virus was not found, and it was again suggested that the vertebrate hosts and possibly the invertebrate vectors varied from one area to another.

RUSSIAN SPRING-SUMMER ENCEPHALITIS

For the past forty years, at least, an epidemic type of human encephalitis has been occurring annually in the forest regions of the Far East, Siberia and the European part of the Soviet Union, the Urals, Karelia, West Ukraine and White Russia. It occurs only during the spring and early summer, coinciding with the activity of ticks. Russian investigators have reported the isolation of the etiologic virus from man, rodents and ticks.¹¹⁵⁻¹¹⁹ They have also demonstrated conclusively the tick-wild-animal-tick cycle and the tick-tick transovarian cycle, with man as an accidental or incidental host.

Studies on the virus itself made in this country by Casals and Webster¹²⁰⁻¹²¹ have shown it to be very similar or identical with the virus of louping-ill of sheep in Scotland, also known to be tick-borne. Silber and Shubladse¹²² reported in 1945 that louping-ill is the tick-borne encephalitis of the western part of the Soviet Union, but that a different virus is responsible for the tick-borne encephalitis in the far eastern area. The tick is both a vector and a reservoir so that accidental transportation of infected ticks, as has already been accomplished for experimental purposes,¹²¹ might easily establish this infectious agent in the tick areas of the United States.

LABORATORY DIAGNOSIS OF THE ENCEPHALITIDES

Virus neutralization and complement-fixation tests are important not only because they can be used diagnostically to establish the titer of antibody in blood but also to determine the prevalence of the disease and the geographic dissemination of its virus. With a known virus, its specific antibody can be demonstrated, and with a known antibody, the identity of a virus can be revealed.

Neutralization Test

The presence of significant amounts of neutralizing antibody indicates previous infection by a virus, even though there may have been no apparent disease. This factor is the basis of the "two or three phase" test. Under ideal conditions, a specimen of serum obtained as early as possible during the acute phase of illness, another one or two weeks after onset, and a third, if necessary, taken still later, three to eight weeks after onset, are subjected to the neutralization test. Since infection by a virus may be clinically inapparent, normal persons may show specific neutralizing antibody.⁶⁷⁻¹²³⁻¹²⁵ Hence, a single positive specimen may be misleading, especially if the person has lived in endemic areas. The reason for selecting the intervals from the earliest time to eight weeks after

onset for test is that this antibody appears at varying times after infection with different viruses. In western equine virus infections, neutralizing antibody appears as early as the fourth day after onset, and in St Louis and Japanese "B" encephalitis from three to seven days to as late as three weeks.

The success of virus neutralization as a diagnostic procedure depends upon the precision with which, in the comparison of serums obtained in the acute and convalescent stages of infection from the same patient, a definite increase of antibody in the later sample is revealed. To measure this increase in antibody (or in the protective power of an antiserum), one of two methods may be used. Undiluted serum is tested against varying quantities of virus¹²⁶, or graded dilutions of serum against a specific quantity of virus¹²⁷.

There are two choices of laboratory recipients for serum-virus mixtures when the neutralizing capacity of a serum is to be tested: the serum-virus mixtures are injected into an animal that is uniformly and highly susceptible (that is, for encephalitis viruses, generally the albino mouse), or the mixtures are injected into developing chick embryos¹²⁶. As a rule, the latter technic merely supplements the former or is used only for special purposes.

The specificity of the neutralization of a virus by its antiserum is generally accepted. However, there are records of cross reactions, but these occur between viruses that have common characteristics, which are reflected by common antigenic complexes. The cross reactions (also encountered in complement-fixation tests) between West Nile, St Louis encephalitis and Japanese "B" encephalitis viruses indicate a relation of the three infections¹²⁹⁻¹³¹. The serologic cross reactions are not pronounced, and laboratory workers circumvent this obstacle by utilizing the fact that the homologous reactions are usually at a definitely higher level, especially when the virus antibody mixture is injected intraperitoneally or subcutaneously. More decided cross reactions (neutralization, complement fixation) occur between louping ill and Russian Far East encephalitis viruses. However, homologous titers are always higher and cross-resistance tests by intracerebral injection exhibit definite differences between the two.

Complement-Fixation Test

Prior to 1937, several workers attempted to apply the complement-fixation reaction to the study of neurotropic viruses. The results were unsatisfactory owing to a lack either of specificity or of appropriate controls. The material from which the complement-fixing antigens are derived consists of tissue extract in which the extraneous material sometimes outweighs the specific antigen. This extraneous material can mask the results of the test, either by its anticomplementary effect or by its capacity of combining with test serums

to produce nonspecific reactions. In 1941 Casals and Palacios¹³² demonstrated the practicability of the test for diagnosis of several neurotropic viruses, using brain-tissue suspensions as a source of antigen. Their method is still employed, with some modifications, and consists of emulsifying infected mouse brain tissue and then centrifuging it. The supernatant is then alternately frozen and thawed until flocculation takes place, when it is centrifuged again. This supernatant contains the antigen, which is highly virulent and can be inactivated by ultraviolet irradiation¹³³ or by heating at 60°C for thirty minutes¹³⁴. Other methods of preparation of antigen are the low-speed centrifugation of infected chick embryos with inactivation by ultraviolet radiation¹³⁵ and the extraction with benzene from infected chick embryos or mouse brains with inactivation by 0.05 per cent formalin¹³⁶.

In preparation of animal hyperimmune (positive control) serums, it was found that the injection of tissue extracts derived from one animal species into another animal species made possible the development of confusing species or organ-specific antibodies^{122, 127, 135}. Fortunately, the tissue component responsible for nonspecific reactions¹³⁹ was found sedimentable at 20,000 r.p.m. In some species this antibody-like substance is thermolabile,^{132, 133} being totally destroyed at 65°C.

It was also found that human Wassermann-positive serums gave, as a rule, a nonspecific reaction with brain extracts¹³² and benzene-extracted antigens¹³⁶, however, this is overcome by heating of the serums at 65°C for twenty minutes.

Since this information became available, the complement-fixation test has become a more satisfactory test for diagnosis of neurotropic virus diseases. However, it has not as yet been accepted for general use as has the neutralization test.

Obtaining and Sending Serum to be Tested

Persons should be bled for test serum after several hours of fasting (usually in the morning before breakfast) and with sterile technic. After 20 cc. of blood is withdrawn, it is allowed to stand for half an hour at room temperature and to clot. Then, after having been centrifuged at 2500 r.p.m. for twenty minutes, clear serum is pipetted off. If a preservative is necessary a 1:50,000 dilution of phenyl mercuric borate can be added (or 1:2,500 borate stock, 1 drop to each 1 cc. of serum, as an estimate). The serum is placed in a hard glass ampoule, which is sealed. If a test tube is used, it should be closed with a cork or rubber stopper, and the top should be completely waxed. A glass container should be filled only to a third of its volume to prevent bursting during freezing. The container is kept at about -76°C by carbon dioxide snow until tested. It should be sent to the designated laboratory by the fastest method, preferably in a vacuum jar holding solidified carbon dioxide. If this refrigerant is not available, the

serum should be sent fluid, provided it can reach its destination within thirty-six hours

PREVENTION OF VIRUS ENCEPHALITIDES

Prevention in this group of diseases consists of vector control and vaccination. With so many species of animals and birds susceptible to the viruses and with the disease occurring among them in nature, control of the primary and secondary hosts is difficult. However, much can be done in the way of vector control on a community-wide scale, and individually. Since the mosquito is apparently the major vector, modern mosquito-control procedures on a community basis should afford some protection during an outbreak. Also, individual measures, such as adequate screening of houses, avoidance of exposure to mosquitoes, and the use of new insecticides and repellents, should be carried out during an epidemic.

The observation of Higbie and Howitt,¹⁴⁰ in 1934, that equine encephalomyelitis virus may be cultivated in ten-day-old developing chick embryos provided the basis for subsequent work¹⁴¹⁻¹⁴⁷ on the preparation of formalin-inactivated vaccines effective in establishing active immunity in horses and mules. The earlier vaccines had consisted of inactivated virus in suspensions of brain tissue from animals infected with the appropriate virus.

Although such vaccines are satisfactory for administration to horses, their high content of chick tissue and egg components makes them potentially dangerous as human prophylactic agents. From 1941-1943, approximately 6103 persons were vaccinated in Manitoba against western equine encephalomyelitis, with relatively mild reactions in general and no fatal results.^{58, 124, 125} During the outbreak of Japanese "B" encephalomyelitis on Okinawa in 1945, 60,000 to 70,000 military personnel received mouse brain vaccine with only three reports of a form of "neuritis" of a questionable character and 19 allergic reactions suggesting sensitivity to formaldehyde.

In the following summer, 250,000 additional persons were vaccinated with only three reports of infectious polyneuritis, which was in no way different from that occurring among unvaccinated personnel in the Far East.¹⁰⁷ Furthermore, the Russians have effectively used a formalinized tissue vaccine to protect man in epidemic areas.¹⁴⁸

Randall et al.,¹⁴⁹ in 1947, prepared a purified formalinized vaccine against eastern, western and Venezuelan viruses and demonstrated upon guinea pigs active immunity against homologous types of virus, even when injected directly into the brain. Moreover, antibodies neutralizing the eastern virus were demonstrated in the serums of guinea pigs after the administration of the eastern type of vaccine and in the serums of human beings after the injection of a mixture of eastern and western types of vaccine. Usually two doses are given a week

apart and neutralizing antibodies appear one or two weeks after the first inoculation. These injections should be given annually.

There is seldom valid reason to recommend the vaccination of the entire group of susceptible human beings in a community against encephalitis. Anyone who, by reason of his work, must be heavily exposed to mosquito bites in an epidemic area should be permitted the protection of the vaccine. However, whether general or extensive vaccination of the most susceptible groups (infants and those over fifty) or military personnel is advisable should be decided by those in charge of public-health administration who can weigh various factors involved in any particular area or group.

Constant vigilance has been maintained in Massachusetts since the outbreak of 1938 to detect additional cases of encephalitis due to the eastern virus. No additional cases have been discovered. No proved cases in horses have been found since 1939.

It is suspected that optimum conditions occurring in the Commonwealth in 1938 favored the spread of the virus from the reservoir host (as yet undetermined) to horses and to man. Certainly the suspected mosquitoes were present in abundance.

It is probable that another outbreak will not occur until the virus again builds up in a reservoir host simultaneously with an unusual abundance of the necessary mosquito vector. The information accumulated in the 1939 state-wide mosquito survey will then be put to practical use.

SUMMARY

The public-health aspects of the six most important viruses that cause epidemic encephalitis are discussed, including the characteristics of the etiologic agents, their possible reservoirs, the usual vectors, the laboratory diagnosis and the possible means of control.

CASE 35241

PRESENTATION OF CASE

First admission A twenty-six-year-old salesgirl was admitted to the hospital complaining of amenorrhea and swelling of her left leg.

Nine years before admission an appendectomy was performed at another hospital. Following the operation she developed swelling of the left leg. This continued up to admission, and was more severe after standing for long periods. Five years before admission the patient's twin sister, upon whom the patient was very dependent, died of "pancreatitis" after two years in a sanatorium for questionable pulmonary tuberculosis. During the following year the patient's weight fell from 145 to 115 pounds. Vague lower abdominal cramps appeared. She became nervous, and developed palpitation, weakness and fatigue. Four months before admission she suffered a severe episode of diarrhea lasting eight weeks, and had as many as ten to fifteen bowel movements for a twenty-four-hour period. There was no blood or mucus. The diarrhea slowly subsided, but there had been no menses since its onset.

Physical examination showed an extremely thin young woman. A Grade II blowing systolic murmur was heard over the precordium, loudest at the apex and second left interspace. A few moist rales were present at both bases. The abdomen was flat, with a right paramedian scar, which was slightly tender. There was a moderate white mucoid vaginal discharge and tenderness in the posterior cul-de-sac. There was +++ pitting edema of the left leg, and slight pitting edema of the right.

The blood pressure was 115 systolic, 80 diastolic.

The white-cell count was 10,750, with a normal differential. The hemoglobin was 14 gm per 100 cc. The urine was normal. The stools were repeatedly guaiac negative. A tuberculin test of 1:10,000 was negative. The sedimentation rate was 0.8 mm per minute. The fasting blood sugar was 100 mg, and the total protein 4.5 gm per 100 cc. The prothrombin time was 23 seconds (control, 18 seconds). The sodium was 145.2 milliequiv and the chloride 100 milliequiv per liter, the calcium 9.6 mg, the phosphorus 5.0 mg, and the nonprotein nitrogen eighteen to forty-three mg per 100 cc.

A sigmoidoscopy was normal. A barium enema was negative, the terminal ileum did not fill. A barium meal showed a normal esophagus and stomach. In the distal portion of the jejunum or proximal ileum there was a delay in the passage of barium, and in this portion there were segments of markedly narrowed bowel in which the mucosal pattern was lost. Throughout the remaining ileum, including the terminal ileum, there were multiple similar areas.

During the first month of hospitalization she was essentially afebrile, and on a low roughage and high vitamin, calorie and protein diet she was comfortable except for abdominal distention.

A Miller-Abbott tube passed into the small bowel produced some relief. An ileotransverse colostomy without bowel resection was performed.

An x-ray film on the sixth postoperative day showed an area of increased density in the left lower chest, and a bilateral superficial-femoral-vein ligation was done under local anesthesia. No clots were found. After one month the patient was gradually weaned from intravenous feedings to a low roughage diet. Slight abdominal distention, cramps and occasional slight diarrhea appeared. She was discharged two and a half months after admission.

Second admission (eight months later) In the interval the patient had severe crampy diarrhea in bouts lasting two or three weeks, often watery but never bloody. She was admitted to the hospital for further study. The serum albumin was 3.76, and the globulin 1.41 gm per 100 cc. There was no change in the x-ray findings, and she was discharged after a week in the hospital.

Third admission (fifteen months later) The patient had remained in fair health, had gained about 25 pounds and had married. She had intermittent

attacks of mild diarrhea (with a slight spot of blood on three occasions), but had periods lasting up to a month when she was entirely normal, with regular bowel movements. There was no abdominal pain. Her menses were now normal, occurring every thirty days and lasting four days. Her ankles and legs had been persistently swollen for a year, more severe toward the latter part of the day. The white-cell count, hemoglobin and urine were normal. A small-bowel series showed extensive areas of narrowing throughout the small bowel, the highest one beginning about 18 cm from the ligament of Treitz. She was discharged after four days.

Fourth admission (fourteen months later). She was comfortable without change in her clinical picture until four months before admission, when she tried to manage a six-room house with stairs, and became fatigued. She noticed that the swelling of her legs increased to involve her thighs, hips and abdomen. Dyspnea on slight exertion, palpitation, sweating, and extreme fatigue appeared. Two months before admission a single dose of a mercurial diuretic resulted in a sudden diuresis of 35 pounds of fluid in two or three days.

On examination superficial edema was present below the ninth thoracic vertebra. There was ascites and ++++ edema of both legs.

The blood pressure was 132 systolic, 84 diastolic. The pulse was 96, and the respirations 18.

The white-cell count was 4500, with a normal differential. The urine was normal. The stools gave a + to ++ guaiac reaction. The serum albumin was 3.13, and the globulin 1.72 gm per 100 cc. The alkaline phosphatase was consistently elevated above 10 units, the highest reading was 15.5 units. The cholesterol was 162 mg, vitamin A 1.1 units, and carotenoids 0.4 units per 100 cc. An oral glucose-tolerance test and a vitamin A test were normal.

She was afebrile, and under low salt and mercurial diuretics the edema subsided readily. She was discharged two weeks later on a high calorie, high protein, high vitamin, low salt diet.

Final admission (one month later). For the first week after discharge she felt well, and had no significant accumulation of fluid. In the subsequent three weeks edema fluid increased unrelentingly in spite of vigorous mercurial therapy. In addition one barbiturate capsule nightly was prescribed by her physician.

There was marked edema in the lower half of her body, and ascites was present. The blood pressure was 110 systolic, 70 diastolic.

The white-cell count was normal. The hemoglobin was 10 gm per 100 cc. The urine was normal. Admission stools were guaiac negative, and neutral fats and urobilinogen were normal. Combined fats were markedly increased. The serum alkaline phosphatase was 19.3 units, the serum

albumin 2.62 gm, and the globulin 1.86 gm per 100 cc. A cephalin-flocculation test was negative in forty-eight hours. The van den Bergh reaction was 0.2 to 0.6 mg per 100 cc. The prothrombin time was 19 seconds (control, 16 seconds), the bromsulfalein test demonstrated 25 per cent retention of the dye in one hour. The fluid obtained on abdominal paracentesis was cloudy and yellow, with a specific gravity of 1.009, and contained 90 white cells and 2 red cells per cubic millimeter, a culture was sterile. The liver edge was palpable one fingerbreadth below the costal margin.

X-ray examination of the esophagus showed no varices. On mercurial diuretics and intravenous therapy, including albumin, the serum proteins were restored. The albumin was 4.49 gm, and the globulin 1.59 gm per 100 cc. The edema persisted however.

The patient, always emotionally unstable, became depressed and during the fourth hospital month gradually became drowsy and unresponsive. A Chvostek sign appeared, but disappeared after intravenous calcium therapy. The coma persisted. She died five and a half months after admission.

DIFFERENTIAL DIAGNOSIS

DR ROBERT R. LINTON. This patient had a number of admissions to the hospital. On the first admission she complained of amenorrhea for four months and swelling of the left leg for nine years. The complaint that she entered with does not strike me as being her chief trouble. I think that becomes more obvious as one reads more of the record. I would like to point out the statement, "four months before admission she suffered severe episodes of diarrhea lasting eight weeks." That is of extreme significance in relation to the remainder of the hospital course and, in fact, to the rest of her life. I am a little disturbed and completely puzzled by the death of her sister from pancreatitis when she was in a sanatorium with pulmonary tuberculosis. I have never associated pancreatitis with pulmonary tuberculosis, perhaps they do occur together.

When I read the record of this first admission I thought, of course, that this patient must have one of two things: regional ileitis or ulcerative colitis, because of the history of severe diarrhea. I will admit that one should not base one's diagnosis entirely on the history of diarrhea lasting for that length of time, but in view of it, I certainly was interested in these two parts of her gastrointestinal tract, the small bowel and the large bowel.

A barium enema revealed marked abnormality in the mid-small bowel down to the cecum, of sufficient severity to produce obstruction of the small bowel so that it was necessary to short-circuit the diseased segment by an ileotransverse colostomy.

A chest x-ray film was taken, and a diagnosis, presumably of pulmonary infarction, was made. Interruption of the femoral vein was carried out.

The fact that no clots were found is of no significance. I personally think if a patient is kept under observation long enough for clots in the common femoral vein to be found, it is comparable to a case of acute appendicitis in which one waits for the appendix to rupture before operating on it.

This case represents a chronic illness involving the intestinal tract. I believe I would leave out the stomach. We have very good evidence—clinically, by x-ray study and by direct inspection of the colon—that it was not involved, and that the disease was localized in the small intestine. It seems to me that this patient had been presented to me to discuss as a reminder of a patient that I had with a similar condition. Unfortunately, I did many more operations on my patient than this patient had, and despite them the disease progressed until the entire small intestine was involved. I do not believe that her amenorrhea had anything to do with the present condition. I think that it was probably secondary to her long-standing debilitating disease. This view is substantiated, I think, because the menses returned after her condition had improved following the ileotransverse colostomy. The edema of her leg, I believe, could have been secondary to an old thrombophlebitis of the lower extremities, which she apparently developed in the left leg at least. The swelling undoubtedly became more marked later on because of the low serum protein. We do not know too much about why people's legs swell, but I am sure that, if there had been obstruction of the lymphatics, the swelling would have been more marked. The left leg swelled, but the right one did not to begin with. I believe that both legs swelled after the femoral veins were interrupted because of the thrombophlebitis, which presumably developed following the ileotransverse colostomy.

It seems to me that this patient's condition is typical of regional ileitis. There are other conditions that one might consider, but I have to rule them out, simply because of ignorance regarding their clinical course. One is tuberculosis of the intestinal tract. I cannot see how it fits into the picture, although it is a possibility. Another is lymphoma of the small bowel. Again, I do not have sufficient evidence on which to base such a diagnosis.

I would like to see the x-ray films before going any farther.

DR STANLEY M. WYMAN: These are a few of the films taken when she first came in. They show a normal chest. The esophagus, stomach and duodenum are not remarkable, and the colon reveals no evidence of intrinsic disease. These are films of the small bowel taken over a three-year period, and they show the abnormal areas of small bowel, this being the terminal ileum, entering the cecum, and this being a loop of proximal jejunum. There are multiple areas of abnormal narrowing, with intervening, grossly dilated segments of bowel. The

mucosal pattern is markedly thickened and grossly abnormal.

DR LINTON: These x-ray findings, I think, bear out the written report, and I do not see how one can make any other diagnosis than regional ileitis, with massive involvement of the small intestine.

There are certain chemical studies that are of interest, some of which I am totally unable to decipher. The alkaline phosphatase, the vitamin A and the carotenoids do not help me much in making the diagnosis. To me, they represent abnormalities in bodily function secondary to long-standing illness. The most striking one, and the one that appears to me most significant, is the drop in serum protein, I suppose owing to the chronic condition. Although it was possible to bring this serum protein up to normal level temporarily, it was impossible to keep it there. Another interesting thing is the Chvostek sign, which is merely mentioned here, I believe that it appears in chronically ill patients with regional ileitis. The exact physiology involved, I am not sure about, but I have seen it in patients who had a large part of the small bowel removed. It apparently develops because of the inability to absorb calcium.

In conclusion, I believe that this patient had regional ileitis. She had a disease that we know very little about. If that is what it was, whether treated medically or surgically, the results are not encouraging. From my experiences, I would say that if one does an ileotransverse colostomy to short-circuit the diseased bowel distal to the uppermost lesions of small bowel, the chances of relieving the patient are slim, and the chances of curing her are nil.

DR J. H. MEANS: I saw this patient twice, in 1945 and again in 1949. We thought the early condition was regional ileitis and the leg condition a postphlebitic one, if I may use the term. Dr Linton saw this patient in 1945. I consulted him and asked if it was subclinical elephantiasis, so called, with postoperative phlebitis, some years before, following appendectomy. I thought the obstruction was lymphatic or venous, or perhaps both. I saw her in the wards when she had swelling in both legs and marked hypoproteinemia, which we supposed was due to lack of small bowel. When I went off service, she was developing a psychosis, and she was transferred to the psychiatric service, where she died. That is all I know. Dr Culver studied her case. Let us call on him.

DR P. J. CULVER: I followed her for two years. When we first saw her she was in good health, in spite of x-ray evidence of widespread disease. Comments were made at the gastrointestinal rounds on how well she was doing. Then she had this dramatic change. She developed ascites of enormous proportion. It was impossible to explain why she had fluid retention from the diaphragm down and nothing up above. There was wasting of the shoulder girdle, arms and face. The edema and ascites did

not respond to mercurial diuretics. A review of her serum protein levels for the preceding two years made it impossible to attribute the ascites to hypoproteinemia, particularly since there had always been a low serum albumin. When we raised the albumin level with intravenous human albumin, we got a high serum level, but it did not relieve the ascites. Because we could not transfer the edema to the upper half of her body when the foot of her bed was elevated on shock blocks we thought that there must be a block in the inferior vena cava to explain what was going on. We called on Dr. Welch for an opinion, but he did not think caval obstruction was the cause of the ascites.

The liver chemical tests were of interest. She had a normal alkaline phosphatase initially, and it became elevated rapidly, enough to suggest an obstructive element in the liver. The remainder of the liver-function tests, with the exception of the bromsulfalein, were normal, indicating something obstructing the excretory mechanism in the liver. This is as far as we could go toward incriminating the liver. As for the hypocalcemia and its clinical manifestation, tetany, this was probably explainable on the basis that most of these people with regional enteritis have a terrific loss of insoluble calcium salts in the stool. An amazing fact was that, in spite of a damaged bowel, she absorbed vitamin A fairly well. Usually, we see a lowered absorption in this disease. The hypoproteinemia was due to the fact that she had lost so much albumin into the ascitic fluid, and into the edematous fluid, in addition to the fact, as Dr. Means has said, that she did not have enough small bowel to carry on.

DR. CLAUDE E. WELCH: The question put up to me was whether the old thrombophlebitis could have progressed to the point where the inferior vena cava was completely obliterated and extended to the level of the liver, producing, perhaps, a Chiari syndrome and ascites, although it seems unlikely that that would be the cause. The patient had normal renal function, and the renal veins were functioning well. We considered further diagnostic measures in the way of venous catheterization, but she was so sick that we decided not to carry them out.

DR. LINTON: May I read the operating note at this stage? It is as follows:

The small bowel was explored from the ligament of Treitz to the cecum. It was in no place adherent. Many typical lesions of chronic regional enteritis were present, interspersed between short segments of normal bowel. There was only one portion of the bowel that had an area longer than 10 cm. not involved in disease, and that was near the terminal ileum about 35 cm. above the cecum, where there was 30 cm. free of disease.

The extent of the disease found raises the question whether an ileotransverse colostomy was the best treatment for the extensive disease in the patient.

DR. CULVER: It was an emergency procedure because of obstruction. The surgeon's hand was forced. It was not an elective procedure.

DR. TRACY B. MALLORY: A small piece of information was left out of the record inadvertently. At one time when the medical service began to consider the possibility of liver disease, a liver biopsy was done and showed chronic passive congestion of severe degree.

DR. LINTON: I had mentioned that the liver-function tests had nothing much to do with her clinical symptoms, except that the liver was suffering as well as the rest, and I explained the increased bromsulfalein retention on that basis, rather than on that of primary liver disease.

DR. MALLORY: We have had a certain number of patients with ulcerative colitis and regional enteritis who, in the course of years, developed markedly fatty livers and, in some cases, definitely cirrhotic livers. That possibility was seriously considered here, but was apparently ruled out by biopsy.

CLINICAL DIAGNOSES

Inanition, with edema.
Regional enteritis
Ascites of unknown cause

DR. LINTON'S DIAGNOSES

Regional enteritis
Bilateral venous thrombosis of lower extremities
Hypoproteinemia

ANATOMICAL DIAGNOSES

Regional ileitis
Hepatic-vein and vena-cava thrombosis (Chiari's syndrome)
Central necrosis of liver, severe
Ascites
Edema of lower extremities, severe
Multiple pulmonary emboli, microscopic
Operative wounds: ileotransverse colostomy and ligation of superficial femoral veins

PATHOLOGICAL DISCUSSION

DR. MALLORY: Post-mortem examination disclosed very severe regional ileitis. There were innumerable areas of involvement of the small bowel, some of them as short as 1 cm. in length and some as long as 10 cm. The highest one, as the x-ray report stated, was only 30 cm. beyond the ligament of Treitz, and the lowest one extended down to the ileocecal valve, so that the patient had really very little intestine except a duodenum and 30 cm. of jejunum that could be considered normal. We did find a thrombus in the inferior vena cava, which was about 10 cm. in length. It started above the level of the renal veins, which were entirely uninvolved, and extended up above the mouth of the hepatic vein and then there was retrograde thrombosis of the hepatic veins throughout the liver, even down to the very small ones, making a characteristic picture of so-called Chiari's syndrome. This was quite consistent with the liver biopsy. The finding of chronic passive con-

gestion of the liver in the absence of heart disease suggests obstruction between the level of the hepatic vein and the right auricle at some point. The liver itself showed rather extensive secondary degeneration, part of it looking simply like extremely marked chronic passive congestion and part of it being a picture of incomplete infarction. The age of the intrahepatic thrombi was variable. Some of them seemed quite fresh, and others showed marked organization and must have been present weeks — and perhaps months or more.

DR CULVER: Do you think this could explain the ascites that had been present for six months?

DR MALLORY: It is hard to estimate the age of these thrombi with exactness. An otherwise healthy person will organize a thrombus comparatively rapidly, a very ill patient may require two or three times as long to effect the same amount of organization. It is quite possible that these thrombi are of longer duration than one would estimate from ordinary criteria.

DR CULVER: Is not the amount of ascites in the case unusual for regional ileitis? In fact, I have not seen a case with more than minimal fluid in the abdomen. Could the ascites be explained by blockage of the lymphatics with an infiltrative reaction throughout the small bowel rather than any other cause, such as liver disease, portal hypertension or hypoalbuminemia?

DR MALLORY: I had not thought of that possibility but did not see any striking evidence of lymphatic dilatation in the bowel, and I would be more inclined to think it was due to portal hypertension.

DR LINTON: The vena cava was not completely occluded?

DR MALLORY: No, perhaps only one third.

DR WELCH: Do you think this was the end result of ascending thrombosis of the vena cava, or possibly that the thrombosis in the liver was more or less simultaneous? The thrombi met in the middle, which is a peculiar picture.

DR MALLORY: It is possible, I cannot say with certainty whether the thrombus started in the hepatic vein or in the vena cava.

DR LINTON: Perhaps it was started by the biopsy.

DR MALLORY: It is frequently recorded in cases of Chari's syndrome that there is thrombosis both in the vena cava and in the hepatic vein.

lateral side of the right thorax, from the level of the sixth rib down into the flanks and around to the back. It occasionally radiated to the region of the anterosuperior iliac spine, but never to the left side, shoulder, scapula or umbilicus. It was steady and sustained, never colicky. The pain was not related to meals. There was no headache or urinary symptoms. His appetite had diminished. The pain subsided after two weeks, but a residual soreness persisted. Attacks recurred about once each month, lasting one or two weeks. The pain was so disabling that he was unable to work and was virtually an invalid. There was no weight loss. The more recent seizure started two weeks before admission.

He had scarlet fever at six years of age, but no cardiac or renal sequelae were recalled. At the age of twelve, he had rheumatic fever, and was confined to bed at home for one year. There were several recurrences until fifteen years of age. Four years before admission he entered another hospital with pneumonia. For many years, he had been aware of vigorous heart action, especially at night, when he was disturbed by the shaking of the bed with each heart beat. He was able to climb one flight of stairs rapidly without feeling excessively breathless. He slept lying flat. There was no ankle edema.

Physical examination showed a pale, asthenic, well nourished man. The heart was markedly enlarged, the apical impulse being prominent and visible in the seventh interspace in the axillary line. Rough and blowing systolic and diastolic murmurs were loudest at the aortic area, and radiated to the neck and the apex. The second pulmonic sound was faint. The rhythm was regular. The lungs were clear and resonant throughout.

On abdominal examination two points of deep tenderness were found in the anterior right flank about two fingerbreadths below the costal margin extending posteriorly for an area about 15 cm in diameter, and in the right lower quadrant just above Poupart's ligament.

The blood pressure was 180 systolic, 30 diastolic.

The white-cell count was 10,200, and the red-cell count 5,300,000. The urine had a specific gravity of 1.012 and gave a +++ test for albumin, the sediment contained occasional white cells and hyaline and granular casts. A culture was negative, and a concentration test reached up to 1.015. The nonprotein nitrogen was 33 mg per 100 cc. The phenolsulfonephthalein test showed 15 per cent excretion in fifteen minutes, and 50 per cent within the first hour. An electrocardiogram was abnormal, suggesting left ventricular strain. The QRS complex was slurred and widened to 0.10 second. There was slight left-axis deviation, with sagging ST segments and inverted T wave in Lead 1 and diphasic T wave in Lead 2, the PR interval was 0.20 second.

CASE 35242

PRESENTATION OF CASE

First admission. A twenty-seven-year-old photographer entered the Out-Patient Department complaining of recurrent attacks of right-flank pain.

Five years before admission, he had an attack of right-sided pain that was very severe and forced him to go to bed. The pain was situated on the

A chest x-ray film showed clear lung fields and a markedly enlarged heart, chiefly in the region of the left ventricle. There was a small amount of fluid in both costophrenic angles.

Intravenous pyelography showed no definite filling of the kidney, pelves or ureters. Some dye was seen in the bladder after twenty minutes. On retrograde pyelogram and cystoscopy only the right meatal orifice was found. Retrograde filling on this side showed a short ureter, but the renal pelvis was superimposed on the mid-sacrum.

Under observation as an outpatient, acute episodes of pain recurred, and eleven months after his first examination he was admitted to the hospital. The previous findings were confirmed, but since his pain diminished in intensity he was discharged eight days later to return at the onset of another attack for a diagnostic novocain block. Another retrograde pyelogram confirmed the previous finding of a single pelvic kidney. The calyces appeared small but were otherwise normal.

Second admission (eight months later) The patient returned because of an acute attack. Right paravertebral novocain injection was employed, and the pain was relieved temporarily.

Third admission (one year later) A right lumbo-dorsal sympathectomy was done, with immediate relief of pain.

Fourth admission (two years later) The patient complained of severe pain, localized to an area 15 cm in diameter just to the right of the spine and below the scapula, requiring demerol or morphine for adequate relief. In addition, in the two years after operation dyspnea on exertion had increased, and on repeated occasions he was awakened by a smothering sensation, which forced him to sit up-right and go to an open window. The heart was increased in size over previous examinations, and loud harsh systolic and diastolic murmurs were heard at the base. Slight presystolic accentuation at the apex and a mid-diastolic rumble were noted. A normal sinus rhythm (rate of 90) was present. The blood pressure was 190 systolic, 50 diastolic.

The sedimentation rate was increased to 11 mm per minute. Moderate numbers of *Staphylococcus albus* and a few colon bacilli were cultured from the urine. The nonprotein nitrogen was 48 mg per 100 cc, and the blood chloride was 111 milliequiv per liter. An electrocardiogram showed a PR interval of 0.20 second and prominent S wave in Lead 2, the T waves were inverted in Lead 1, diphasic in Lead 2 and upright in Lead 3. Sweating and skin-temperature tests demonstrated complete sympathetic regeneration. A Graham test was negative. Therapy included digitalization, a large fluid intake and demerol for pain.

After two months the patient was transferred to another hospital for chronic convalescent care, and remained there for four months.

Fifth admission (seven months later) The patient was readmitted complaining of recurrent pain in the right posterior thorax. The physical findings included marked pallor and forceful arterial pulsations in the neck. The heart was markedly enlarged, the point of maximal impulse being at the anterior axillary line in the seventh interspace, a protodiastolic gallop was present at the apex. The following murmurs were found: a Grade III, rough, aortic systolic murmur, a Grade III, long diastolic blow at the base, left sternal border, apex and axilla and a Grade II, rather high-pitched apical systolic and an apical diastolic rumble. The lungs were clear. The liver edge was palpable at the costal margin, with tenderness. There was slight ankle edema.

The blood pressure was 230 systolic, 0 diastolic.

The sedimentation rate was 58 mm in sixty minutes. The red-cell count was 4,280,000, with a hemoglobin of 9.5 gm per 100 cc. The nonprotein nitrogen was 78 to 125 mg per 100 cc. The chloride was 109 milliequiv, and the carbon dioxide 16.6 milliequiv per liter, and the creatinine ± 2 to ± 9 mg, the calcium 7.5 mg, and the phosphorus 5.5 mg per 100 cc.

Final admission (three years later) The complaint at this time was during the interval in which the patient was seen frequently as an outpatient and inpatient. His complaints were right-chest pain (relieved only by sedation), dyspnea and ankle edema, and repeated severe epistaxes requiring packing and blood transfusions. On examination bilateral moist rales were heard at both bases, more marked on the right, with slight dullness on the right. Right-upper-quadrant tenderness in the abdomen was noted. There was a +++ pitting edema behind the malleoli. The blood pressure was 240 systolic, 40 diastolic.

The white-cell count was 21,100, and the hemoglobin 7.2 gm. The specific gravity of the urine was 1.010, with a +++ test for albumin and a + test for sugar. Many white cells and amorphous granular material were present in the sediment. The nonprotein nitrogen was 200 mg, the fasting blood sugar 105 mg, and the total protein 6.1 gm per 100 cc, and the carbon dioxide 10.5 milliequiv, the sodium 124.5 milliequiv, and the chloride 90 milliequiv per liter.

The patient developed progressive respiratory distress, with increasing moist rales in both lungs. He died on the seventh hospital day.

DIFFERENTIAL DIAGNOSIS

DR. HOWARD B. SPRAGUE Those who took care of this patient had the opportunity of watching him for seven years. I have had less than one day to consider this situation. I hope they were happier about it than I am. It does seem, however, that there is enough in the history to explain why the patient died, but I am not sure what caused his

prolonged disability — namely, this peculiar kind of pain

To begin with, he began to have trouble when he was twenty-two years old, and he had for about half the time in the next seven years recurring right-flank pain, which lasted one or two weeks at a time and came on about once a month. That leaves him not much free time without pain. I assume from this history that he had rheumatic heart disease with aortic involvement — aortic regurgitation and some degree of aortic stenosis. There was a questionable mitral diastolic rumble, which could have been an Austin-Flint murmur, but on a statistical basis I suppose we would say that there was both mitral and aortic involvement. There was apparently congenital absence of the left kidney and a solitary pelvic kidney on the right side with a short ureter, which would indicate that it was a developmental affair. There was normal rhythm in the heart — that is, no auricular fibrillation, and predominantly an aortic lesion. This does not influence us toward the thought of multiple embolic phenomena. Certainly a patient cannot have emboli every two or three weeks for seven years, I would think, without having more to show for it. The pain was relieved by both the paravertebral block and the right lumbar sympathectomy. Dr. J. C. White is here and will presumably tell us about this later. But since nothing is said in the history about whether anything peculiar was seen when the operation was performed, I shall assume that probably nothing was seen. He had progressive anemia, progressive renal failure, uremia and a questionable urinary infection. The epistaxis was presumably on the basis of hypertension and renal state, although one has to think of active rheumatic fever and nosebleeds.

Let us consider this pain, which had a distribution as high up as the sixth rib in the back but which seems mostly to have been right-flank pain and below the costal margin, at times to the crest of the ilium. It seems to have been more below the ribs than up in the chest, and there is nothing in the x-ray report to suggest anything wrong in the chest. There does not seem to have been anything on which to base a suspicion of gall-bladder or liver difficulty. Of course, acute recurrent liver congestion that occurs in mitral stenosis has to be thought of too, but this does not quite seem like that. He did not have a large tender liver related to the attack. The Graham test was negative. The distribution of this pain would seem to me to be renal in its position, and I am interested to know, since he had only one kidney and it was down in the pelvis, whether he maintained the ordinary renal distribution of pain, if he had trouble with that kidney.

Perhaps Dr. White would be willing to answer that for

Dr. J. C. White. I would expect he had, because it would drag the nerve supply with it. When I was working in the Anatomical Laboratory of Professor Hovelacque in Paris, I dissected a cadaver with a very similar pelvic kidney, which derived its blood supply from the common iliac artery. The nerve supply came down from above in the usual fashion.

Dr. Sprague. That was the way I had argued — perhaps the nerve supply would be more likely to maintain its normal relation with the kidney than its blood supply. If we think in terms of development of the kidney in that area, and its failure to "ascend," it was actually being dragged down by the short ureter, which did not allow its blood supply to develop normally. I see nothing in the history to suggest urinary obstruction — at least there was nothing resembling a Dietl crisis, and aologic study would not indicate dilatation of the kidney. I have been informed that the x-ray films are not available at the present time, but that is the way that I interpret it from the history. So I am going to say, in spite of congenital anomaly of the kidney, that there was rheumatic rather than congenital heart disease, with aortic and perhaps mitral involvement, and that there was a progressive change in this solitary developmentally abnormal kidney in the nature of a true nephritis, perhaps of vascular origin with secondary infection. He had uremia and mounting hypertension, and then, to explain the pain, I am forced to fall back on the relation between the heart, aorta and the abnormally placed kidney. I was intrigued to think about a multitude of vascular anomalies commonly occurring in this region to account for this as being vascular pain in some way, probably radiating over an extensive pathway, but it may be that the kidney was so placed in relation to the aorta, and bound down by adhesions, that the severe aortic regurgitation acted in some way to irritate the attendant nerves. I would like to find out what was really wrong with this patient.

Dr. White. The urologists believed that this patient did have an ectopic kidney. That was fairly well proved. We asked them if they would do a retrograde distention of the kidney pelvis and single ureter, but they were reluctant to do so, because it was his only kidney. That would have proved whether the pain of which he was complaining in his paroxysms was of renal origin. Be that as it may, he did not have pain in the flank or groin after operation. When he came in two years later the urologists were willing to pass a ureteral catheter up to the pelvis and distend it, they found that it produced no pain. It was therefore evident that the kidney was denervated and that the pain he was having in the chest was not of renal origin. The operation was similar to that done for hypertension, the twelfth rib being taken out. I removed about 5 or 6 cm. of the major

splanchnic nerve and the sympathetic ganglionated chain from the tenth thoracic to the second lumbar segment, which would be sufficient to denervate the normal kidney. I wonder if Dr. Sprague has any explanation why the patient continued to have right thoracic pain? I have seen one patient with a tense liver capsule from cardiac failure who had pain of this sort, and I have also seen continuous discomfort in patients with active rheumatic heart disease. I remember one such case that Dr. T. Duckett Jones and Dr. Edward F. Bland had at the Good Samaritan Hospital, and they asked me to do a paravertebral injection. The patient had intermittent angina pectoris and steady pain in the right chest. Both types of pain were relieved following alcohol injection of the cardiac nerve.

DR. SPRAGUE: That was probably a mitral case.

DR. WHITE: The patient, a young woman, as I recall her, had aortic regurgitation, but I do not remember whether she had mitral disease as well.

DR. WILLIAM CHAPMAN: As I recall, the first pain in the case under discussion was located between the vertebra and medial border of the scapula and was reproduced by injection of 6 per cent saline solution in the same segment on the other side, which suggested a cerebrospinal or somatic pain. One expected, as Dr. Sprague did, that it was related to the grossly enlarged heart, and it was difficult to see how the enlarged heart could be pressing on the right side.

DR. SPRAGUE: I was trying to get out of my dilemma by saying that by sympathectomy we pushed the pain higher as we push anginal pain to the other side in some sympathectomized patients.

DR. WHITE: Yes, anginal pain may appear on the opposite side, and occasionally it may shift up into the jaw.

DR. SPRAGUE: True, but I was not quite clear about the amount of regrowth in the sympathetics.

DR. WHITE: I think that very often regeneration of peripheral vasomotor fibers, and much more rarely of the visceral nerves, may occur.

CLINICAL DIAGNOSES

Uremia

Chronic nephritis in single congenital ectopic kidney

Rheumatic heart disease

DR. SPRAGUE'S DIAGNOSES

Rheumatic heart disease, aortic regurgitation and stenosis and slight mitral stenosis

Congenital solitary pelvic kidney, with renal pain

Chronic glomerulonephritis and uremia

ANATOMICAL DIAGNOSES

Rheumatic heart disease, aortic stenosis and regurgitation

Adhesive pericarditis, chronic, with calcification

Congenital anomaly—single pelvic kidney

Chronic glomerulonephritis

Hyperplasia of the parathyroid glands

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: I think our autopsy findings were very much like Dr. Sprague's clinical diagnosis. We can explain the cause of death very readily, I am not sure that we can explain the cause of pain. The patient had the largest heart that we have ever seen in this laboratory (it weighed 1500 gm.), and he evidently had three causes for that enlargement. One was a severe rheumatic involvement of the aortic valve, with both regurgitation and stenosis. The mitral valve was essentially normal. He also had an adherent pericarditis, with considerable amounts of calcification in the pericardium. He unquestionably had hypertension on the basis of renal disease.

There was only one kidney, which lay in the pelvis and had a short ureter. The kidney had two arteries, the source of one of which was at the bifurcation of the iliac vessels, but the other smaller artery was not traced to its source. The single kidney weighed only 110 gm. and was scarred and granular, without, however, any dilatation of the pelvis. The microscopical sections showed an old, severe glomerulonephritis, so that there is ample explanation for renal failure. He had moderately enlarged parathyroid glands, as one would expect with such long-standing renal insufficiency. We found no involvement of the mediastinum that we could recognize, and except for the large heart and the adherent pericardium there was nothing in the thoracic cage that would explain the later episodes of pain in the thoracic region.

are that with increasing knowledge they are making up their minds in favor of free enterprise and voluntary systems of health insurance in which they can determine their own stake. They are willing to go into partnership with their doctors.

The continuing education of the public along these lines has been assumed by the medical profession, which is in the best position to carry on such a course of instruction. Its extension must be in the hands of informed laymen whose interests are obviously those of the public that they represent.

Every physician, nevertheless, as was indicated at the gathering of physicians and representatives of women's auxiliaries held in Boston on May 1, as an unofficial spokesman of his profession. Armed with the material that is directed to him through organized professional channels, he is delivering to his own segment of the public accurate information for further intelligent distribution.

While words must constitute the greater part of the ammunition in this battle for the continuance of an improved American way of life, consistent with liberty and the pursuit of happiness, words are fortunately not often lethal. They have their dangers, however, and too heavy a barrage must not be laid down. The old refrain "It's a terrible death to be talked to death" must still be borne in mind. There is a limit even to the amount of propaganda that one can sustain, and survive.

A WILLING PARTNERSHIP

It is an accepted thesis that the most important consideration in selling the idea of good medical care to the American people is to make them aware of what constitutes such care, and then to deliver it. They must be informed of its limitations as well as its accomplishments. They must know what it is worth in dollars and cents, and why. They must be directed toward the fairest and most economical way of meeting those costs.

From here on, mystery and magic, the ancient cloaks of medical grievance, are out.

Already, thanks to the kind and well intended efforts of various persons and organizations working for the adoption of compulsory health insurance, the people are taking great interest in the quality and distribution of medical care. The indications

EPIDEMIC ENCEPHALITIS IN RETROSPECT

ELSEWHERE in this issue of the *Journal* Ayres and Feemster present a nine-year to ten-year recheck on all the children who survived the 1938 outbreak of eastern equine encephalomyelitis in Massachusetts. The fact that only 1 child out of 34 is known to have come through unscathed is indisputable evidence of the violence of the infection with the virus of this particular disease. Twenty-five of the cases ended fatally, and 7 of the 9 survivors have varying degrees of mental and physical handicaps.

It is fortunate that a virus that causes such a stormy course seldom spreads to man. When it is considered that 70 per cent of human beings and 90 per cent of horses die of the infection with the

eastern virus, compared to only 10 per cent of the human beings and 20 to 30 per cent of the horses with the western virus, it can be understood why large outbreaks can occur in the western part of the country, where the latter is the predominating variety, whereas only a few isolated cases or small outbreaks occur in the eastern areas, where the eastern virus is more frequently found. An etiologic agent that kills off most of the hosts attacked has difficulty in surviving.

The progress report in this issue summarizes present knowledge of the public-health aspects of the six more important viruses that cause epidemic encephalitis. Much additional information is needed to provide a clear understanding of the peculiar geographic localization, not only of the eastern and western viruses but also of the virus of the St. Louis encephalitis. All these diseases can be transmitted by insect vectors prevalent in the eastern United States as well as in the West, but up to the present time most of the outbreaks have occurred west of the Mississippi River.

A state-wide mosquito survey carried on in 1939, as a consequence of the 1938 outbreak, furnished much useful information regarding the varieties and habits of the mosquitoes in Massachusetts. This information will be valuable if another outbreak of eastern equine encephalomyelitis should occur, or if one of the other two viruses should be transported into this area.

—WHO HELP THEMSELVES

THE American Red Cross performed such a variety of heroic services to the country during the war that it is hard to bear in mind the continuing value of some of them in the uneasy days that have succeeded the conflict. Of special importance in this respect is the training in the elements of home nursing that so many women received in those days. This training, less dramatic than first aid, was equally useful, less impressive than automobile repairing, it was more practical.

It should be a source of comfort in innumerable households as well as a contribution to the sense of security of many family physicians to know that

the Home Nursing Courses of the Red Cross are not only continuing but expanding their services.

These courses are divided into two units, one on the care of the sick and one on mother, baby and family care. Each, independent as a unit although complementary to the other, consists of six two-hour lessons. They are taught by qualified graduate nurses. Elementary as they are, they may serve the purpose of turning a willing but ineffective member of the family into one capable of caring for patients who are not critically ill or completely helpless, and for giving adequate attention to mothers and babies. Such service, particularly as it may be augmented by the visiting nurse, can save many hours of expensive hospitalization and in many instances render unnecessary the search, so often fruitless, for a high-priced nurse willing to go into the home. Information regarding the courses may be obtained from any Red Cross chapter.

The paradoxical situation exists today in which the products and the skills of science and industry are virtually beyond the reach of a considerable proportion of householders. Service of any nature has become so dear or so scarce that a return to the days of personal self-reliance is almost inevitable. More and more must the homeowner of today learn through necessity to saw a straight line and to set a pane of glass.

In matters ranging from replacing buttons to patching pants, from putting pans under leaking roofs to conquering the complexities of bed baths, the old adage that God helps those who help themselves is being reaffirmed. The hand-worked sampler may have given way to offset printing, but Home Sweet Home, while still the dearest place on earth, can be made a little less expensive if every member of the family makes some personal contribution!

GRIM REAPER

TRAFFIC deaths in the United States, according to The Travelers Insurance Companies, dropped 1 per cent in 1948. The total, in round figures, was 32,200 as compared with 32,500 in 1947. Personal injuries, however, increased 8 per cent to a total of 1,471,000, the 1947 figure having been 1,365,000.

Pedestrians, apparently, can jump faster, even if no farther

More than a third of the deaths and nearly a quarter of the injuries were attributed to excessive speed, and this has been the important factor in recent years. Like Mr Toad of Toad Hall, too many human beings experience changes in personality when under the influence of intoxicating motion. This applies particularly to the more adventurous, less cautious ages between eighteen and twenty-four, which are responsible for more than their share of both deaths and injuries.

It is difficult to know surely whether American automobile manufacturers are creating or supplying a demand when they continue to produce increasingly speedy and increasingly costly motor cars. Every conservative instinct cries out for the opposite policy, but it appears that the majority of democracy's fellow travelers live literally for the moment only.

MASSACHUSETTS MEDICAL SOCIETY

Presidential Address

Your vote of confidence in me is deeply appreciated. No member of the Massachusetts Medical Society receiving this great honor could possibly fail to be duly impressed. I know that there are many among you more deserving of this recognition than I. Having observed the work of the Society closely for many years and pursuing a careful study of its activities during the past twelve months, I realize the tremendous responsibility you have placed upon me. It is with full awareness of my own inadequacies that I accept this position as your moderator. I assure you that I am fully cognizant of the fact that this is no dictatorship — no one-man show. I earnestly beg of you to give the Society your best effort, and to give me your guidance and counsel throughout the coming year. We must work in close co-operation and in harmony, without selfish interests but with a steadfast purpose for the good of the Society as a whole and for the benefit of humanity.

I suppose every president who has preceded me has believed that his specific term of office came at a critical period. Doubtless many have regarded their terms as offering an unparalleled opportunity for the Society to turn its attention to the problems of the moment. Always there have been emergency measures of one kind or another to be dealt with, and always, as now, the constant desire to advance medical education and improve medical care. This attitude, which was the prime motive in the organization of the Society one hundred and sixty-eight years ago, has never changed. There has been steady progress in the past so that we can well take pride in the quality of medical service now available in this state and in this nation. We cannot accept a complacent attitude concerning these matters. The hope is that never in the history of the Massachusetts Medical Society will there be a smug feeling of satisfaction regarding our accomplishments that will in any way detour us from the straight and narrow road in seeking a higher level

The serious national problems before us are demanding our constant attention. Our educational program is going well, and the people of this country are being awakened to their situation. It is apparent that they are eager for knowledge concerning all matters pertaining to their health and to their rights as citizens. Over 600 organizations in the United States have passed resolutions opposing compulsory health insurance. This is encouraging, and the effort expended appears to have been worth while. We must not allow these favorable reports to lull us into inactivity however. We must learn and dispense the true facts with constant vigilance and without interruption. We have the satisfaction of paying for this program ourselves even though we are also paying through taxation, in part, for the propaganda of our clever opponents.

We shall need to marshal our strongest forces on the national battlefield for some time to come. We have, however, reserves that are available for a continuation of our efforts to advance the art and science of medicine. These are and always have been carried out for the prevention of disease, for the improvement of health and for the relief of the sick.

Your many committees set up to study our various problems and to expedite the responsibilities of the Society have been carefully evaluated. Some whose purposes have been accomplished are recommended for discharge. The personnel of new ones endorsed by you tonight will be announced after due thought and consideration.

You have approved of the recommendation of the Committee on Public Health to appoint a subcommittee for the purpose of developing pilot diagnostic clinics. It is my understanding that this is to be done in co-operation with the various specialty groups already working along these lines, and that such clinics are to be staffed by the medical personnel of the district in which they are established and in already existing community hospitals. The beneficial effects already demonstrated by

the Tuberculosis League, the State Cancer Society, the Committee on Diabetes and the Heart Association are well known to you. If the mechanism of clinics for general examinations can be satisfactorily worked out for all concerned, we shall have made a great forward step. It is requested that those of you who are skeptical of such a venture offer constructive criticism and lend your aid to this endeavor.

American medicine has been severely criticized about the inadequacies of medical care. Much has been said regarding the shortage of doctors. We are told that, in certain localities at least, emergency medical service is difficult to obtain, particularly on week ends and holidays as well as at night. We have also had reverberations that are not to our credit regarding the charges made, in some instances, for professional services rendered. This appears to be a proper time to consider seriously these problems and first of all to find out what the true situation is and to see what needs to be done about it. We realize that such complaints are greatly exaggerated and that an isolated instance may make a bad impression for the Society as a whole. On the other hand it is to our best interests to rectify these errors if they exist.

Without any doubt, a nation-wide survey concerning the health needs of people should be made. It is hoped that a commission set up along the lines of the Hoover Commission will be established to carry out such a study. Since it will be necessary for each state to participate in such a program, it seems that we should be in a better position if we considered looking into our own situation now. It would be necessary to have each district participate in this procedure with the eventual co-ordination of the facts. What we can do about inadequacies, if they exist, will be a matter for future consideration.

I have had the privilege during the past year of attending the majority of the meetings held by your various committees. The sacrifice of time and the tedium of travel do not interfere with the seriousness of purpose that these men display. The Society as a whole and the citizens of the state it serves should be duly grateful for such devoted service. Since there are so many committees already, you may not be willing to support me in the request I make for one more. I hope, however, that you will and that we can start our survey of the availability of adequate medical care in the Commonwealth.

In conclusion, I should like to make a strong appeal to the district presidents. It is obvious to all that there are times when it is impossible for a committee man to attend a stated meeting of his committee. It appears, however, that these

absentees are more apt to be representatives of certain of our districts. I am sure that if the district president would study the situation and more carefully make his appointments we should have a better representation. We want the advice and counsel from all areas and urge that every effort be made to make our society truly representative.

Again, I thank you for your confidence in me and once more ask for your help and counsel, and for your charitable and lenient attitude when my procedures fail to meet your full approval.

ARTHUR W ALLEN

CORRESPONDENCE

MAKE HASTE SLOWLY

To the Editor There is no doubt that most doctors are opposed to President Truman's plan of health insurance. But how many of them failed to vote against the politicians who have undertaken the transformation of our republic into a socialized democracy is of pertinent interest.

As members of a learned profession, we should naturally embrace the conservative. Whatever socialistic changes we may happen to favor we should prefer to have come gradually. We certainly can hardly approve of the rate at which stark socialism has been growing in this country. We are well aware of the waste and inefficiency of the divers mushrooming bureaus, which tend to destroy our individuality and to weaken our souls.

In our next political campaign, may it not be more discreet for us to resist socialism in general as individuals rather than as a group exposing our profession to the charge of selfishness and trade-unionism?

Worcester, Massachusetts

NOTICES

ANNOUNCEMENT

Dr Donald T Chamberlin announces the removal of his office from 422 Beacon Street, Boston, to 1180 Beacon Street, Brookline.

SOUTH END MEDICAL CLUB

A luncheon meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, June 21, at 12 noon. Dr John G Downing will speak on the subject "Local Therapy in Dermatology."

Physicians are cordially invited to attend.

94TH INFANTRY DIVISION LECTURES

The 94th (Bay State) Infantry Division is sponsoring a series of monthly lectures by prominent physicians in their respective specialties. The fifth lecture will be held in the auditorium of Boston University School of Medicine, 80 East Concord Street, Boston, on Tuesday, June 28, at 8 00 p m. Dr Henry M Lemon, Captain, Medical Corps Reserve, will speak on the subject "Recent Advances in the Diagnosis of Malignant Disease."

All interested physicians, whether reserve officers or not, are cordially invited to attend this carefully planned program. Reserve officers will be given one point credit. Excellent films will also be shown during this period.

ESOPHAGEAL ATRESIA WITH TRACHEOESOPHAGEAL FISTULA*

Epidemiologic and Teratologic Implications

THEODORE H. INGALLS, M.D.,¹ AND RICHARD A. PRINDLE, M.D.[†]

BOSTON

THE causative agents of atresia of the esophagus must be primarily genetic or else act during prenatal life, for the defect is present at birth. The evidence bearing on the subject has been brought together here for analysis, and is presented as a stimulus to further research on the problem of etiology.

This report is based on a study of 107 infants with esophageal atresia (102 with associated tracheoesophageal fistula) seen at the Children's Hospital from January, 1936, through 1948 or born at the Boston Lying-in Hospital (6 cases) between 1934 and 1945, inclusive, 90 died during infancy and the autopsy records of 70 were available for study. Also included are 10 histories of pregnancy terminating in the birth of a child with the anomaly. The clinical data were noted in case records of the Children's Medical Center in Boston, or gained by correspondence with attending physicians.

CLINICAL DESCRIPTION

One of the first case reports ever published still remains an illuminating and compact description of the basic symptomatology and pathology. Thomas Gibson¹ described this case as follows:

About November, 1696, I was sent for to see an infant that could not swallow. The child seemed very desirous of food and took what was offered it in a spoon with greediness, but when it went to swallow it, it was like to heave, and what should have gone down, returned by the mouth and nose, and it fell into a struggling convulsive sort of a fit upon it. It was very fleshy and large and was two days old when I was called to it but the next day died.

The parents being willing to have it opened I took two physicians and a surgeon with me. We cut open the thorax and taking out the gullet (with the windpipe, lung etc.) continued to the stomach. Then we made a slit in the stomach and put a pipe in its upper orifice, and blowing, we found the wind had a vent but not by the top of the gullet. Then we carefully slit up the back side of the

gullet from the stomach upwards, and when we had gone a little above half way toward the pharynx we found it hollow no further. Then we began to slit it open from the pharynx downwards and it was hollow till within an inch of the other slit, and in the imperforate part it was narrower than in the hollowed. This isthmus (as it were) did not seem ever to have been hollow, for in the bottom of the upper and the top of the lower cavity there was not the least print of any such thing, but the parts were here as smooth as the bottom of an acorn cup.

Then searching which way the wind had passed when we blew from the stomach upwards, we found an oval hole (half an inch long) on the fore side of the gullet opening into the *aspera arteria* a little above its first division, just below the lower part of the isthmus above mentioned.

This is a perfect description of the commonest type of esophageal atresia, the lower trachea (*aspera arteria*) communicating with the distal esophagus, the proximal portion being atretic.

EPIDEMIOLOGY

Many points of epidemiologic importance were not covered in each of the 107 records reviewed. Therefore in some of the following sections the series total is expressed as less than 107 by reason of excluded records — those not contributing to the specific data sought. To determine the frequency with which esophageal atresia occurs, the obstetric experience at the Boston Lying-in Hospital was studied. In addition the epidemiologic observations of previous investigators²⁻⁴ are combined here for analysis.

Because esophageal atresia is frequently accompanied by tracheoesophageal fistula (84 per cent of 245 cases⁴) the two conditions have nearly always been studied as one entity. For purposes of brevity the term tracheoesophageal fistula is hereafter abbreviated as TEF, and broadly used.

Frequency

Six cases of TEF (1 in a stillborn infant) among 30,497 live births were found in the records of the Boston Lying-in Hospital for the years 1934 to 1945, inclusive. On this basis the frequency of TEF, in the Boston area, may be estimated as at least 0.2 per 1000 live births, the major variable prob-

*From the Department of Epidemiology, Harvard School of Public Health, the Departments of Pediatrics and Pathology, Harvard Medical School, and The Children's Hospital of the Children's Medical Center. This work was aided by a grant from the Perkins Fund.

[†]Assistant professor of epidemiology, Harvard School of Public Health, associate physician, Children's Hospital.
¹Intern, Surgical Service, Presbyterian Hospital, New York City, formerly voluntary assistant with the Department of Epidemiology, Harvard School of Public Health.

ably being the missed case—the stillbirth and asphyxial death in which no autopsy was performed

All observers are agreed that esophageal atresia is a rare condition. Murphy⁵ found 13 cases recorded on death certificates in Philadelphia during a five-year period when 166,451 live births occurred—not quite 1 per 10,000 live births

Case Mortality

Before surgical methods were applied to the treatment of TEF, survival was a rare accident dependent on the existence of a defect so small as to be of no critical consequence. Plass² assembled data relative to the length of life of 120 babies with the anomaly as shown graphically in Figure 1. Five were still-

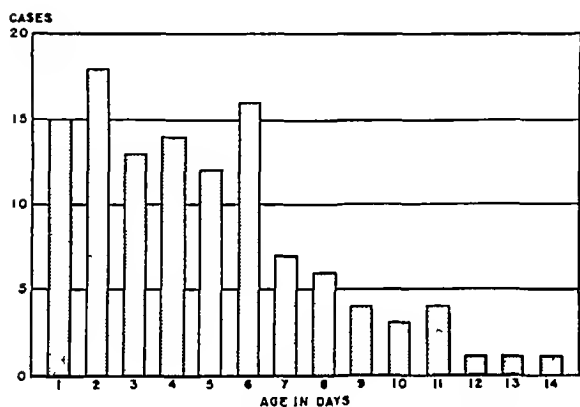

FIGURE 1 Age at Death of 115 Babies with Tracheoesophageal Fistula (Based on Data of Plass²)

born. Mean survival time for the other 115 may be calculated as 4.8 (± 3.5) days.

Swenson⁶ reports that with modern surgery 57 of 113 patients operated upon in the last eight years at the Children's Hospital, Boston, have survived, and only 5 postoperative deaths have occurred in the last 32 patients.

Familial Occurrence

None of the families of the 107 infants in this series was known to include another member with esophageal atresia or TEF either in the same or in a preceding generation.

Among the histories of 136 babies with esophageal atresia, Plass² found none with multiple familial occurrences, but Lanman,⁷ in 1940, reported the condition in a brother and sister, born one year apart. No case of the anomaly recurring as a familial trait in successive generations has been encountered in a comprehensive review of the literature on the subject.

Sex Incidence

There were 62 male infants and 45 females in this series. Added to 25 males and 19 females in

two previously reported series,^{2, 4} a ratio of 87 (57.6 per cent) males to 64 females is obtained. Normal expectancy for Massachusetts, 1939 to 1943, inclusive,⁸ is 52.6 per cent males; the difference is not significant.

Birth Weights

Birth weights recorded for 87 infants with TEF were significantly lower than those of 1000 babies of a general lying-in-hospital population, as shown in Figure 2. The birth weight of 18 of these infants whose mothers had hydramnios averaged 5 pounds, 2 ounces, that of the remaining 69 averaging 6 pounds, 1 ounce.

Relation to Maternal Factors

Age. The ages of 75 mothers who gave birth to a baby with TEF are compared with those of mothers in Massachusetts during the years 1939 to 1943, inclusive (Table 1). The disease appeared more frequently than was to be expected by chance among the progeny of older women, though this trend is far less striking than that for mongolism.⁹

Maternal marital status. Four of 102 mothers (39.2/1000) were unmarried (a fifth, though married, had the baby illegitimately), normal expectancy for the general white population, United States Registration Area, 1939 to 1944, inclusive,⁸ being 18.4/1000.

Previous miscarriages and stillbirths. The birth of 19 of 79 infants with TEF had been preceded by a miscarriage or stillbirth, 12 by one, 4 by two, and 3 by six such pregnancies. The 79 mothers had a total of 277 conceptions, of which 32 (11.6 per cent) ended in spontaneous abortion, as compared with an incidence of 10.6 per cent in 1150 pregnancies over a six-year period studied by Hertig and Livingstone¹⁰ in a private practice at the Boston Lying-in Hospital.

Birth order of the affected child. In 76 records 30.3 per cent of the mothers were found to be primiparas. According to Gates,¹¹ 41.2 per cent of children in Canada are expectedly first-born. Expectancy for this series computed by the Greenwood-Yule rule¹² is given in Table 2. As in mongolism¹³ the risk was found to be greater with each successive pregnancy.

Maternal health. Among 87 case records evidence of chronic maternal disease during pregnancy was encountered 12 times. Hyperemesis gravidarum was noted 3 times, 3 mothers had goiter, 3 had pre-eclampsia, and 3 others had pelvic deformities, 2 had chronic pyelitis, and 1 had tuberculosis with effusion and pneumothorax. The significance of such findings is problematic. Acute illnesses and ante-partum hemorrhages that could be localized in time tended to occur in early pregnancy as shown in Table 3 and 4.

Unusual placental environment. The clinical observation of earlier writers^{2, 14} that a significant

association exists between TEF and maternal hydramnios was confirmed by finding of the condition 30 times among 87 mothers. In addition, abnormalities of the placenta (Table 4) were encountered

anomaly (of the heart). During the tenth pregnancy the mother developed hydramnios, and at term the baby was found to have TEF. A subsequent pregnancy resulted in a living child, a twelfth in a miscarriage in the 6th month, and a thirteenth in a living child.

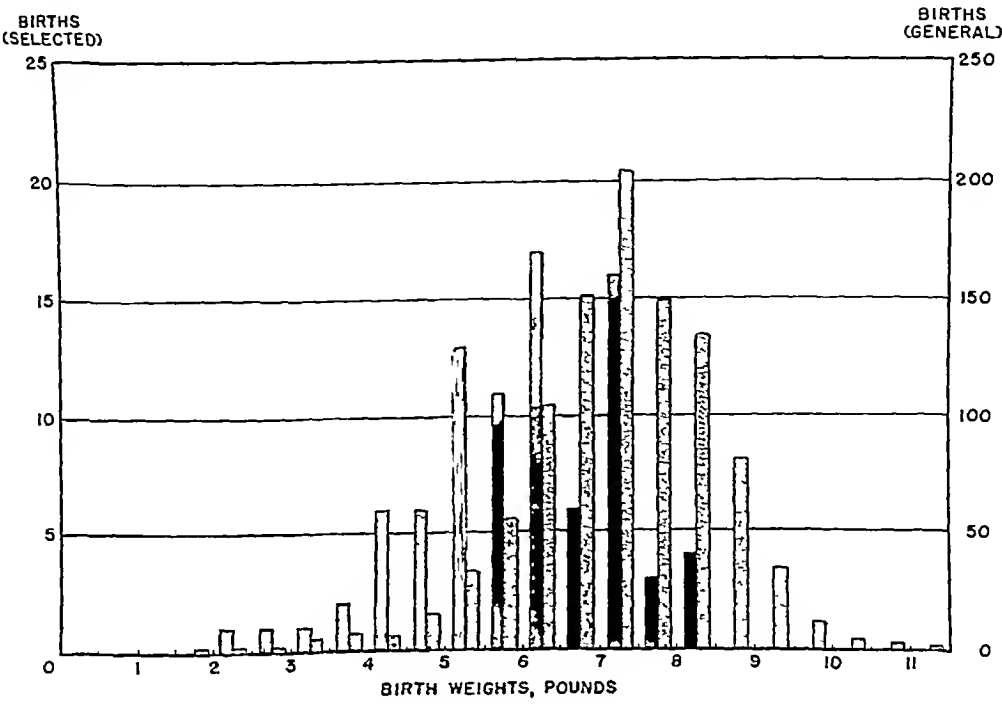

FIGURE 2 Distribution of Birth Weights of 1000 Living Babies of a General (Lying-In) Hospital Population (Stippled Bars) and 87 Living Babies with Tracheoesophageal Fistula (Shaded Bars)

frequently enough to suggest that particular search for similar associations should be made in the future. Four pairs of twins as the product of 107 births

CASE 2 A 20-year-old primipara gave birth to twins after a pregnancy complicated by hydramnios. Excess fluid was observed in the amniotic sac of 1 infant with TEF (who also exhibited mongoloid features) but not in that of its normal fellow.

CASE 3 A 31-year-old woman had had a miscarriage, and irregular periods prior to conception of the baby with

TABLE 1 Maternal Age and Esophageal Atresia *

MATERNAL AGE	BIRTHS	
	INFANTS WITH ESOPHAGEAL ATRESIA	GENERAL POPULATION MASSACHUSETTS (1939-1943)
15-19	2	18 911
20-24	16	99 185
25-29	20	114 040
30-34	19	78 094
35-39	14	37 611
40-44	0	9 909
45-49	1	650

* Among 75 mothers of infants with TEF the mean age was 29.17 yr (standard deviation 6.25). Among 358 400 mothers in the general population the mean age was 28.18 yr (standard deviation 5.85). The difference of the means was 0.99 and the standard deviation of the difference 0.229. The critical ratio was 4.3.

TABLE 2 Birth Order among 76 Infants with Tracheoesophageal Fistula

BIRTH ORDER NO	OBSERVED	EXPECTED %	EXPECTED CT

is four times expectancy, although the finding could be due to chance.

The following brief case reports suggest a relation of TEF to maternal or placental factors.

CASE 1 A 40-year-old woman with a goiter of about 15 years' duration had had nine pregnancies resulting in living children of whom only the seventh is known to have had a congenital

TEF. Pregnancy was characterized by frequent bouts of sore throat with low-grade fever. During the 4th and 5th weeks while traveling by rail during the summer of 1943 she was without drinking water for over 24 hours and developed "heat prostration," with a temperature of 104 to 105°F for 2 days. A third pregnancy, again associated with intermittent

sore throats, ended in the birth of a normal infant. Chronically infected tonsils were subsequently removed with relief of symptoms referable to the throat.

CASE 4 A 38-year-old previously married woman had had two pregnancies resulting in a normal child, and a miscarriage (at 6 weeks) 2 years prior to the birth of a baby with TEF. Hydramnios had been noted as early as the 6th or

Sore throat with heat prostration (Case 3)	1	Fourth to fifth week
Acute upper respiratory infections (Case 9)	1	First trimester again in last trimester

7th month, and a 35-lb. weight gain had been recorded. The placenta was found to have a velamentous insertion of the cord.

CASE 5 A 19-year-old primipara, who had had pyelitis treated with a "sulfa drug" from early pregnancy, delivered an infant with TEF.

CASE 6 A 19-year-old primipara, who had undergone an operation for appendicitis and correction of a "tipped womb" in the 1st month of pregnancy, gave birth to the defective infant.

CASE 7 A 24-year-old mother, whose one previous pregnancy had ended normally, developed pneumonia at the end of the 1st month of her next pregnancy. The infection lasted about 4 weeks and was treated with one of the sulfonamides. At term the baby was found to have TEF.

CASE 8 A 48-year-old woman had had 11 living children and 6 miscarriages. She had been operated upon for a ruptured appendix and for goiter during the 3 years preceding the 18th pregnancy, which was complicated by symptoms of pre-eclampsia and resulted in a defective infant.

CASE 9 The third pregnancy of a 35-year-old woman whose previous 2 children were normal resulted in a baby with TEF. She had suffered from a severe cold and cough during the first and "grippe" during the last trimester of gestation. Subsequently a fourth, normal child was born.

CASE 10* The mother stated that she had taken 30 pills of quinine sulfate (30 gm.) early in the 3rd month of her pregnancy to induce abortion.

The same data that suggest a relation between TEF and an unusual placental environment raise the possibility that the fetal disease is secondary to disturbances of the maternal organism or placenta. As long ago as 1867 Dareste¹⁵ described thermal injuries of the developing hen's egg, which resulted in arrested growth of the enveloping membranes. Such arrests preceded development of ocular, cardiac and other abnormalities of the embryo. Moreover, Mall¹⁶ (1908), after a lifetime investigation of the subject, concluded that faulty placentation — as manifested, for example, in ectopic pregnancy — was

the most important causative factor of acquired maldevelopment in human embryos.

Though placenta previa, placenta accreta, circumvallate placenta and velamentous insertion of the cord were each found only once, the collective finding is provocative. It is reasonable to infer that cases of ante-partum bleeding also represented similar specific placental disorders. The association of placenta previa with ante-partum bleeding and an increased incidence of fetal defects has been established by many investigations.^{5, 17} According to Irving,¹⁸ placenta accreta probably results from an imperfect development of the decidua, and "as in placenta previa the frequent bearing of children seems to be an etiologic factor." Williams¹⁹ describes the velamentous insertion of the cord as occurring "comparatively often (9 twins to 1 single) in twin pregnancy, and in single ovum twins is supposed to play a part in the production of hydramnios." Of 47 cases of circumvallate placenta studied by Hunt and his co-workers,²⁰ 15 were characterized by free or spotty vaginal bleeding or drainage of amniotic fluid before the fourth month of gestation.

Fetal mortality was 50 per cent. The authors believe the placenta becomes cup-shaped because of early degenerative changes along the border that interfere with the blood supply of the fetus. In compensation, villi grow beneath and beyond the fibrous limit of the frondosum and are covered by the chorionic membrane. The heaped-up villi surround the margin of the placenta until increasing tension causes tears, bleeding or seepage of amniotic fluid. Unquestionably, such placental diseases could affect the nutrition or oxygenation of the fetus although it is impossible to estimate the role played by each of the multiple factors possibly involved,²¹ such as anoxia and vitamin deficiencies.²²

EMBRYOLOGY†

Fully 90 per cent of the cases under discussion present a single, definite pattern. There is a per-

†We are indebted to Dr. F. T. Lewis of the Department of Anatomy, Harvard Medical School, for the preparation of this section and permission to use Figure 4.

*Reported by permission of Dr. Johannes Ipsen.

sistent communication between the trachea, near its bifurcation, and the esophagus, and just above this fistula there is a transverse division of the esophagus that is abnormal at any stage of development. An embryologic interpretation of this combination is all that can be attempted here. Apparently, the first case of the anomaly to be reported in a young embryo was found in what Minot²³ regarded as

FIGURE 3 Sagittal Section of a Human Embryo of 181 mm, with atresia of the Esophagus and Tracheoesophageal Fistula. The full length of the blind upper segment of the esophagus is not included, but the portion of the trachea from its fistula to the bronchial bifurcation is shown. The lower segment of the esophagus, in a fusiform dilatation passes out of the section before reaching the diaphragm (Harvard Embryological Collection, Series 1129, Section 171.)

a normal specimen of 181 mm, with an estimated age of forty days. At that stage the abnormality was as fully established as at birth (Fig. 3), and the writer who discovered it sought its explanation in much younger embryos.²⁴

Broman,²⁵ in his monograph on the development of the omental bursa, had reported that in human embryos of 34 mm, the common cleft-like cavity that later becomes vertically subdivided into the ventral trachea and the dorsal esophagus is closely flanked on either side by similar extensions of the peritoneal cavities. These extensions he named significantly the right and left "pneumatoenteric recesses," but without recognizing their possible relation to the fistula and atresia. Any fluid that they contain would be separated from that within

the amnion and within the yolk sac, but at that age it would not be separated from subplacental fluid within the chorion. By connection with the pericardial cavity the contents of the recesses might be subject to pressure changes as the heart filled and emptied. Compression of the foregut between the recesses could divide the esophagus along their dorsal borders and produce the characteristic anomaly under discussion. They change in form rapidly, as the left one disappears and the right gives rise to the superior recess of the omental bursa. In an older embryo, which still measured only 3 mm, Broman has shown the anterior ends of these recesses crossing the esophagus, and yet already below the site of the anomaly.

An embryo of 4 mm, figured as a whole by Bremer,²⁶ who clearly reconstructed most of its

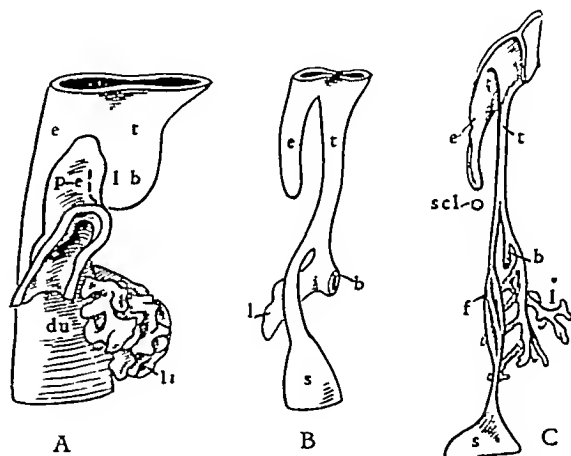

FIGURE 4 Semischematic Lateral Views of Models of Human Embryos, Showing the Development of the Anomaly

A—40-mm normal (?) embryo modeled by F. T. Lewis, B—normal 8-mm stage (Broman²⁵), with the anomaly added, and C—the 181-mm specimen (Fig. 3) modeled by Dr. Albert F. Boretti. In A the esophagus (e) is still undivided from the trachea (t), to which the pyriform lung bud (lb) is appended. P-e demonstrates the right member of the paired pneumatoenteric recesses, undue pressure in which may produce the anomaly. du = duodenum, li = liver. In B, e = upper segment of the esophagus, t = trachea, b = right bronchus, l = left lung, and s = stomach. In C, as in B, with scl, where the anomalous right subclavian artery arises, f = a fusiform dilatation of the lower segment of the esophagus, above the collapsed stomach (s).

organs, is used in Figure 4A to show how the associated atresia and fistula presumably arise. Malformation of the pneumatoenteric recesses, perhaps with undue pressure from their contents, in a brief period toward the close of the first month, could produce it. At 8 mm it should be well established (Fig. 4B). In a misshapen 8-mm thoracopagus Ysander²⁷ has figured mirror-image cases, one in each thorax of the double monster, but since the "bronchi show repeated branching," the specimen is surely stunted. The general relations in

our 18 1-mm specimen are shown in Figure 4C a very similar 19-mm anomaly has been described by Gladstone²⁸

Formerly, the anomalous occlusion of the human esophagus was ascribed to pressure from the neighboring arteries. The dorsal aortas, converging to join behind the intestinal tract, meet at first at too low a level to obstruct the esophagus (a comparison with the description of Congdon²⁹ is of interest). Later, as the lengthening trachea and esophagus push down through their vascular encirclement, the fork formed by the junction of the two dorsal aortas comes to lie in the gap between the upper and lower segments of the anomalous esophagus. There, free from the resistance usually encountered, it has a marked tendency to persist as the "low

origin of the right subclavian artery." Often, it is associated with other anomalies of the arterial trunks, especially of the vertebral arteries (as in the 18 1-mm specimen), which may well affect the general nutrition of the fetus.

Two other consequences of the early transection of the esophagus may be expected—one occasionally and the other frequently. Normally, although the digestive tube is elsewhere pervious throughout, its lumen is temporarily interrupted by epithelial septums in the duodenum, and the anus is imperforate. These occlusions, both of which are present though not yet abnormal in the 18 1-mm specimen, tend to persist. The anal opening should form in embryos of the ninth week (22 to 30 mm), but for some reason still unknown the imperforate condition can persist, and it does so especially in association with an earlier interrupted esophagus.

TERATOLOGY

Coexisting anomalies that are prominent in the syndrome of esophageal atresia and TEF (Table 5) involve entodermal and mesodermal derivatives actively differentiating during the first half of the

second month of embryonic life when the trachea and esophagus are also undergoing rapid development. The significance of such defects may be evaluated in comparison with expected embryologic sequences (Table 6).

Autopsies performed on 70 infants revealed all but 3 to have TEF. Fifty-five had a total of 145 coexisting defects as shown in Table 5, such as dextroaorta, coarctation of the aorta, Meckel's diverticulum, atresia ani, horseshoe kidney and vertebral dysplasias. The findings confirm a previous study of Ipsen and Okkels,³³ who made the reasonable inference that such recurring anomalies originate around the same time as TEF. They reported autopsies of 5 infants with TEF and compared findings of 30 published cases. Over three fourths showed other associated malformations, which the authors called synchronisms, most common were atresia ani and defects in development of the urogenital tubercle, of the hand or of the heart and great vessels. They traced the stages by which the trachea normally develops and differentiates from the esophageal primordium in relation to growth (crown-rump length) of the embryo and discussed the significance of synchronisms as a means of establishing the time of developmental arrest. For example, the coexistence of atresia ani and rectovaginal fistula with TEF was interpreted as a manifestation of synchronous arrests of development about the sixth week of fetal life, before perforation of the anal membrane had taken place and before completion of the partition between the rectum and urogenital sinus.

Although simple arrest of differentiation may serve to explain some of the anomalies listed in Table 6 (such as imperforate anus), additional ablation or dissociation* of the entodermal tissues is necessarily postulated to account for other types (for example, transverse division of the esophagus), which have no counterpart in the normally developing embryo. Proof exists (Figure 3) that TEF may be present as early as the 18 1-mm—or second-month—stage of life, and whatever the mechanisms of pathogenesis, the kinds of anomaly listed in Table 6 suggest the need for clinical study of the events of early pregnancy in the search for causative factors.

DISCUSSION

The nature of both the primary anomaly and the associated defects shows that TEF is determined long before birth, and proof exists that the defect may be present as early as the second month (25-mm to 25 0-mm stage) of embryonic life. Whether the malformation is of genetic or acquired origin is the first problem to be decided.

*This term is defined as follows by Mallory: "The repair of a simple wound in the embryo is always associated with further development of the surrounding parts and in case the process ends in a perfect result normal development still remains with or without regeneration. When however the embryonic tissues become mixed, we have a new condition quite unlike any pathological change found in the adult. This pathological condition I shall term dissociation."

In the combined series of Plass² and ourselves TEF was never recorded as having appeared in successive generations or recurring in the same generations of 243 families. Although the possibility of a genetic origin is not disproved by negative findings, the positive teratologic observations of this study permit the formulation of an alternative hypothesis. On the basis of the morphology of the tracheoesophageal defect and that of associated arrests (Table 5), the syndrome is postulated as acquired during early fetal life — with departure from normal sequences of development (Table 6) occurring at about the fifth or sixth week. If this

embryologic findings on which the inference rests await confirmation by others, the biologic principle postulated has been conclusively established for the better part of a century by investigators in the field of experimental zoology.¹⁵⁻¹⁷ The teratologic findings in the present study imply that TEF also is a function of host development, for all the recurring synchronisms involve entodermal or mesodermal structures differentiating at the fifth or sixth week of embryonic life.

The lacking evidence necessary to prove a hypothesis that TEF and its synchronisms represent departures from normal development during the

*Sources of data: Dodds¹⁸; Keibel¹⁹ and Mall²⁰ and Ayres²¹

interpretation is correct the biologic pattern of TEF is analogous to that previously described for mongolism²⁵ except for basic differences in the stages and organs involved by disease.

The principle that a specific agent acting on the embryo may give rise to widely divergent teratologic manifestations in human beings²⁶ as well as animals^{15-22, 27} has been amply confirmed by observations that numerous cardiac, dental and cerebral synchronisms characterize the syndrome of post-rubella congenital cataract.²⁸ The facts pertinent to mongolism were interpreted to indicate that a specific clinical defect may be engendered by multiple unrelated agents, and that the particular result was a nonspecific function of the stage (eighth week) of embryonic development — not a specific property of the agent. Although the epi-

early part of the second month of embryonic life caused by agents acting through the mother and placenta relates to their specific identification and demonstration of activity at this period. The kinds of agent to be considered and tested as possible causes of prenatal disease of the conceptus have been the subject of study by Ingalls and Gordon.²¹ Agents were grouped in three categories: infectious (rubella, syphilis), chemical (nutritional deficiencies, toxic and metabolic disturbances) and physical (mechanical trauma, structural disease of the uterus). A relatively high incidence of maternal illegitimacy observed in this series, if confirmed, would suggest an occasional connection with attempted abortion — with the agent either mechanical or chemical (quinine in Case 10). A possible connection with spontaneous threatened abortion

(and the agents that produce it) is suggested by the finding that 6 of 29 mothers had ante-partum vaginal bleeding. Five of these 6 bled during the first trimester of pregnancy. That infectious agents are involved in some cases is suggested by the fact that 5 of the 6 cases of acute illness were localized in early pregnancy instead of being scattered throughout. Such evidence is necessarily fragmentary and inconclusive, for TEF occurs rarely, 100 cases such as those assembled here representing the product of about half a million births. The future investigation of such a rare condition lies with the large lying-in hospital. If the mother's prenatal course has not been recorded in satisfactory detail it should be reviewed immediately after the baby is born—before the events of early pregnancy are no longer accessible. We hope that this article will prompt physicians to record and publish further data by which the hypothesis set forward here can be either confirmed or discarded. The question at issue is not merely the etiology of a rare syndrome but also principles underlying cause and prevention of all malformations acquired during prenatal life.²¹ It is likewise increasingly evident that the basic problem is not clinical, embryologic, bacteriologic, biochemical or genetic, but an aggregate of those disciplines, which includes also application of epidemiologic and statistical methods.

SUMMARY

The causative agents of congenital atresia of the esophagus must be primarily genetic or else acquired during prenatal life because the defect is present at birth. A review of the records of 107 infants with the condition revealed no case in which the defect appeared in successive generations or recurred in the same generations of a family, 102 of the infants had an associated tracheoesophageal fistula (TEF) and significant associations were also observed with anomalies of the cardiovascular, gastrointestinal, genitourinary, respiratory and skeletal systems. On the basis of the morphology of the tracheoesophageal defect and that of associated arrests the syndrome is postulated as acquired during early fetal life—with departures from normal sequences of development occurring at about the fifth or sixth week. If this interpretation is correct the biologic pattern of TEF is analogous to that previously described for mongolism except for basic differences in the stages and organs involved by disease.

A study of maternal factors confirmed previous observations of a significant association with hydramnios. Twins were encountered in 4 cases, 6 mothers had ante-partum hemorrhage (5 in the first or second month), and 6 also suffered acute infections or metabolic disturbances in the first trimester of pregnancy.

The hypothesis is made that esophageal atresia, tracheoesophageal fistula and certain commonly

associated defects represent departures from normal development about the fifth or sixth week of embryonic life caused by agents acting through the mother and placenta. This hypothesis should be tested by future observations since the question at issue not only is one of specific etiology but also involves principles underlying the larger phenomenon of acquired congenital malformations.

The heart is moderately enlarged, globular and extremely soft and flabby. It measures 15 by 13 by 6 cm and weighs 450 gm. The epicardial surface is slightly dull and presents a few dark-crimson petechiae, particularly on the posterior surface. There is a moderate amount of subepicardial fat. The myocardium is soft, flabby and light red brown. The endocardium is smooth and glistening. The coronary arteries are soft and patent. There is minimal fusion of the commissures of the cusps of the aortic valve, with slight thickening of the cusps near the commissures. Histologic sections of the heart show the pericardium at points to be covered with fairly old, unorganized fibrin. The underlying pericardium contains diffuse and focal infiltrations of moderate numbers of lymphocytes, histo-

myocardium, cardiovascular collapse (shock and decompensation), pulmonary congestion and edema, slight, marked passive congestion of the liver, spleen, kidneys and intestine, moderate cerebral congestion and edema, bilateral hydrothorax, slight retroperitoneal edema, focal necrosis and fatty degeneration of the liver, dilatation of the stomach, calcified mesenteric lymph node, slight aortic atherosclerosis and old, healed appendectomy scar.

DISCUSSION

In 1948 O'Hallaren and Lemere¹ reported 2323 cases of conditioned-reflex treatment of chronic alcoholism with emetine without a warning of the dangers to the heart. They state that "the treatment is a safe procedure if administered by properly trained personnel." They report 3 deaths, 1 from congestive heart failure and 2 from coronary occlusion. They present no program to prevent such a tragedy as is reported above. The safety of this procedure could be increased if the properly trained personnel is on the alert for signs of cardiac toxicity.

In 1947 Dack and Moloshok² brought the literature up to date but reported no deaths specifically cardiac in origin. Six deaths were described as occurring after a total of only 0.6 gm (10 gr), but the majority followed 1.2 gm (20 gr) or more. The patient in the case reported below received 0.75 gm (12.5 gr) hypodermically, in addition to a small amount by mouth several minutes prior to vomiting.

Electrocardiographic changes after administration have been reported as follows: ventricular fibrillation (in rabbits)³, intraventricular block, inversion of T waves and cardiac arrhythmias (in experimental intoxication in cats)⁴, T-wave depressions in all leads, chiefly in the limb leads in man⁵, a T wave of the coronary type in Lead I, with precordial pain persisting for about an hour in man⁵, auricular fibrillation after six daily injections of 0.02 gm ($\frac{1}{2}$ gr) in man⁶, ventricular tachycardia and finally ventricular fibrillation in rabbits—the minimal intravenous lethal dose in these animals is about 2 mg per pound of body weight⁷, increase in auriculoventricular conduction in man⁸, and premature systoles, both auricular and ventricular but ventricular predominantly in man⁵.

These changes are evidently reversible if the subject survives. Berman and Leake⁷ found no marked permanent changes in tracings after daily intravenous injections approximately equivalent to 1 mg per pound of body weight in rabbits.

Boyd and Scherf⁴ observed that electrocardiographic alterations gradually disappear within forty-five minutes in dogs. However, Klatskin and Friedman⁸ and Dack and Moloshok² reported that in man abnormalities persisted for two months or more.

Though most of the experimental investigation has been in animals, several writers have studied the cardiologic effects of emetine in patients with amebic dysentery treated with the drug. Hardgrove and Smith² studied 72 patients with dysentery in the Canal Zone receiving 0.6 gm of the

FIGURE 2 Section of the Apical Portion of the Right Ventricle (Phloxine and Methylene Blue Stain $\times 133$)

cytes and plasma cells. At points in the pericardium are small foci of extravasated erythrocytes accompanied by a small number of neutrophils. The myocardium throughout is slightly edematous, and large numbers of muscle cells contain minute fat vacuoles. Occasional muscle cells are undergoing ischemic necrosis and are being infiltrated with histiocytes, lymphocytes or rarely by neutrophils. The tissue planes of the myocardium are infiltrated with small numbers of lymphocytes, histiocytes and rare plasma cells and eosinophils, this cellular infiltration is more marked in the right ventricle than in the left (Fig. 2). Sections of the anterior descending coronary artery show a slight intimal fibrosis, with a very small amount of atheromatous debris. Sections of the conduction system are not remarkable.

There is marked acute passive congestion of the liver, spleen, kidneys and intestine. There is moderate cerebral congestion and edema and slight passive congestion and edema. Each pleural cavity contains approximately 400 cc of clear fluid.

The final diagnoses were toxic myocarditis, chronic fibrinous pericarditis with petechiae, chronic myocarditis with focal necrosis, fatty degeneration and edema of the

drug in ten days. They found minor electrocardiographic changes in 52.7 per cent but concluded that with these doses emetine is not dangerous — though electrocardiographic studies should be made before, during and after treatment. The delayed appearance of electrocardiographic abnormalities must be stressed. Dack and Moloshok² described changes often delayed until one or two weeks after discontinuation of the treatment as in the case reported above. They conclude that absence of electrocardiographic changes during treatment does not warrant continuing the drug beyond a certain dose. Klatzkin and Friedman⁸ concluded that toxic manifestations may occur at any level of dosage depending on individual susceptibility to the drug. They found that the drug is cumulative in the myocardium and that rest periods between courses of the drug should therefore be adequate.

Rinehart and Anderson⁹ have studied the effect of emetine on cardiac muscle in rabbits. They found lesions similar to the Aschoff reaction of acute rheumatic fever. The changes were both acute and chronic. The former consisted of interstitial edema of the muscle, and the latter of necrosis of fibers and degenerative swelling. Focal proliferation of interstitial tissue resulted in response to necrosis of muscle fibers. Lymphocytes, plasma cells, eosinophils and polymorphonuclear neutrophils were found in such foci. Nuclei of muscle fibers showed changes in size and distribution of chromatin interpreted as evidence of injury. Small cellular scars about necrotic muscle fibers were found in chronic intoxication. The lesions were of distinctly greater severity in the heart than in skeletal muscle or liver.

There is no known specific treatment for the cardiac damage due to emetine. One is left with symptomatic management and the usual measures for the handling of cardiac failure, which include rest, sedation, plasma, oxygen, salt-free diet and the judicious use of digitalis and quinidine. Prevention is all important. It is suggested that rules be set up to govern all patients being given conditioned-reflex treatment for alcoholism by means of emetine. Experience of others and the lack of cardiac supervision of this case during treatment suggest the following rules as minimum require-

ments: an electrocardiogram should be taken before, during and one or two weeks after treatment; suspected organic heart disease should contraindicate treatment; the total dose of emetine should not exceed 0.6 gm (10 gr) in any one course; at least two months should elapse between courses of treatment in patients who show any electrocardiographic changes during treatment; when significant electrocardiographic changes occur, treatment should be stopped at once, and signs of toxicity — namely, diarrhea, fatigue, dyspnea, muscular tremors or weakness — and dizziness should be carefully watched for daily; and if these develop the heart should be watched with great care (an increasing tachycardia with the patient at rest calls for at least temporary cessation of treatment).

The prognosis in these cases is good if the early signs of cardiac damage have been heeded, since the pathologic process is reversible.

SUMMARY

A death apparently due to the toxic action of emetine on the myocardium is reported. The drug was used in the conditioned-reflex treatment of chronic alcoholism in a healthy young man.

A program designed to prevent a recurrence of such a tragedy is suggested.

A dosage limit of 0.6 gm (10 gr) in any one course should not be exceeded.

MEDICAL CARE FOR THE AMERICAN PEOPLE*

Is Compulsory Health Insurance the Solution?

LELAND S. MCKITTRICK, M.D.†

BROOKLINE, MASSACHUSETTS

MR OSCAR R. EWING, Federal Security Administrator, in his report to the President¹ urges compulsory Government health insurance as an essential part of a long-range program to improve the health of the nation. He points out that the 5,000,000 men rejected by the draft as unfit for the armed forces, the 4,300,000 man years of work lost through bad health and the national loss of \$27,000,000 in national wealth through sickness and partial and total disability are evidences of the bad state of the national health, and that at least 70,000,000 people in this country will have difficulty in providing adequate minimal medical care for themselves and their families.

How do these more prominent reasons for the establishment of a federal insurance program stand up under factual analysis? Is there a real need for such a program? If not, what are the more important reasons for opposing it at this time?

Will Compulsory Health Insurance Improve the Nation's Health?

We, as physicians, recognize the need for continually improving the many factors that contribute to better health. But are we, and is the public, properly informed when we are told that the way to better health is through compulsory health insurance? The following quotation from Simons and Sinai² is most instructive:

When insurance systems are being urged upon governments, one of the strongest arguments offered is that improvement in general health will follow prompt, universal medical care. After the system has been adopted, one of the most amazing things to the outside observer is the almost complete absence in the vast amount of discussion of any reference to public health in relation to insurance. Moreover, not even the most intense partisan of insurance has ever attempted to present any statistical proof that insurance has any effect upon the general death- and sickness-rate. No sort of statistical manipulation has ever been able to show any correlation between the movements of death-rate in insurance and non-insurance countries. They have declined in both at about equal rate, according to sanitary and health measures and other influences, but no difference in any way traceable to insurance can be discovered.

This is the more remarkable since water protection, better housing, tuberculosis care, isolation, immunization, and numerous other health measures do show such traceable results. At no point has a disappointment been greater than in the failure of insurance as a preventive measure.

Contrary to all prediction, the most startling fact about the vital statistics of insurance countries is the steady and

fairly rapid rate of increase in the number of days the average person is sick annually and the continuously increasing duration of such sickness.

The average recorded sickness for each person per year practically doubled in Great Britain and Germany after the installation of Government insurance.² What evidence does Mr. Ewing have to suggest that the effect of Government insurance upon work days lost through sickness will be any different in this country than in others?

We still read that the high percentage of rejections in the military recruitment program has provided striking evidence of the unsatisfactory state of the nation's health and that for this reason a national health insurance program is essential. We, as physicians, know that there are millions of men in this country in good health who will not meet the rigid requirements for combat duty in the armed forces. We know that at least 80 per cent of those rejected could not have been rehabilitated by any medical care known at this time, and we know that of the approximately 20 per cent who might have been influenced by medical care, it would have been necessary for them to have consulted the doctor, to have accepted his recommendation and for the treatment to have been completely successful.³

We, as a profession, are the first to recognize the importance of improved sanitation and other public-health measures. They are fundamental to any program to improve the nation's health, but provision of these is in no way dependent upon or to be confused with a compulsory health insurance program.

Is Compulsory Health Insurance Necessary to Provide Medical Care to Half the Population?

What are the facts concerning the "70,000,000 people" who "will have difficulty in providing adequate minimal care for themselves and their families"?

About 28 per cent of the families of this country had incomes under \$2000 in 1946.⁴ Many of these can pay nothing or only a portion of the cost of a serious illness. The indigent are provided for in the present Administration bill (S 5) only when "equitable reimbursements to the account on behalf of such needy or other individuals have been made, or for which reasonable assurance of such reimbursements has been given, by public agencies of the United States, the several states" and so forth. The same agencies could readily purchase such care

*Presented in part at the Women's City Club, Boston, Massachusetts, February 1, 1949.

†Clinical professor of surgery, Harvard Medical School; surgeon in chief, Palmer Memorial Hospital; visiting surgeon, Massachusetts General Hospital.

from medical care programs already in existence or in process of formation. There is, then, no need for a compulsory Government health insurance agency to assure proper care for this group.

Approximately 50 per cent of our families are now earning between \$2000 and \$5000 a year. Good medical care is and will remain costly. The total expenses associated with a serious illness are too high for most of these families to meet without difficulty at the time of the sickness. However, many own automobiles, television sets and electric refrigerators, and, as a group, they spend a large amount on alcoholic beverages and other things. These are accepted as a part of the American life. But, at the same time, if these families had to pay cash for their automobiles, for their electric refrigerators or for their television or radio sets, many would not be in a position to buy them. Is it fair to say that because they cannot pay cash for these items they cannot afford them? Because this same group cannot pay for a major illness at the time it occurs is it just to assume that they cannot afford to pay for it? Because a mechanism to spread the costs of serious illness must be made available to these families, why must it be done under the costly, inflexible and inefficient machinery of federal Government before thorough exploration of reasonable alternatives?

We need have no great concern for those with incomes over \$5000, although we must also accept the fact that it is customary for most of us to adjust our standards of living pretty well to our incomes, to the end that many families with annual incomes between \$5000 and \$10,000 will have difficulty in paying large medical bills at the time at which they are incurred. Many of these recognize the importance of spreading the cost of illness, and for them such a mechanism would be a convenience though not a necessity.

We have now in this country the highest quality of medical care, the best teaching and the most productive research of any country anywhere. As the science of medicine has improved to make this possible, the costs have increased. We have not developed a satisfactory means of paying these increased costs. Industry was faced with, and successfully met, a similar problem in selling its technical products. Because we as a profession have failed to lead the way, we as a nation are now being urged to make a complete change from a system of medical practice that places emphasis on quality of service and direct responsibility to the individual and his family, to a system that had its concept in the Bismarckian philosophy, which puts emphasis on quantity rather than quality, and which fixes the ultimate responsibility of the physician to the central Government rather than to the patient.

We are unable to find any factual evidence to support the contention that compulsory health insurance will improve the health of the nation. A

sound program to afford medical care to the needy is not dependent upon a Government insurance system. There is urgent need for developing a method of paying for the medical care of the large segment of our population who cannot, or would prefer not to, meet the payment for serious illness when it comes. Does our failure to have provided a mechanism for doing this justify a complete change from any possible solution of this problem on a voluntary basis to a system of compulsion that has been tried in so many foreign countries and has as yet provided no country with the quality of medical care equal to ours?

Does Compulsory Health Insurance Meet the Qualifications of a Good Medical Care Plan?

Without careful analysis it might seem very reasonable for all of us to pay a tax to the federal Government, which, in turn, takes the responsibility of supplying us with and paying for our medical care whenever we need it. It is a very easy matter, in writing, from the platform or over the air, to develop a logical and apparently practical program. It must be remembered, however, that a successful program to provide prepaid medical care is dependent upon certain fundamental principles. The more important of these are free choice of physician, mutual co-operation of the public, those rendering professional services and the administrative agencies, continuing improvement in the quality of care given, the teaching in medical schools and research, and a total cost of the program in keeping with the general economy of the community.

Free choice of physician. Only a short time ago Mr. Ewing⁵ assured the public that from the patient's point of view there was absolutely no difference between the present system and that which the Administration was proposing (compulsory health insurance) except that the Government would pay the bill. If this is true it means that you as a patient can go to any physician you wish at any time, provided he is available and is willing to accept you. At present he is limited in the number of patients he can care for only by the number who seek his services or by the number of working hours in his week. Since those who can are expected to pay for his services, he is spared a multitude of demands upon his time for minor, insignificant complaints. The fact that longer hours mean greater income is an incentive for him to be available to prospective patients throughout most of each twenty-four hours. Mr. Ewing knows and his advisers know that a medical care plan of the magnitude proposed cannot remain solvent if the physician is paid each time he sees a patient. They know that removal of any financial responsibility from the patient will greatly increase the demands upon the physician's time for unimportant complaints. They know that the number of patients a physician will

be permitted to care for must be limited. Every prospective patient in a community must register and have his name on some doctor's panel. The best known doctor in each community will be in the greatest demand, and in fairness to all, those first applying must be accepted until the panel is filled. When his panel is filled, all others desirous of being under his care must select another doctor or will be assigned to one by those responsible for carrying out the plan. Moreover, there will undoubtedly be a certain number of the most successful and older physicians in each area who may well prefer not to become part of such a program. Under compulsory health insurance the free choice of physician cannot be assured to anywhere near the degree that it is available at the present time.

Co-operation. Co-operation between those giving, those receiving and those administering any plan is essential. Co-operation means mutual confidence and mutual respect.

We hear Mr. Ewing⁵ over the public radio say that there will be absolutely no change in the relationship between the patient and the doctor, except that the Government pays the bill, and that the maximum payment that anyone will have to meet is \$1.40 per week. We know that it will be absolutely impossible to maintain, under a Government program, the private practice of medicine as it now exists. We know, and Mr. Ewing should know, that a maximum of \$1.40 per week on the part of the worker, in addition to a like amount from the employer, cannot possibly support the comprehensive program outlined. Such statements are misleading and do not inspire the confidence of an enlightened public or of the medical profession.

Mr. Ewing¹ states that there are 325,000 lives lost in this country each year that we have the knowledge to save. We are not told the basis for these figures, but we read that 117,000 of these lives are lost through heart disease and cancer. We know that the death rate for heart disease among the physicians of the country is higher than it is in the population at large.⁶ We do not believe that lack of medical care is responsible for the greater number of our profession who die each year of this condition, and therefore we fail to understand how a compulsory health insurance program will help save the lives of others who have heart disease. We know that in the state of Massachusetts only 0.3 per cent⁷ of those coming to our cancer clinics have delayed in coming because of economic reasons. We do not know how to make an earlier diagnosis of cancer of the internal organs, many of which give symptoms too late for cure. We do not know how to remove from the patient the fear of reality, dread of an operation and other factors that postpone early diagnosis and treatment of cancer. We are certain that the introduction of a compulsory health insurance program will not alter these factors and therefore

will have little effect upon the death rate from this disease.

We are, therefore, at a loss to understand the basis for Mr. Ewing's figures or how we, as a medical profession, can have confidence in an agency and its administrator that are responsible for giving to the public this kind of information. Nor do we understand how Mr. Ewing can have confidence in and co-operate with a profession of which he says, "Which is the more important? The personal, selfish business and professional values of 180,000 practicing physicians in this country, or the health and well-being of some 68,000,000 of our population?"⁸

Surely there is nothing in the material discussed above to assure the type of mutual confidence and respect that is essential to the smooth running of so important a program.

Quality of care. Whenever compulsory health coverage has been adopted, the emphasis has been on quantity and not on quality of care. This was so in Germany, was and is so in England, is so in New Zealand, and, if adopted, it will be so here. Unethical though it may be, it is common practice to get everything possible from anything as remote from the individual and as wealthy as a government. Seeing too many people with minor transient complaints and nothing wrong dulls the doctor's perception for the early signs of serious disease. History taking and examinations become superficial and a matter of routine.

Good medical care cannot be assured by legislation or by any mechanism of payment. It is personal, individual and intangible, and it depends not only on the training and experience of the physician, upon his scientific accomplishments and facilities but, more than anything else, upon the intensity and thoughtfulness with which he applies these to the individual patient who is sick. A feeling of responsibility directly to the patient and to his family, as well as ethical competition between physicians for the confidence of the public, is the more important factor in assuring each patient the personal care that he wants from his doctor. Any third party coming between the patient and his physician may interfere with this relationship, but when Government assumes complete responsibility for paying the physician and for providing medical care to the patient, such a relationship cannot survive.

It is difficult to foresee just how far reaching the effect of compulsory health insurance might be upon the actual care of the more complicated illnesses. What, if any, effect might it have upon the training of young men in preparation for the actual care of the sick? To those of us who are actively interested in preparing young men for the specialties, it is disturbing to learn that in New Zealand many desirable young doctors are not being attracted to the ranks of the future specialists and

teachers because the "unnaturally swollen rewards of general practice"⁹ can be enjoyed after a much shorter and less arduous period of training than that necessary to qualify them for the all-important responsibilities of the specialists and of teaching.

The cost of compulsory health insurance, as now advocated, is not insurance. There is no calculated risk, no payment of a premium to cover the cost of specific benefits and no contract. It is a form of taxation and should be recognized as such.

Comprehensive medical care is not an insurable risk. The demands upon such a program will be unlimited, indeterminate and uncontrollable. Abuse of the privileges is easy and attractive and therefore likely. The cost will be unpredictable and inordinately high.

In Berlin, the cost for sickness insurance almost doubled per member in the five years between 1925 and 1930,¹⁰ resulting in the "Emergency Decree" of July, 1930. In New Zealand,¹¹ the total income from social-security taxes in 1945-1946 amounted to 15,000,000 pounds, and it was necessary to take 7,000,000 pounds from the consolidated fund to meet the total expenses of the social-security program. One year later, in the budget for 1946-1947, it was expected that 20,000,000 pounds would be received from the social-security taxes, owing to an increase in the rate. But during this year it was anticipated that 18,000,000 pounds, an amount almost equal to the total income of the social-security agency, would be taken from the consolidated fund to meet the expenses. This represents a social-security budget of 38,000,000 pounds, or 60 per cent of the revenue from all sources for the previous year.

In England, three months after the beginning of the present health program, Mr. Bevan made the following statement:

Because things are free is no reason why people should abuse these opportunities. This is a great test of the maturity of the British people in so far as they have all of the resources of the medical profession at their disposal without charge. If any individual abuses the opportunity, he must reckon with a sum total which might add up to one too grievous to carry and for which it would be very difficult to continue to provide.

Two months before the end of the fiscal year the Ministry of Health asked for \$233,820,000 in addition to the original estimate of \$598,700,000 to meet the expenses of the program for the first nine months.¹²

We find little to comfort us in the report of the subcommittee of the Hoover Commission,¹³ which studied the medical care program for which the Government is now responsible. The many evidences of extravagance and waste in money and in manpower are forcefully presented—for example, the Government pays \$20,000 to \$51,000 per bed for construction of hospitals in areas where voluntary hospitals are doing this for \$16,000 per bed. In the New York area, hospitals contemplated

or under construction will approximate a cost of \$105,200,000, which the commission, after careful investigation, finds it difficult to justify. In Houston, Texas, the Veterans Administration is letting bids for a 1000-bed hospital at an estimated cost of \$25,000,000, which the Commission believes would be unnecessary if the unoccupied beds in other governmental hospitals in that area were utilized. Evidence of the effect of the "free" hospital care of a Government-controlled program upon its cost is found in a comparison of the length of stay of patients after similar operations in voluntary and in Government hospitals (Table 1).

Not only is the actual cost for the care of each illness much greater in the Veterans Administration than in voluntary hospitals, but also the longer

TABLE 1 *Average Hospital Stay in Voluntary and Government Hospitals*

OPERATIVE PROCEDURE	AVERAGE HOSPITAL STAY	
	VOLUNTARY GENERAL HOSPITALS	VETERANS ADMINISTRATION HOSPITALS
	days	days
Appendectomy	7.8	14.3
Tonsillectomy	1.4	15.1
Hemorrhoidectomy	6.9	34.5
Herniotomy (inguinal)	10.5	27.0

stay means that more beds are necessary to take care of the same number of patients. More beds means more construction, more personnel, more cost.

The people of this country must realize that there is no such thing as mass production of medical services. Each examination, whether x-ray or clinical study of the patient, is a personal service and one that takes time, and will remain costly if well done, even under the most efficient type of program. Such a program as advocated by Mr. Ewing cannot possibly be paid for by payroll deduction but may necessitate a bottomless pit with limitless money. This can only mean a tax burden out of all proportion to the benefits received.

Free choice of physician, co-operation, continuing improvement in the quality of care given and a total cost in keeping with the local and national economy cannot be expected if compulsory health insurance is adopted. Because we believe these to be essential to a successful medical care plan, we are opposed to compulsory health insurance until sincere and co-ordinated efforts to attain these objectives by other means are made and found wanting.

Off with the Old, on with the New?

There are many who are very close to the problem of bringing good medical care to the American people who believe that a country so large and so diversified as ours may not lend itself to any single

over-all plan, that our objective should be to provide the most widespread distribution of the best available medical care at the lowest cost possible, that our planning should be concentrated upon the end rather than the means, and that only through programs carefully planned and efficiently administered will we later have the experience and background necessary to put into effect that program which most nearly meets these objectives. The adoption of compulsory health insurance would eliminate any possibility of experimentation outside the structure of the compulsory, centrally controlled plan. "Once the whole employed population, wives and children included, is brought within the scope of compulsory sickness insurance, the great majority of doctors, dentists, nurses, and hospitals find themselves engaged in the insurance medical service which squeezes out most of the private practice on the one hand, and most of the medical care heretofore given by public authorities on the other. The next step to a single national medical service is a short one."¹⁵ Are we ready to discard completely the tremendous advances made by non-profit and commercial agencies during the past ten years, or should our efforts be intensified to eliminate the many defects now recognized in present plans with the expectation that from these experiences will evolve a program that will be practical, effective, efficient and available to all who desire it?

Who Shall Be Our Keeper?

When we as a nation become dependent upon the Government for our medical care we come to think of the Government as a paternal agency to which we turn and upon which we become increasingly dependent. Bismarck recognized the importance of this when he put a compulsory health insurance program into effect in 1883. Since that time the adoption of a compulsory, Government-controlled medical care program has been one of the most important early steps in the more complete socialization of a country. This was so in Germany, and it is so in England and in New Zealand. If this is the will of the American people, it should be so here, but we should be remiss if we did not point out the implications of making the Government rather than ourselves responsible for anything so personal and so essential as medical care. We are told that this is not socialized medicine, that it is no different from "buying fire insurance" (Ewing). But when the Government takes complete responsibility for providing a service, when we are compelled to pay a tax to the Government for that service, and when the Government in turn regulates and pays those who provide it, that

service is socialized and is subject to the evils of political control

* * *

There is little evidence that compulsory health insurance will improve the health of the nation or that it is necessary to assure adequate medical care to the American people. There is much to suggest that such a program would gradually lower rather than continue to improve the quality of care received and that its cost would be inordinately high. We therefore oppose its adoption.

We believe that provision of adequate medical care for those unable to obtain it by voluntary prepayment plans or by direct payment is the responsibility of local or state government aided by charitable agencies and, if necessary, by federal grants-in-aid to state programs. Such a program is in no way dependent on compulsory health insurance.¹⁶

We recognize the necessity of spreading the cost of serious illness by the development of more effective voluntary plans than those available today. We believe that the medical care of those able to purchase it through such plans or by direct payment is the responsibility of the individual, not of the Government.¹⁶

The development and perfection of a complete medical care program presents many problems the solution of which is not yet at hand. However, the rapid advances in medical care during the past decade suggest that, given further opportunity and with the complete co-operation of all concerned, — the public, those furnishing the services and the various private and Government agencies, — this country can develop a most effective and efficient medical-care program and still retain the initiative and individual freedom that have made it so great.

PRACTICAL ASPECTS OF BETTER MEDICAL CARE*

ARTHUR W. ALLEN, M.D.

BOSTON

IN A discussion of the plans for better medical service to the people of the United States it seems logical to me that we should take into account what has been accomplished along these lines. We can be justly proud of the fact that the American people have available to them better medical care than the people of any nation in the world. I wish to bring to your attention some of the important factors that have brought this about and to offer some feasible suggestions about how we may still improve this service to humanity.

MEDICAL EDUCATION

The basic principle of good medical care arises in the education of the physician. Thirty-five years ago anyone could choose the medical school that he found the cheapest or nearest to his home or on the basis of the reputation of some of its teachers. Through the efforts of the Council on Medical Education and Hospitals of the American Medical Association, standards were developed for the medical schools of this country. These standards were based on adequate equipment and a proper proportion of full-time teachers. About seventy medical schools in the country meet these requirements, and all but three or four of the ones that could not meet them have ceased to exist. Massachusetts was one of the last states to legislate against the substandard school, with the result that we have a large number of the graduates of such schools practicing in this state. Through the efforts of the graduate teaching program of the Massachusetts Medical Society and the introduction of the so-called Gallupe Plan, which urges hospitals to aid in the education of the physician, these men are becoming well trained, safe and valuable doctors in their communities. A survey is now being made in the eighteen medical districts of the Commonwealth to ascertain the effectiveness of this educational program with the view of expediting the situation as rapidly as possible.

HOSPITALS

Early in the history of the American College of Surgeons it became obvious that the educational background of the surgeon was the hospital in which he received his postgraduate training. On the basis of equipment, laboratories, nursing, records, staff conferences, pathological studies and so forth, standards were set up. A survey of all the hospitals of 100 beds or over in 1922 revealed that less than 13 per cent could fulfill these require-

ments for adequate patient care and adequate resources for the training of the surgeon. By constant effort on the part of the American College of Surgeons 94.6 per cent of these hospitals have now met the standards. If we include the smaller community hospitals down to 25-bed capacity the percentage drops to 90.

THE PUBLIC HEALTH SERVICE

Article II of the Constitution of the American Medical Association states "The objects of the Association are to promote the science and art of medicine and the betterment of public health." The Public Health Service has always had the complete support of the medical profession. The prevention of disease is the first and most important concept of our entire medical care program. I am informed that there are many vacancies in the Public Health Service and that in many communities there are inadequate facilities. To correct these deficiencies we may accomplish our greatest improvement in the program for better medical care of our people.

Smallpox, typhoid fever, malaria, tetanus, scarlet fever and diphtheria took a heavy toll of our forebears. These diseases have been so completely reduced to a minimum that the average medical student may consider himself lucky if he has the opportunity to see a case.

RESEARCH

Through the elevation in standards of medical education and hospital facilities for research many life-saving contributions have been made. Diabetes and pernicious anemia are outstanding in this category. There are hundreds of well trained medical scientists working steadily to discover the cause of cancer, arthritis, multiple sclerosis, arteriosclerosis and many other diseases not yet conquered. The discovery and development of the sulfonamides, penicillin, streptomycin and other antibiotics has lowered the incidence of death from pneumonia, peritonitis, septicemia and other illnesses caused by bacteria to a remarkable level. The better understanding of the chemistry of the body and the methods of bringing about a chemical balance in the tissue fluids has contributed greatly to the safety of surgical procedures particularly. Through research we may hope to reduce the incidence of disease and thereby increase life expectancy.

SPECIAL AGENCIES

Here in Massachusetts we are particularly aware of the many voluntary agencies engaged in special

*Presented at the Women's City Club, Boston, February 1, 1949.
†Consultant in surgery, Massachusetts General Hospital.

fields to care for the victims of various diseases. Our Greater Boston Community Fund has about forty of these on their list for aid. In addition we are cognizant of the March of Dimes for poliomyelitis, the work of the Tuberculosis League, and the national campaigns for heart disease, diabetes and arthritis. The American people are so constituted that they not only recognize their obligation to their fellow men but also feel the satisfaction of service and the joy of giving.

Urban communities have naturally more nearly covered these problems than the rural districts have. It must not be overlooked, however, that such agencies as the Commonwealth Fund, with its direction toward hospital service and medical education, have demonstrated the possibilities along these lines. The Bingham Associates, in conjunction with Tufts College Medical School, have proved the value of their service to rural areas in New England.* The frontier nursing established by Mrs. Breckenridge in the mountains of Kentucky is familiar to most of us here in Boston. There are doubtless many other voluntary organizations functioning in various districts that are less well known to us.

THE PRESENT SITUATION

The results of our present efforts are well illustrated by the report of Dr. Louis I. Dublin,¹ Second vice-president and statistician of the Metropolitan Life Insurance Company, who states

the American people never were healthier than in 1948, and the prospect is for continued improvement in 1949. The 1948 death rate will establish a new low in our country with a figure of slightly below 10 per 1000 population. This unprecedented record was achieved despite changes in our population structure, such as a large increase in the number of infants and a rise in the proportion of old people, both of which tend to increase the total death rate. Mortality rates in 1948 fell at every age period of life. The death rate from many important diseases touched new low levels, tuberculosis outstanding. In 1948 this disease will be down almost to 30 per 100,000, a reduction of about 40 per cent in the last ten years. The death rate from pneumonia was about 10 per cent under the previous low in 1947, owing largely to the ever-increasing use of sulfa drugs and penicillin. Infant and child health have achieved a splendid record, and mortality in infancy and childhood were at record-breaking low levels. Death of mothers in childbirth continued to decline. The mortality registered for chronic diseases of the heart, cancer and diabetes presented a different picture but show little change in the aggregate of the 1947 figure.

A further illustration is furnished by the following quotation:

Out of 1000 live babies born, one-quarter, or 250 babies, were doomed to death before attaining age 24 under the mortality conditions of 1900-02. The comparable age is now 59, with the majority of surviving persons, of course, living a good many years longer. This improvement is nothing short of amazing. Think of it: Three-quarters of the rising generation, the vast bulk of our new citizens, have a minimum longevity expectation now nearly $2\frac{1}{2}$

times greater than was the case a scant half century ago. And this statement does not allow for the further improvements which will be achieved, if present trends continue, during the lifetime of these new citizens.²

THE PROBLEM

The indigent have for many years received good medical care. This is accomplished through various tax-supported measures at the local level and by various philanthropic agencies including the voluntary hospitals. It has been the part played in this type of care by the voluntary hospitals that has resulted in the almost insurmountable deficits with which these institutions are now struggling. With the high tax rates it becomes more difficult for public-minded and generous citizens to meet the needs. The cost of medical care has been more than doubled in the past few years. Wages of all hospital personnel except doctors have been increased, and the hours of work shortened. Although it may be proved statistically that a dollar today will buy what 50 cents would have bought before World War II, it certainly does not work out that way as far as hospital care of patients is concerned. One of the great needs at present is to arrange for some adequate source to cover the actual cost of the care of the indigent patient.

The well-to-do also get adequate medical care. They can afford the physician of their choice and pay the specialist or consultant a regular fee. They can also meet the increased costs of hospital and nursing care.

There is a large percentage of the population who earn enough for the needs of themselves and their families until a major illness intervenes. These people form the backbone of our industry and are the ones who must have a plan whereby they can feel independent and meet the crisis of illness without either resorting to charity, which they abhor, or running into bankruptcy.

A survey prepared for and released by the American Life Convention, American Mutual Alliance, Association of Casualty and Surety Companies, Bureau of Accident and Health Underwriters, Health and Accident Underwriters Conference, Life Insurance Association of America, Life Insurance Conference and the National Fraternal Congress of America shows that more than a third of the nation is protected by some form of voluntary hospital insurance. Voluntary insurance plans for surgical and medical expenses cover approximately 26,000,000 persons. Newer types of protection account for an estimated 9,000,000 persons. Under the benefits for loss of income due to disability, 31,000,000 persons are protected. This represents more than half the employed civilians in the country. The number of persons covered under group insurance policies and under Blue Cross plans is 56 per cent greater than that at the end of 1945 and 241 per cent greater than that at the end of 1941.

*The recently developed Nashoba health center in Townsend, Massachusetts, is an excellent illustration of the voluntary solution to the health problem. This unit, built in co-operation by five surrounding communities, is a matter of local pride, and may well be used as a standard pattern for areas throughout the United States.

The carriers insuring against hospitalization expenses include insurance companies and fraternal societies, with an estimated 21,000,000 covered. Blue Cross Plans account for 28,000,000 persons.

In Massachusetts these insurance plans cover 60 per cent of the population. Blue Cross alone protects 2,000,000 of the 4,500,000 people in this state. Blue Shield in Massachusetts covers 750,000 persons.

The rapid growth of these voluntary plans throughout the nation is evidence that a high percentage of our citizens are self-respecting, independent-minded people. It could well be estimated that these voluntary plans will within a few years take care of the majority. I think we should give this a more adequate trial since the growth of such measures has been so spectacular.

Under these plans Dr. Paul R. Hawley,¹ chief of the Blue Cross and Blue Shield Commission, says

the quality of medical care now being furnished in the United States is highly satisfactory. The quantity of medical care available leaves something to be desired, especially in the matter of more hospital beds and more nurses in every community and more physicians in many rural areas. The cost of good medical care is a matter of concern to many people.

WHAT IS BEING DONE

The Voorhees Subcommittee of the Hoover Commission has pointed out that there is a considerable amount of duplication and overlapping of effort in the Government-controlled medical services. It is heartening to learn that cognizance of this study is already taking effect. Early in January, 1949 the following information was released:

Secretary of Defense Forrestal made public the most detailed list of recommendations yet submitted by the Hawley Board, coincident with the first meeting of the new civilian advisory group which will succeed that board. The report, which Forrestal emphasized, has not yet received his approval, calls for decommissioning of two Army and one Navy general hospital, reductions of three Army general hospitals to station status and of 48 Army station hospitals to dispensaries, joint staffing of military medical installations that are used in common by personnel of Army, Navy and Air Force, joint utilization of specialists and consultants, establishment and joint staffing of specialty centers — tuberculosis and neuropsychiatry, for example. Signers of the 75-page report were Dr. Paul R. Hawley, chairman, Surgeons General Raymond W. Bliss (Army) and Clifford A. Swanson (Navy), Air Surgeon Malcolm C. Grow and Rear Adm. Joel T. Boone, executive secretary of the board.²

We now have more doctors per capita (1.710) than any nation in the world except Jewish Palestine, which is admittedly a temporary situation. It is true that the doctors are not evenly distributed, and there tends to be concentration in cities and in states regarded as having more pleasant climatic conditions. We may find that arrangements can be made to obtain a better distribution and thereby better service to those areas that need it. The statement so often made that we need more doctors requires further study. Perhaps we do, and if so something can be done about it.

That we do have a shortage of nurses seems apparent to all. When we take into consideration that the first graduate nurse, Linda Richards, received her diploma from the New England Hospital for Women and Children in Boston only seventy-five years ago it really seems miraculous that we are as well off as we are. Efforts are being made and plans are in operation to supplement the trained nurse with one of less training to carry much of the load. This major problem in the care of the sick will, I am sure, adjust itself into a much more rational and logical plan of nursing care than we have had in the past.

We have been agreeably impressed with the functioning of the Veterans Administration. Under the guidance of Dr. Hawley and Dr. Magnuson the American veterans receive better medical care than any other group of people. This was brought about by the selection of the staff doctors of Veterans Administration hospitals by so-called dean's committees. Full-time heads of services are well trained men. To help them, there are as many part-time consultants as are needed. These men are from the teaching institutions and bring all the new, tried and tested products of the research laboratories and medical clinics of the community to the veteran. There is no opportunity under such a system to subject these patients to obsolete methods or political rackets.

It is necessary for us to explore completely the medical needs of the nation. Each state must make its own survey. What is lacking in Massachusetts will probably be quite different from the shortcomings in Mississippi. Having done this in a careful manner, we should find ways and means of correcting the deficiencies.

On the basis of the experience of the Veterans Administration, I believe that a health plan for the nation could be evolved that would completely take care of the situation. This must vary according to the needs of the locale. Perhaps the most important problem is public health in a broad sense. This may be interpreted as including diagnostic facilities. In many places the facilities are already available, including existing hospitals both voluntary and Government controlled. In many areas the Veterans Administration hospitals already existing and those in the process of construction could serve. In some areas special diagnostic centers will need to be built. It would be possible in isolated areas for special diagnostic features to utilize mobile units.

These diagnostic centers should be under local and state control and the staff approved by the medical schools or, in states where no medical school exists, by the universities. It should be made possible for any citizen to avail himself of this diagnostic clinic. If he can afford to pay he should do so. If he has hospital insurance this should be taken into account. If he is indigent his services

should be paid for on a prearranged schedule by the community — a part by the local taxpayers, a part by the state and a part by philanthropy, the deficit under such a plan being borne by federal taxation

This, some of us think, would work, and it would assure the best medical service available in the country and would not be hampered by politics. It would cost something, but it would cost a great deal less than any federal-controlled, compulsory scheme that has been suggested, and it would not inter-

fere with the system of free enterprise on which this nation was founded and on which it has grown to be the greatest nation in the world

MEDICAL PROGRESS

PSYCHOSURGERY

MILTON GREENBLATT, M D,* AND PAUL GRAVES MYERSON, M D†

BOSTON

AN EDITORIAL¹ in 1940 referred to "radically wrong," "meddlesome surgery," which was a "violation of the Hippocratic oath." An opposing view was expressed by Fiamberti² "In the present state of affairs, if some are critical about lack of caution in therapy, it is on the other hand deplorable and inexcusable to remain apathetic, with folded hands, content with learned lucubrations upon symptomatologic minutiae or upon psychopathic curiosities, or, even worse, not even doing that." The first opinion is written by a man who fears an indiscriminate cutting of lobes and hemispheres by unconscionable surgeons, and the second by one who is motivated by the depressing picture of the hopeless, deteriorated, backward schizophrenic patient. Strong opinion and emotional bias continue to becloud the issue of psychosurgery.

The earliest psychosurgery is accredited to G Burckhardt, superintendent of a mental hospital in Switzerland, who, in 1890, operated upon the brains of 6 disturbed psychotic patients. There was 1 postoperative death, 1 recovery and at least 2 postoperative convulsive complications. But Burckhardt was impressed with the possibilities of this method.

At the International Neurological Congress held in London in 1935, Fulton and Jacobsen³ reported briefly on behavioral changes that developed in 2 chimpanzees after bilateral ablation of the frontal association areas. Stimulated by this report, Egas Moniz,^{3, 4} in 1936, introduced bilateral prefrontal lobotomy in man.

*Instructor in psychiatry, Harvard Medical School; chief of laboratories and research, Boston Psychopathic Hospital; senior physician, Massachusetts Department of Mental Health; attending specialist, Mental Hygiene Division, Veterans Administration.

†Assistant professor in psychiatry, Tufts College Medical School; instructor in psychiatry, Harvard Medical School; physician-in-charge, Department of Nervous and Mental Diseases, Boston Dispensary; associate in psychiatry, Beth Israel Hospital.

TYPES OF PROCEDURES

Bilateral Lobotomy (Leukotomy)

Moniz and the neurosurgeon Lima first tried injection of alcohol into the frontal association areas and later invented a leukotome, a trocar-like instrument from the end of which a wire loop or a cutting edge could be protruded. Rotation of this loop within the frontal lobes cut cores in the white matter. Moniz made a superior approach on either side, 3.0 cm from the midline, and 1.5 cm anterior to a vertical line passing through the base of the tragus. He advised cutting four to six cores in each frontal lobe located at various subcortical levels. Among the complications encountered were sphincter disturbances, sluggish pupils and anisocoria. He also called attention to transient apathy, loss of initiative and disorientation, and said that there were "no grave repercussions in the part of intelligence or memory." Moniz stated that a third of his patients recovered, a third improved, and a third were not benefited. His best results were in agitated depressions, and his poorest results were in chronic schizophrenia.⁴

The Moniz technic has been modified, wholly or in part, by many surgeons. In America, the first lobotomies for mental disease were done in 1936 by Freeman and Watts, who became the chief proponents of psychosurgery in this part of the world. Their experiences with over 500 lobotomy cases have been summarized in a series of publications,⁵⁻²⁸ including a scholarly and interesting book, based on the first 80 cases, written in 1942.²⁹

Freeman and Watts have used a lateral or temporal approach entering at a point 3 cm behind the outer canthus and 6 cm above the zygoma. A blunt knife is introduced, with proper precautions

against too deep an entry, and the white matter in each frontal lobe is then severed along the coronal plane. Freeman and Watts have emphasized careful localization of the point of entry and adjustment of the plane of section in relation to clinical requirements. Deviation of the plane of section by as little as 5 mm may spell the difference between success and failure.²² Their standard operation has been used in 63 per cent of their cases, a radical or more posteriorly placed section in 37 per cent, and two or more operations in 12 per cent.^{9, 26} More anteriorly placed sections are employed in affective disorders, and more posteriorly placed sections in the schizophrenic disorders. Reoperations are usually done in a more posterior plane. The more anterior the incision, the less alteration in the patient's behavior, and the more posterior the incision, the greater the likelihood of interfering with area 6, with subsequent prolonged incontinence, convulsive seizures or transitory Babinski and grasping reflexes.¹⁵ Although the location of the plane of section is doubtless important, Mettler and Rowland,³⁰ on the basis of post-mortem studies, have pointed out that even when the Freeman and Watts lobotomy point is carefully defined on the skull, there is significant variation in the location at which the leukotome is inserted into the brain.

Yahn^{31, 32} has recently reported on 209 cases, 161 of which were operated on by the Moniz method and 48 by the Freeman and Watts method, but unfortunately for this comparison many of the latter were previously operated on by the Moniz technic. Yahn believed that superior results were not necessarily to be expected from the more extensive cutting in the Freeman and Watts technic. Although his results are not conclusive, the work represents one of the few attempts to compare different procedures in a single clinic.

Another noteworthy modification of the psychosurgical procedures has been developed by McGregor and Crumie³³ in England, where there is considerable enthusiasm for the surgical treatment of serious mental disorders.³⁴ McGregor and Crumie have devised an instrument with a rotating blade that is introduced 3 cm behind the eye and 5 cm above the zygoma and cuts a core 3 cm in diameter in the center of the lobe, in the coronal plane. The Great Britain Board of Control,³⁵ which in 1947 reviewed 1000 cases submitted to psychosurgery in various English centers, stated that there was little uniformity in the neurosurgical method used in that country.

Ström-Olsen and his associates,³⁵ in 1943, used both the Crumie technic and the method of Freeman and Watts, separately and combined, in 30 chronic cases with no hope of recovery by other methods and arrived at the conclusion that the Freeman-Watts procedure should be used in the long-standing psychotic conditions, and the Crumie technic in the less severe cases.

In June, 1937, Lyster³⁶ did the first "open" operation. Approaching each frontal lobe superiorly, he turned a rectangular osteoplastic flap and with the aid of a specially lighted speculum attempted to separate the white fibers under direct vision. Lyster took pains to separate particularly the inferior frontal fibers because they connect frontal lobes with thalamus and hypothalamus—areas that are believed to have an exceptional role in the regulation of emotion and states of tension. Perhaps the chief exponent of the Lyster technic is J. L. Poppen, who with his associates has performed over 500 lobotomies by this method since 1943. Poppen³⁷ has introduced minor modifications of his own but adheres to the principles of superior approach, direct visualization of everything that is done and strict attention to fibers in the inferior or orbital aspects of the frontal lobes. The proponents of the "open" method believe that hemorrhage can be more successfully avoided by this technic, that it is possible to localize more accurately the plane of section in relation to cerebral structures, and to estimate more reliably the percentage of white fibers cut in that plane.^{37, 38} Statistics presented before the International Conference in Psychosurgery in 1948³⁹ indicate that the mortality is higher in the "closed" than in the "open" method. A recent poll of neurosurgeons in this country⁴⁰ reveals a preference here for the open technic, in foreign centers "closed" methods still prevail. No superiority for either procedure has been claimed in relation to postoperative seizures.

Unilateral Lobotomy

At a panel discussion in 1941, Lyster⁴¹ reported that he had done unilateral lobotomies in 4 cases, with good psychiatric results. The change was not so striking as when the operation was done on both sides, but a good unilateral operation might be as good as a partial bilateral operation. Freeman and Watts,²⁹ however, on the basis of their experience, concluded that both lobes must be operated on to obtain good results. Gavle and Neale⁴² and Van Waganen⁴³ also had unsatisfactory results with unilateral lobotomy.

On the other hand, there are data to suggest that unilateral lobotomy cannot be considered therapeutically worthless. Schwarz⁴⁴ performed a therapeutically successful unilateral lobotomy in a patient with a long history of a depressive state that showed a potentiality to remit after electroconvulsive treatment. Meyer and Beck⁴⁵ noted a case that showed considerable clinical improvement after a unilateral leukotomy.

Scarff⁴⁶ reported 10 cases in which ipsilateral, contralateral or bilateral pain was treated by unilateral lobotomy. The results were good in 7 cases. There was suggestive evidence that pain was more successfully relieved if the ipsilateral dominant

lobe were cut than if the contralateral nondominant lobe were cut. Curiously, 2 patients with bilateral pain were relieved by a one-sided operation. The results of the Boston Psychopathic Hospital group⁴⁷⁻⁴⁸ on unilateral lobotomy certainly indicate that further study of this operation for mental disturbances or for chronic pain would be eminently worth while.

Bilateral Orbital Leukotomy

Much thoughtful consideration has been given to avoiding unnecessary sacrifice of brain tissue. Some workers have been particularly impressed with an array of observations that have pointed up the special significance of the inferior or orbital aspects of the frontal lobes in determination of the personality. When Freeman⁴⁹ first experimented with the coring method of Moniz, he observed that "cores in the lower part of the frontal lobes produced a higher incidence of good results than cores placed in the upper part of each frontal lobe." Dax and Radley Smith,⁵⁰⁻⁵² using the McGregor-Crumble leukotome and with a temporally oriented approach, carried out important studies of the comparative effects of leukotomies in various parts of the frontal lobes on separate series of cases. In 1946 they reported the results in patients who had received an "upper section," a "middle section," and a "lower section."⁵¹ In some cases horizontal sections were also made. These authors reported that depressions were most readily relieved by lower sections, aggressiveness of catatonic schizophrenia by an upper incision, and paranoid schizophrenia by a middle and horizontal section. In 1948 before the International Conference of Psychosurgery,⁵² they spoke of the desirability of the use of inferior or orbital sections in passive, apathetic depressions, in which the operation releases hyperactivity, euphoria and extroversion, and of superior or high sections, cutting fibers from areas 9 and 10, in cases with increased psychomotor activity. Additional middle and horizontal sections were used when more extensive leukotomy was desired.

In 1945, Hofstatter, Smolik and Busch⁵³ reported on 30 cases in which they had sectioned only the inferior quadrants bilaterally, using the Freeman and Watts method. They described improvement in 3 cases with affective psychosis, 1 with obsessive-compulsive neurosis, a decrease in somatic complaints in neurasthenia and significant improvement in various types of schizophrenia.

In two recent reports, Reitman⁵⁴⁻⁵⁵ further analyzed the cases operated upon by Radley Smith and stressed that the postoperative adjustment of patients who had received the orbital cut was superior to those with sections located elsewhere. Concerning the orbital cut, patients showing shallow affect, introversion, depersonalization or lack of initiative responded better than those suffering tension, anxiety, restlessness or aggression. Sym-

toms such as euphoria, overactivity and extroversion (often coupled with aggressiveness) were most likely to follow the orbital leukotomy.

Frontal Lobectomy (Unilateral and Bilateral)

Frontal lobectomy, prior to the advent of psychosurgery, was done only for serious disease in the frontal areas — tumors, epileptogenic scars, chronic abscess, meningocerebral adhesions or brain-crushing injuries of the frontal lobes. Prefrontal lobectomy has been extended by Peyton, Noran and Miller⁵⁶ to the treatment of mental illness in the absence of gross intracranial disease. This method was chosen because it allowed direct visualization of the operative field, the plane of section could be determined by visible landmarks, and the field could be inspected against hematoma. Furthermore, cerebral tissue could be removed, weighed and examined microscopically, and no devitalized tissue was left behind. Fourteen cases were reported in February, 1948, including 3 of severe psychoneurosis and 11 of schizophrenia — all with hopeless prognosis and five years or more of hospitalization. One patient died of accidental ligation of the anterior cerebral artery. Sensorial clearing required ten days on the average. Convulsive seizures developed in 4 cases. No patient made a complete recovery, 2 were considered markedly improved, and 9 moderately improved. Psychometric tests were not quoted.

Transorbital Lobotomy (Bilateral)

Fiamberti² (1937) thrust a "trocar" through the orbital plate and then either injected 10 per cent formalin or cut cores in the white matter of the frontal lobes with the Moniz leukotome. Freeman²⁸ determined on cadavers that by this method openings in the orbital plate could be made well behind the frontal sinuses, lateral to the ethmoids and anterior to the attachment of ocular muscles. Openings into the base of the frontal lobes were 3 cm lateral to the longitudinal fissure and 2 cm behind the frontal pole. Fibers in the central portion of the frontal pole were severed anterior to the rostrum and insula. The anesthesia was achieved by two or three electric shocks.

Postoperatively, Freeman²⁸⁻⁵⁷ stated that the patients had little more disturbance than would be attributable to the electric shocks. Fatuous euphoria, bland indifference and purposeless activity, often seen after the standard lobotomy, were not observed, but striking relief from anxiety was experienced by the patients, as with the conventional lobotomy. Complications were observed in only 2 of 10 cases, and incontinence was seldom seen. A third of the schizophrenic patients and half the involutional patients responded favorably to operation combined with electric shock. None of the unfavorable personality defects noted after prefrontal lobotomy were observed after transorbital

lobotomy, therefore, Freeman has suggested considering this operation earlier in the course of serious mental disease

Jones and Shanklin⁵⁵ used the transorbital lobotomy in 41 chronic cases. Worthwhile results (good or fair) were obtained in 80 per cent of the group. There was marked relief of anxiety and inner turmoil. The patients were ambulatory shortly after the anesthesia had worn off. The only significant complications were orbital ecchymosis, enuresis (in 3 cases) and transient unilateral ptosis (in 1 case). The authors recommended transorbital lobotomy in patients refractory to electric-shock treatment for whom a major lobotomy was contraindicated.

Topectomy (Bilateral)

In March, 1948, the Columbia-Greystone Associates⁵⁹ announced that a study was in progress to determine the effects of bilateral removal of areas of frontal cortex upon chronic mental disease. This study was undertaken in an effort to treat patients by means of a relatively small and precise surgical lesion, and to avoid the undesirable personal defects that often accompanied conventional lobotomy. An attempt was made to control the study by simultaneous observation of matched cases in which the patients received sodium amytal and phlebotomy.⁶⁰ An open-bone-flap operative procedure was utilized, and the areas removed included in all cases the medial or parasagittal portion of the superior frontal gyrus, approximately the rostral third of the superior frontal gyrus and an adjacent portion of the middle frontal gyrus. In patients studied less than a year, Lewis⁶¹ reported almost specific reduction in psychotic anxiety, no impairment in intelligence, learning, memory or abstraction, and no deaths, convulsions, persisting incontinence or personality deficits. The percentage of paroles after four months among patients operated on was significantly higher than that among controls. Removal of Broca's area did not lead to aphasia, and removal of the premotor area resulted in no permanent loss of motor function. LeBeau⁶² has done topectomies in 10 cases of uncontrollable agitation. There were 3 postencephalitic cases, 2 manic-depressive cases, and 5 patients suffering from epileptic seizures. LeBeau observed no blunting of the personality or social initiative and no change in convulsive episodes. No deaths occurred in the group. He also removed areas 9, 10 and 46 bilaterally in 8 cases of intractable pain, with therapeutic benefit. LeBeau considers the results of bilateral topectomy as good as those of lobotomy, although the former operation is a major surgical procedure.

Thalamotomy (Bilateral)

A psychosurgical technic that has received considerable professional attention is thalamotomy, as described by Spiegel et al.^{63, 65} By stereo-

toxic methods they made small circumscribed lesions in subcortical areas, with only minimal injury to overlying cerebral structures. In the treatment of psychoses, it was necessary to make at least five lesions in each dorsomedial thalamic nucleus with destruction of approximately a seventh of the nucleus before appreciable results could be obtained. Eight patients were operated upon, with 1 death, and 4 were sufficiently improved to go home. The method can be used in the treatment of unbearable pain by combining lesions of the spinothalamic system in the midbrain with lesions of the dorsomedial nucleus of the thalamus (mesencephalothalamotomy). The procedure was also recommended for treatment of convulsive disorder of subcortical origin.

Cortical Undercutting (Bilateral)

This method was recommended by Scoville⁶⁶ as a substitute for psychosurgery of the ablation type, which generally requires several tedious hours and large cranioplastic bone flaps. Scoville's operation is done in one hour, requires two trephine openings and produces little bleeding. The areas selected have been areas 9 and 10 of Brodmann (because of the success reported by others in ablation or leukotomy of these areas) and the orbital and cingulate areas because of their known influence on the autonomic nervous system and personality of animals. Undercutting of the posterior orbital surface (areas 13 and 47 of Brodmann) has not produced the sham rage and maniacal behavior reported in animal ablations of these areas.

The psychiatric and therapeutic results of this operation are not as yet available.

Bilateral Medial Lobotomy (Bimedial Lobotomy)

In 1945 Smith⁶⁷ showed that the anterior cingulate gyrus when stimulated produced autonomic effects — dilatation of the pupils, piloerection and cardiovascular and respiratory changes. Smith ablated the anterior cingulate gyrus (area 24) in monkeys and observed they became unusually tame and easy to handle, and Ward⁶⁸ noted that the animals lost shyness, fear of man, hostility and "social conscience." Ward suggested that psychotic patients might be benefited by an operation restricted to the cingulate area, a more radical lobotomy being thus avoided.

These considerations among others prompted workers at the Boston Psychopathic Hospital⁶⁹ to observe a series of cases in which the medial aspects of both prefrontal lobes were sectioned in an "open operation," using the superior approach of Lysterly and Poppen. Particular effort was directed toward sectioning of the white matter related to the anterior cingulate gyrus on either side. Thus far the results in 14 cases followed four to six months indicate that the bimедial operation is therapeutically efficacious. Five patients were significantly

improved, 4 of whom were discharged home. Many symptoms characteristic of patients who received a full bilateral lobotomy were also found in patients who received bimedial or unilateral lobotomy — for example, weight gain, increased appetite, outspokenness and reduction in activity level.

Anatomic Considerations

The great variability of lesions produced by psychosurgery has been stressed by Dax et al.,⁵¹ Meyer, Beck and McLardy⁷⁰ and Yakovlev.⁷² The plane of insertion of the leukotome and also the amount of hemorrhage varied considerably in the cases reported by Meyer and his co-workers. In some of their patients who recovered the lesions were surprisingly incomplete and circumscribed, and structures near the midline were not involved. In other cases, either considerable improvement followed unilateral leukotomy, or the damage to one frontal region was negligible. In one case the prefrontal lobes were not involved at all.

McLardy and Meyer⁷¹ indicate from pathological correlations with clinical improvement that no coronal segment is always involved when improvement occurs, although the central segment comes closest to being so. More segments were involved in the improved than in the unimproved group, and greater improvement, as a rule, occurred with the more posterior cuts.

Freeman²⁹ calls attention to degeneration of the medial dorsal nucleus of the thalamus as one of the constant findings in pathological specimens. Projections from the thalamus to the cortex are apparently much stronger than those from the cortex to the thalamus. Damage to the anteromedial nucleus and to the lateral ventral nucleus may also occur.

The pathological studies yielded new data concerning anatomy of the thalamus. They established the fact that in man the central part of the medial dorsal nucleus projects upon the frontal pole, the medial portion on the base, and the lateral portion upon the convexity. Freeman believes that the pathological studies lend support to the hypothesis that the medial dorsal nucleus is the anatomic substrate for emotional experience.

Tracts theoretically divided by a full bilateral prefrontal lobotomy are those connecting the thalamus with the frontal cortex, the prefrontopontine system or Arnold's bundle, the corticostriate tracts, the uncinate fasciculus, the fasciculus cinguli and the long association tracts.

LeGros Clark⁷³ cautions against assuming that the frontal cortex is merely an association area, for the frontal cortex is also an important afferent projection area similar to the visual or auditory cortex. He stresses the intimate two-way connection between the frontal lobes and hypothalamus. The dorsomedial nucleus is essentially a relay station for transmission of impulses originating in the hypo-

thalamus to the frontal lobes, and the anterior nucleus of the thalamus, which projects upon areas 23 and 24, is the terminal station of the mammillary body that receives the afferent tracts from the whole of the hippocampus (fornix system). Areas 23 and 24 (anterior cingulate gyrus) are now thought to have suppressor functions like areas 8, 6 and 4.

Thus, a great portion of the frontal-lobe cortex may be regarded as a projection area, receiving the products of activity of the hypothalamus in the same way that the visual cortex is the projection area for retinal activities.

Theoretical Considerations

In developing the concept of the use of surgery in the treatment of mental disease, Moniz believed that in the abnormal personality, pathologic ideas dominated the patient's mind, becoming fixed by the functional grouping of certain cells in abnormal relations in the frontal areas, and that beneficial results could be wrought only by destroying these morbid constellations.

Freeman, at first, was impressed by the marked reduction of tension in lobotomized patients and particularly the diminution of affect that formerly attached to pathologic ideas. This in turn seemed to be the very basis of the new interest in the outside world and appeared to release energies formerly trapped within the morbid framework. The thalamus was seen as an important emotional center that provided the energy connected with pathologic ideas, and severance of connections between thalamus and frontal cortex was the necessary step to reduce the emotional charge of abnormal ideas or to "bleach" the affect attached to those ideas. According to Freeman, the patient is fundamentally overly concerned with himself, suffers from anxiety and tension as he sees himself in relation to other human beings and to society at large, after the operation self-consciousness is reduced, foresight and insight are diminished, and emotion, which is still present, attaches itself to external happenings rather than to inner experience. Thus, after lobotomy the hallucinated patient may still hear voices but is not bothered by them, and the patient with cancer and fear of death casually admits to pain but is no longer deeply concerned.

Recently, Freeman has stated that foresight and insight are no longer tenable as hypotheses to explain the function of the prefrontal lobes and has focused his emphasis upon consciousness of self in its manifold forms as the primary business of the frontal lobes.

A further hypothesis that has been advanced tries to relate the function of the frontal lobe to the structure of modern dynamic psychology. According to this theory, damage to the prefrontal areas impairs the patient's "ability to perceive threats to his ego-organization." Since his formerly

marked defensive reactions are no longer called into action, he is freed from maladaptive behavior

INDICATIONS AND RESULTS

Lobotomy has generally been considered a procedure of last resort.²³ Consequently, the patients, particularly in the early stages of its use represented hopeless and chronic forms of mental disease, for the most part relegated to custodial care. Some of them were particularly disturbed persons who, because of hyperkinetic syndromes and suicidal or homicidal impulses, were troublesome problems of management to hospital administrators.⁷⁴⁻⁷⁵ The follow-up studies of this material have helped to sharpen the indications somewhat, but large clinics have not departed from the use of the operation as a last resort, doubtless because irreversible brain destruction is implicit in this form of treatment.

Freeman and Watts²⁴ offer the opinion that results of prefrontal lobotomy are slightly better in females, Jews and Negroes. Better results have been reported for mental disease of short duration than for disease of long duration, but, especially in the affective disorders (manic-depressive and involutional psychosis), duration of illness is not so important as clinical picture, degree of tension and so forth. Patients with higher education are likely to make better postoperative adjustments than those with meager educational possibilities.

From the point of view of nosology, lobotomy is first indicated in the affective psychoses (involutional psychosis and manic-depressive psychosis) that have been disabling for long periods and refractory to electric-shock treatment. In manic-depressive psychosis when more than half the patient's lifetime is spent in the hospital, lobotomy should be seriously considered.⁷⁶⁻⁷⁷ The results in the affective disorders have been encouraging, and many who would otherwise have been doomed to untold months of misery have been relieved of their suffering and reclaimed to some degree of useful living.

Data gathered by Walker⁷⁸ from 12 authors indicated that of 150 patients with affective disorders treated by psychosurgery 63 per cent made social recoveries, 19 per cent were markedly improved, 13 per cent showed little or no change, and 3 per cent died. In 250 cases classified as manic-depressive collected by the Great Britain Board of Control,²⁴ 48 per cent of patients were considered recovered and 35 per cent improved. Considering the lack of uniformity in surgical procedures and in methods of appraising results, the similarity of results from various centers is astonishing.¹²⁻¹⁶⁻¹⁷

⁷²⁻⁷⁶ Satisfactory outcome is uniformly reported in a half to three fourths or more of the cases.¹²⁻¹⁶⁻¹⁷

⁷²⁻⁹¹ Lobotomy has not been so successful in schizophrenia as in the conditions mentioned above

Insulin and convulsive-shock therapy are considered therapeutic prerequisites in schizophrenic patients prior to lobotomy provided that a significant possibility of improvement with these therapies exists.⁷⁸ Patients with paranoid and catatonic schizophrenia usually fare better than those with simple or hebephrenic types. The familiar factors that are recognized as favoring a more hopeful outcome—such as good prepsychotic personality adjustment,⁹⁵ sudden onset, a clinical picture featuring turmoil⁷⁴⁻⁹⁶ and depression,⁹⁴ remitting tendency and favorable, if temporary, response to convulsive therapy—also apply in shaping the prognosis of schizophrenic patients after lobotomy.

Walker⁷⁸ collected information from 16 clinics indicating that of 298 schizophrenic patients who received lobotomy 17 per cent made social recoveries, 24 per cent were markedly improved, 59 per cent showed little or no change, and 0.7 per cent died. The results collected by the Great Britain Board of Control²⁴ revealed that of 599 patients 16 per cent recovered and 63 per cent improved. In most series, about a third of the cases of schizophrenia show good results.¹⁵⁻¹⁷⁻³¹⁻³²⁻⁵¹⁻⁵²⁻⁵⁴⁻⁷⁴⁻⁷⁵⁻⁹⁹⁻⁹⁰⁻⁹⁷⁻¹¹⁵ Only Heilbrunn and Hietko¹¹⁶ were disappointed with their results in 11 adult patients with schizophrenia, and Freeman and Watts²⁴ with their results in 11 cases of schizophrenia that had begun early in childhood.

Considerable enthusiasm exists for the use of lobotomy in long-standing obsessive-tension-ruminative states that have been progressively disabling.⁹⁻¹¹⁻¹⁷⁻⁷⁴⁻⁹¹⁻⁹³⁻⁹⁷⁻¹¹⁷⁻¹¹⁸ Of 29 patients with psychoneuroses primarily of this type studied by the Great Britain Board of Control²⁴ 7 per cent recovered and 59 per cent improved.

Thorpe¹¹⁹ and Rizzatti¹²⁰ pointed out the value of lobotomy in severe behavior disorders associated with psychoses of chronic encephalitis.

Lobotomy has been considered contraindicated for constitutional psychopathy associated with cruelty, aggression, irresponsibility²⁴ and antisocial habits.¹²¹⁻¹²³ Alcoholism is not improved by lobotomy and may be made worse.²⁹ Organic deterioration from severe arteriosclerosis, senility, general paresis and so forth has been considered a contraindication by some authors (Frank¹²⁴). Myerson and Myerson⁵⁵ have reported good results in chronic depressive states in patients over sixty years of age, and point out that age in itself does not necessarily contraindicate lobotomy provided the clinical picture is a favorable one.

Freeman and Watts¹⁵⁻¹⁹ noted that some patients who suffered from severe pain coupled with anxiety, depression, gloomy foreboding and fear of death were greatly relieved after lobotomy. When the fear of future disability was allayed, pain was borne with equanimity. The operation has been applied in pain of phantom limb, focal neuralgia, mucous colitis, crippling arthritis, anginoid syn-

improved, 4 of whom were discharged home. Many symptoms characteristic of patients who received a full bilateral lobotomy were also found in patients who received bimedial or unilateral lobotomy — for example, weight gain, increased appetite, outspokenness and reduction in activity level.

Anatomic Considerations

The great variability of lesions produced by psychosurgery has been stressed by Dax et al.,⁵¹⁻⁵² Meyer, Beck and McLardy⁷⁰⁻⁷¹ and Yakovlev.⁷² The plane of insertion of the leukotome and also the amount of hemorrhage varied considerably in the cases reported by Meyer and his co-workers. In some of their patients who recovered the lesions were surprisingly incomplete and circumscribed, and structures near the midline were not involved. In other cases, either considerable improvement followed unilateral leukotomy, or the damage to one frontal region was negligible. In one case the prefrontal lobes were not involved at all.

McLardy and Meyer⁷¹ indicate from pathological correlations with clinical improvement that no coronal segment is always involved when improvement occurs, although the central segment comes closest to being so. More segments were involved in the improved than in the unimproved group, and greater improvement, as a rule, occurred with the more posterior cuts.

Freeman²⁹ calls attention to degeneration of the medial dorsal nucleus of the thalamus as one of the constant findings in pathological specimens. Projections from the thalamus to the cortex are apparently much stronger than those from the cortex to the thalamus. Damage to the anteromedial nucleus and to the lateral ventral nucleus may also occur.

The pathological studies yielded new data concerning anatomy of the thalamus. They established the fact that in man the central part of the medial dorsal nucleus projects upon the frontal pole, the medial portion on the base, and the lateral portion upon the convexity. Freeman believes that the pathological studies lend support to the hypothesis that the medial dorsal nucleus is the anatomic substrate for emotional experience.

Tracts theoretically divided by a full bilateral prefrontal lobotomy are those connecting the thalamus with the frontal cortex, the prefrontopontine system or Arnold's bundle, the corticostriate tracts, the uncinate fasciculus, the fasciculus cinguli and the long association tracts.

LeGros Clark⁷³ cautions against assuming that the frontal cortex is merely an association area, for the frontal cortex is also an important afferent projection area similar to the visual or auditory cortex. He stresses the intimate two-way connection between the frontal lobes and hypothalamus. The dorsomedial nucleus is essentially a relay station for transmission of impulses originating in the hypo-

thalamus to the frontal lobes, and the anterior nucleus of the thalamus, which projects upon areas 23 and 24, is the terminal station of the mammillary body that receives the afferent tracts from the whole of the hippocampus (fornix system). Areas 23 and 24 (anterior cingulate gyrus) are now thought to have suppressor functions like areas 8, 6 and 4.

Thus, a great portion of the frontal-lobe cortex may be regarded as a projection area, receiving the products of activity of the hypothalamus in the same way that the visual cortex is the projection area for retinal activities.

Theoretical Considerations

In developing the concept of the use of surgery in the treatment of mental disease, Moniz believed that in the abnormal personality, pathologic ideas dominated the patient's mind, becoming fixed by the functional grouping of certain cells in abnormal relations in the frontal areas, and that beneficial results could be wrought only by destroying these morbid constellations.

Freeman, at first, was impressed by the marked reduction of tension in lobotomized patients and particularly the diminution of affect that formerly attached to pathologic ideas. This in turn seemed to be the very basis of the new interest in the outside world and appeared to release energies formerly trapped within the morbid framework. The thalamus was seen as an important emotional center that provided the energy connected with pathologic ideas, and severance of connections between thalamus and frontal cortex was the necessary step to reduce the emotional charge of abnormal ideas or to "bleach" the affect attached to those ideas. According to Freeman, the patient is fundamentally overly concerned with himself, suffers from anxiety and tension as he sees himself in relation to other human beings and to society at large, after the operation self-consciousness is reduced, foresight and insight are diminished, and emotion, which is still present, attaches itself to external happenings rather than to inner experience. Thus, after lobotomy the hallucinated patient may still hear voices but is not bothered by them, and the patient with cancer and fear of death casually admits to pain but is no longer deeply concerned.

Recently, Freeman has stated that foresight and insight are no longer tenable as hypotheses to explain the function of the prefrontal lobes and has focused his emphasis upon consciousness of self in its manifold forms as the primary business of the frontal lobes.

A further hypothesis that has been advanced tries to relate the function of the frontal lobe to the structure of modern dynamic psychology. According to this theory, damage to the prefrontal areas impairs the patient's "ability to perceive threats to his ego-organization." Since his formerly

there have casually mentioned that such cases arise, without discussing them in detail.

Relapse Following Improvement

Four cases of relapse are mentioned by Dax and Radler-Smith¹² among 129 patients who received operation 8 of 100 by Parry¹³ and 4 of 100 by Frank.¹⁴ Details are inadequate.

STUDIES

Psychologic Studies

Hunt¹⁵ was the first to study cases of prefrontal lobotomy. Forty selected patients operated on by Freeman and Watts were observed before and three weeks or longer after operation. A large battery of tests being used. Hunt found no evidence that total intelligence was decreased. Speed of performance was slowed, but accuracy improved on the average. There were better attention, fewer peculiar responses and greater tendency toward objectivity. Some patients accomplished more work with less strain and fatigue.

Kisler^{12,13} studied Rorschach tests in 20 cases followed up to one year after lobotomy and found that the differences before and after lobotomy were not substantial. Improvement in performance of the Rorschach test and clinical improvement did not necessarily parallel each other. Organic signs were usually attributable to the psychotic process, and in general it was difficult to separate the psychotic, preoperative personality from the effects of the lobotomy.

Robinson¹⁷ studied 10 selected cases in which the patients received lobotomy against 10 control cases matched for diagnosis and Binet vocabulary score. Many tests were pressed into service. Some aimed specifically at suspected deficit areas. Again no impairment in general intelligence appeared.

Porteus and his colleagues¹⁸⁻²⁰ found insignificant changes in I Q tests (Binet) but marked impairment in the maze test. The maze test is purported to measure planned initiative, foresight, executive ability, capacity to consider several possibilities at once while action is delayed and power to sustain attention.

Babcock¹⁴ carefully studied a case of anxiety neurosis before and after lobotomy, and her results were interesting because her subject lacked the gross psychotic personality disintegration of most of the other patients studied psychometrically. The patient was quicker after lobotomy but made more errors, had a shorter memory span, could not recall as much of what he learned, was slower at perception of new conditions and demonstrated poorer judgment.

Other psychometrists such as Van Waters,¹² Brody¹² and Atwell¹⁴ agree that although personality changes may be grossly apparent, evidence of brain damage due to the lobotomy is not regularly

seen as in many of the supposed postoperative effects on performance may be related primarily to changes in attitude, and that there is often a tendency in the favorable case to recuperate from such losses.

Holstead and Cowan²¹ is significant from the standpoint of the use of standardized brain damage in symptom cases or tests that proved highly differentiating in brain injury, lobectomy and anoxia. Malin²² reports an outstanding exception to the generally negative results of other writers. He used I Q tests. In 7 cases of bilateral frontal lobectomy and 8 of unilateral frontal lobectomy, he found a consistent drop in general intelligence measured by the Bellevue-Wechsler intelligence scale.

In general, it may be said that the psychologic studies have yielded a poor harvest so far as tests of general intelligence or brain damage are concerned. The many strikingly negative results in cases with gross frontal lobe destruction have pointed up the coarseness of the present psychologic instruments used for detecting brain damage. These studies have so far indicated that lobotomy produces much less disruption of psychologic functions than lobectomy does.

Psychologic tests for personality changes have been more fruitful, on the whole, but as yet have brought forth little of definitive value in the realm of measurements of drive, of frustrational response or of social dynamics.

Physiologic Changes after Lobotomy

During the operation, cold climatic extremities often become warm and moist, the blood pressure falls particularly after sectioning of the first quadrant and diffuse perspiration may occur. Nausea and vomiting are also frequently noted as the fibers in the second lobe are cut. Urinary incontinence may be noted directly after lobotomy—a complication most troublesome to nurses. Inadequate control of anal sphincters on the other hand, rarely occurs. Soon after operation many patients show markedly increased appetite and gain in weight. For a few days after lobotomy the patient may be in bed in a drowsy-nergic state usually motionless but capable of brisk arousal by stimuli to which he may even appear hyper-reactive.¹⁵

Everly had one hypertensive patient whose blood pressure fell to normal and remained normal. Freeman had 3 hypertensive patients who showed prolonged lowering of the blood pressure after lobotomy. Chapman and his associates¹⁴ have very carefully studied both normotensive and hypertensive patients before and after lobotomy and have described a lowering of blood pressure, greater in hypertensive than in normotensive persons with a gradual return to preoperative levels within three months. Statistical evaluation failed to reveal a significant difference in preoperative and post-

dromes, tabes, carcinoma,²⁵ and so forth Poppen²⁸ described the case of a hopeless drug addict who was bed ridden, emaciated, and in constant torture because of severe discomfort and pain in the left side of the head along the distribution of the fifth nerve — although it had been divided intracranially. After lobotomy this patient was marvelously improved, and no longer required morphine. Hawkes and Gotten¹²⁵ compared prefrontal lobotomy with cordotomy for relief of intractable pain associated with carcinoma. Cordotomy was followed by extreme weakness, bladder paralysis and often incomplete relief of pain. Lobotomy produced spectacular relief of pain and nullification of anxiety relative to the carcinoma, and, furthermore, no narcotics were required after lobotomy. Lobotomy was considered far superior to cordotomy in the relief of intractable pain.

Scarff¹⁶ has recently tried unilateral lobotomy for relief of pain with notable success. Dynes¹³ ¹²⁶ reported on both bilateral lobotomy and unilateral lobotomy in a series of cases of pain studied at the Lahey Clinic. Relief of suffering was accomplished by this operation. In general, patients with metastatic cancer were more greatly benefited than those who displayed an exaggerated pain response in the presence of long-standing emotional instability. No anxiety, fear or concern over impending death was manifested in cases of cancer. The results appear to establish this procedure as a definitely useful tool in selected cases in the fight against unbearable pain.

Several authors have stressed symptom traits or syndromes that correlate well with eventual outcome. For example, a good deal of emotional tension ("tortured self-concern") is considered a favorable sign. Excitement, resistiveness, stupor, destructiveness and combativeness are favorable in schizophrenia, whereas docility, vagueness and apathy are contraindications.¹⁵ Peters¹⁴⁷ analyzed statistically a large number of preoperative traits and came to the conclusion that a heightened activity level (restlessness, agitation, euphoria, excitement and so forth) was favorable to improved social adjustment after lobotomy. Particularly beneficial results have been claimed for excited psychotic patients with pulmonary tuberculosis, lobotomy apparently provides much needed physical and mental rest.

Taxing clinical judgment is the decision not only whom to lobotomize, but *when* to lobotomize. The operative risk, possible personality deficits and the disadvantages of delay must be weighed against the probabilities of obtaining comfort, more satisfactory social and economic adjustment and a place in the community.

Postoperative Confusion

Freeman and Watts believe that patients showing the best postoperative results are those who

are confused, dull and retarded for several days or weeks after the operation. Confusion following sectioning of the fourth and last quadrant is taken as a sign that a sufficient number of white fibers have been sectioned. Kisker,¹²⁸ Mever⁷⁰ and Petersen,⁹⁸ however, have not found confusion to be a significant element in improvement, whereas Gayle and Fishburn⁹⁷ believe that there is a somewhat better outcome in cases with postoperative confusion and incontinence.

COMPLICATIONS OF LOBOTOMY

Among the physical and neurologic complications of prefrontal lobotomy, Freeman and Watts²⁹ list vomiting, sweating, blood-pressure change, borborygmus, coma, ocular changes, frontal ataxia, staggering, fainting spells, heart changes, intolerance to drugs and hemichorea — as symptoms that do not persist. Symptoms that may persist include increased appetite, masked facies, vesical incontinence, rectal incontinence, convulsions, Babinski sign, aphasia, reflex grasping and hemiplegia. Sphincter disturbances have been mentioned by Ström-Olsen²⁵ and Peyton et al.⁵⁶

Convulsive seizures, a significant operative complication, have been reported from many centers. Stevens and Mosovich¹⁰⁹ reported an incidence of 33 per cent among 30 cases. Peyton et al.,⁵⁶ using bilateral frontal lobectomy, reported 4 cases among 14 patients operated upon, and Watts and Freeman²⁶ an incidence of 12 per cent among 250 cases. At the Boston Psychopathic Hospital the incidence of postoperative seizure complication has been about 10 per cent in 500 cases.¹²⁹ The seizures are usually few in number, however, many seizures and status epilepticus have been observed. The onset varies between days and years after operation, the larger number develop seizures between three months and one year postoperatively.

Grand mal is the principal type of seizure recorded by Greenblatt and Levin¹³⁰; Jacksonian seizures and attacks of rigidity were observed in a few cases only. No petit mal or psychomotor attacks were noted.

Deaths

The reported mortality has ranged from 1 to 4 per cent in the larger series — somewhat higher in "closed" than in "open" operations. Cerebral hemorrhage is the prime cause of death, with meningitis, pneumonia, ligation of the anterior cerebral artery, cardiac failure and anesthetic sensitivity claiming occasional lives.

Deterioration

Perhaps because of the hopeless nature of most cases in which the operation was performed, patients considered worse after lobotomy were indeed rare. Eleven cases were mentioned out of 1000 collected by the Great Britain Board of Control³¹ and 8 out of 618 collected by Zeigler.¹³¹ Other au-

Affectivity Although disabling depression, anxiety, and agitation are relieved, the patients may pay for the relief — in bilateral lobotomy, with a more superficial or shallow affective life.¹⁵⁵ Buoyancy and euphoria may result, particularly from the orbital operation.⁵⁹ In addition, some patients display irritability and aggressiveness, and a sudden flaring up of temper may occur when they are frustrated, with just as sudden cooling down, after the explosion, the patient is usually incapable of keeping alive a grudge.

Sexual Behavior after Lobotomy

Sexual behavior in the majority of cases does not seem to undergo any great alteration, according to Freeman and Watts.¹⁵⁹ Postoperatively, inertia may reduce the tendency toward gratification, on the other hand, the suppression of restraining forces may lead to freer expression along sexual lines. Lack of self-depreciating ideas permits normal appetites to emerge. Thus, the sex adjustment of married partners may sometimes be improved, and in some cases there is a return of sex interest that has been dormant for months or years prior to operation. The attitude toward sex is more objective and matter-of-fact, the patient may be less modest, unabashed or frankly outspoken. Only a few cases of exaggerated sexuality are recorded by Freeman and Watts, and no cases of sexual perversion or socially offensive conduct. Hutton has seen no antisocial or amoral behavior. McKenzie and Proctor,⁹⁰ however, state that 25 per cent of their cases showed "hypersexuality" with return to normal in nine to eighteen months.

Levine and Albert¹⁶⁰ studied 40 co-operative patients who had improved clinically after lobotomy and were functioning in their own homes. In general a decrease in sexual drive and in degree of gratification in sexual experience was noted. The intensity of pleasure accompanying the sexual act was usually less. Interpretation of this phenomenon was difficult in view of the long duration of illness and hospitalization of some of the patients with either abstinence or lack of normal gratification during that period. The dream and fantasy life was apparently impoverished. In a few cases sexual activity was increased, and some patients who had previously been inhibited for long periods became sexually interested. Two patients were excessively demanding after operation, one was an elderly gentleman who weaned his wife because of his abnormal appetite and "staving" power, the other was a young unmarried man who before operation was an inhibited obsessive-compulsive, and who afterward indulged lustily in both sex and drink and boasted of his prowess. Levine and Albert were impressed with the fact that sexual behavior after operation was generally kept well within the patient's moral bounds.

REHABILITATION

Impressed with the hypothesis that after lobotomy there is a new opportunity to crystallize personality organization into a more wholesome pattern, many workers have stressed the importance of proper rehabilitation programs designed to promote the full growth potentialities of each patient after operation. The great difficulty has been selecting programs properly individualized for each patient.

Immaturity, child-like behavior, lack of initiative and procrastination^{9, 10} are traits that have to be dealt with during the rehabilitation period. Suggestibility, lack of emotional restraints, greater interest in environment and less resistance to socializing are traits that favor progress in rehabilitation.⁵⁹ The necessity of beginning the work of readaptation as soon after lobotomizing as possible is emphasized by Whitman,¹⁶¹ Ewald et al.,¹⁶² Farmer¹⁶³ and others. Prolonged convalescence in the hospital, where rehabilitation can be carefully managed, rather than early discharge to an unorganized environment is favored, particularly by the English group of workers (Frankl and Mayer-Gross¹⁶⁴ and Fleming⁵⁹). Early discharge to the family may be attempted only when the relatives are mature with wholesome attitudes toward the patient,^{24, 161, 162} and when adequate supervision can be exercised at all times. Families should be chosen as carefully as patients, according to Watts⁹; Fleming⁵⁹ asserts that rehabilitation and re-education are the most important part of the whole treatment program. Readjustment and reintegration of the lobotomized patient may continue for three to five years. The rehabilitation period is therefore extremely long by any ordinary standards, hence, both long-range and short-range planning programs become a necessity.

During the rehabilitation period electric-shock and insulin-shock therapy may be used with success, even though the patient may have failed to respond to these procedures prior to operation (Whitman¹⁶¹ Fernandes¹⁶⁶ and Schrader and Robinson¹⁶⁷). Schrader and Robinson¹⁶⁷ state that electric shocks given after lobotomy appear to shorten the period of recovery and augment favorable results. Freeman and Watts⁹ used electric-shock therapy after lobotomy, particularly when improvement was followed by relapse.

We are indebted to Charles Atwell, M.A. for his help in preparing the section on psychologic studies and to Mrs. Loretta Smith, librarian of the Boston Psychopathic Hospital, for assistance in compiling the references.

operative blood-pressure levels when sufficient time was allowed for recovery from the traumatic effects of the operation

The cause of the increase in appetite and weight is not thoroughly understood. Some are inclined to attribute the phenomenon wholly or in part to loss of tension, increase in contentment and self-satisfaction—that is, removal of cephalic inhibitions to eating. Improvement of gastrointestinal function has also been invoked to explain the phenomenon, for indigestion, dyspepsia and peptic ulcer are generally relieved postoperatively.

The explanation of the phenomenon of urinary incontinence has received some attention. Generally the wetting is attributed to indifference, apathy and neglect. It is found more commonly in the disorganized, deteriorated patients than in those who are well preserved. Rinkel, Rosen and Levine¹⁵² have made important observations bearing on the mechanism of wetting. They have shown that after lobotomy the bladder is often contracted, and the capacity low.

Members of the Boston Psychopathic research group (Rinkel et al.¹⁵³⁻¹⁵⁵) have attempted to appraise the stability or instability of the autonomic nervous system by response of the adrenergic or cholinergic system to specific stimulation. After operation patients with chronic schizophrenia showed a more pronounced blood-pressure and pulse-pressure rise to intravenous administration of epinephrine than that before operation. The carotid-sinus reflex, too, appeared to be more responsive to stimulation, for cardiac slowing and asystoles were more common after operation than before. The data were taken to indicate that the autonomic nervous system was for a time released from higher control by lobotomy.

After operation the patient is frequently hyper-reactive to many stimuli, often shrinking back from physical contact. Nurses find it difficult to take rectal temperatures, give baths or change head dressings. Removal of sutures is often violently resisted, and a very exaggerated reaction may accompany a venipuncture that was preoperatively accepted as routine. This reaction tends to be worse if the patient is allowed to anticipate the pain or discomfort.

PERSONALITY CHANGES AFTER LOBOTOMY

Is there a lobotomy personality? Earlier in the history of psychosurgery it was feared that lobotomy would reduce the patient to vegetable status, however, experience has taught that although considerable alteration may occur in the individual pattern, the core of the personality remains much the same—usually, to paraphrase Moniz, “there are no grave repercussions” in the part of the personality. Furthermore, the total personality constellation may change to a more wholesome adaptive type in which disorganizing fears, obsessions,

anxieties and even delusions and hallucinations have been mitigated or lost.

Widening experience leads one to a profound respect for the heterogeneity of personality modifications resulting from lobotomy. Quite opposite personality changes may, for example, be affected in patients who before operation presented similar psychoses. In some persons aggression may be allayed by lobotomy, in others, aggression may be released by lobotomy—what transpires apparently depending upon how the frontal association areas served the patient in question.

Changes of personality after lobotomy may be discussed under the following headings:

Drive. This aspect of the personality is usually, but not always, represented as being reduced. Thus, various authors speak of a postlobotomy apathy,^{70 110} laziness,^{156 157} lack of initiative,^{70 52} loss of spontaneity,³⁵ indolence,¹⁰ lethargy, reduction of active reactions to passive ones¹¹¹ and somnolence, particularly in the immediate post-operative period. Ambition and goal-directed enterprise are often wanting, being replaced by contentment with a matter-of-fact, simplified existence.^{156 157} On the other hand, the drive may be taken out of suspicious, hostile and aggressive attitude, the delusional or distorted fantasy life of the patient may be gradually uncharged, or episodes of unbridled violence may be muffled, allowing the patient to be tolerated among his fellows. Some patients, quite contrary to the general run, after lobotomy take up life with renewed vigor and return to challenging occupations with diligence and industry.

Self-concern. Perhaps the most specific functions of the personality attacked by lobotomy are those that relate to anxious self-concern and uneasy self-preoccupations. Tension, agitation, obsessive brooding,⁸³ self-consciousness, shyness,¹²¹ and excessive reserve are reduced. The patient is often less sensitive to criticism, rebuke or scorn.

Outwardly directed behavior and social sense. The patient is usually more accessible, for his energies are no longer so closely tied up with himself. He may turn his attention more toward reality, take notice of external influences and conditions, behave more appropriately in the group, seek out and enjoy others and no longer actively retreat from social intercourse. In his social relations, however, he may lack tact and diplomacy, may be abrupt in manners and speech, speak his mind without concern for the remote possibilities of his actions and make quick decisions without the advantage of deliberation. However, antisocial or amoral behavior has not been a conspicuous problem among lobotomized patients, and behavior is usually well within the bounds of the patient's former moral code.

DIFFERENTIAL DIAGNOSIS

Dr T DUCKETT JONES Since the age of twenty-one this case had been a problem of clear-cut, severe rheumatic heart disease. We have in a large follow-up group a reasonably large number of persons with severe heart disease, all of them with mitral stenosis who are blood spitters. They do not necessarily at the time have any evidence of pulmonary edema or any evidence of pulmonary infarction, but over a period of years at frequent intervals they spit blood. The great majority of them have no evidence of active rheumatic fever. Many of them have been studied both in the hospital and outside with regard to x-ray examination of the chest, white-cell count, sedimentation rate and electrocardiograms. They have always been essentially normal so far as anything indicative of active rheumatic fever is concerned. The actual basis for the blood spitting can be explained much more accurately by Dr Mallory, but I would assume it was on the basis of extensive changes in the pulmonary vessels, which have been mentioned by a number of observers in the past, particularly Parker and Weiss.¹

I am surprised that no mention is made of the left auricle in the x-ray examination, because I think he must have had mitral stenosis. What the two attacks of pneumonia mean, I do not know. Whether it was really lobar pneumonia or pneumococcal infection is questionable. The rheumatic patient, however, does have attacks of pneumonia at times and for some strange reason over a period of years has survived them quite well, even before the days of modern therapy.

Obviously, this man had real mitral stenosis. I do not know what the relation between the so-called grippe and his decreasing cardiac reserve was. I doubt very much if it meant that he had active rheumatic fever, although that is a possibility. The liver was palpable and tender on examination in the Out Patient Department—four years before his final admission, so that he is known to have had failure for a long time.

The calf pain, I think, is possibly the first evidence that this man may have had bacterial endocarditis, and I raise the question immediately whether or not he was having emboli. It is obvious that he was considered as a possible or probable case of bacterial endocarditis at the time of the hospital admission.

"The apical beat was maximal in the sixth interspace, 7 cm. to the left of the midsternal line." I would strongly question that measurement, because it is rather obvious that the patient had a very extensive cardiac hypertrophy and I believe that most sixth-interspace hearts are well out and not 7 cm.

The heart "had an irregular rhythm, with an apical rate of 96 and a radial rate of 80." I think

that indicates that he had definite fibrillation, which shot his rate up on partial digitalization, but I so somewhat doubt this because his previous difficulty was too much digitalis. I assume that the presenting feature of a mitral diastolic murmur had disappeared with the onset of auricular fibrillation, but is customary but not 100 per cent so. There is nothing in the description of the murmurs to indicate aortic as well as mitral disease, but most patients with rheumatic heart disease, with an impulse in the sixth interspace, have some aortic as well as mitral disease. I therefore think that he also had some aortic disease, although the description of the murmurs is not sufficient to make that a definite diagnosis.

The enlargement of the liver is to be expected because he had obvious cardiac failure. The cause of the splenic enlargement will be mentioned later. Both liver and spleen were tender, which might mean that he had splenic infarcts, I am not sure. Engorged livers are usually tender. It is perfectly obvious that whoever examined him was thinking in terms of the leg veins as a possible source of his trouble—a pulmonary infarct that happened a day or two prior to admission.

The blood picture was probably on the side of infection.

I believe it is likely that these urinary findings were of more importance than the ordinary urinary findings that one sees in congestive heart failure—more of that later.

There was some concentration of the nitrogenous products, and, of course, the carbon dioxide was reduced by more than 50 per cent.

The first thing to decide now is whether or not he had bacterial endocarditis superimposed on his rheumatic heart disease. He lived only about five weeks after the tooth extraction, and yet apparently he had been in no very different status in the few months prior to that extraction. In addition, the short duration would make it necessary for the endocarditis to have been an acute process, and the course was not that of acute bacterial endocarditis—that is, a high, striking temperature, usually with chills, and a rapidly progressive septic course. There was no sepsis, no fever, no chills, and no bacteria, which is somewhat against bacterial endocarditis, and the course was short for a subacute process. He had no positive cultures, which is evidence against subacute bacterial endocarditis but does not necessarily rule it out. In addition, he had real mitral stenosis, and it is unusual to have bacterial endocarditis on a severely damaged valve. Of course he may have had mild aortic disease, and the bacterial vegetations may have been placed there. Since no note was made that confirms aortic-valve involvement, and since he did have severe rheumatic heart disease, with real mitral stenosis, and auricular fibrillation, I submit that he did not have bacterial endocarditis.

CASE 35251

PRESENTATION OF CASE

A thirty-nine-year-old Russian-born man, a clerk, entered the hospital because of malaise and low-grade fever.

Twenty-six years before admission, at thirteen years of age, the patient had an attack of rheumatic fever for which he remained in bed for ten days. Twenty years before admission he had another attack of arthritis. He first noted dyspnea on strenuous exertion eighteen years before admission and occasionally he spat bloody material. In that year he had an episode of acute failure after swimming half a mile. Subsequent examination revealed an apical diastolic murmur, and on x-ray study the left ventricle was enlarged. He gradually restricted exercise and was comfortable except for occasional periods of hemoptysis, often, but not always, brought on by exertion. He had pneumonia twice and numerous upper respiratory infections. About nine years before admission while doing only light office work he complained of insomnia that was due mostly to dyspnea. He had a long-drawn-out, rumbling diastolic murmur at the apex, with a presystolic accent transmitted along the sternal border. Six years before admission the patient developed grippe and enteritis and thereafter had progressive muscular weakness that incapacitated him. Severe breathlessness, sometimes in attacks, and insomnia were prominent. The liver was palpable and tender. There was no ankle edema. The diastolic murmur was much louder. An electrocardiogram four years prior to admission showed auricular fibrillation with partial auriculoventricular block and a heart rate of 50. He had been taking digitalis and doses of ammonium chloride for several months. Following readjustment of the dosage of digitalis the muscular weakness disappeared, and the heart rate increased. He was able to work about twenty hours a week with infrequent exceptions from that time until the episode of fever. One month before admission the patient had a tooth extraction. He then developed malaise, anorexia, loose bowels and a temperature varying up to

100.6°F. These symptoms, in addition to marked weakness, persisted until admission. The chronic cough and dyspnea continued. Small amounts of white sputum were raised. In the three days preceding admission he had generalized aches and severe bilateral calf pain. An x-ray film taken outside the hospital the day before admission was said to have shown pulmonary infarction. Four blood cultures taken during the present illness were said to have been negative.

Physical examination showed an orthopneic and mildly cyanotic man breathing at a rate of 36 per minute. The neck veins were prominent. Over the right lower and middle lobes resonance was impaired, and voice and breath sounds were increased. Many crackling rales were present, and expansion on that side was limited. The apical beat was maximal in the sixth interspace 7 cm. to the left of the midsternal line. The heart was enlarged, the border of cardiac dullness extending to the right. It had an irregular rhythm, with an apical rate of 96 and a radial rate of 88. The first sound at the apex was very forceful. There were Grade II apical systolic and diastolic murmurs. The pulmonic second sound was greater than the aortic second sound. The abdomen was distended, and the spleen and liver were palpated 3 and 7 cm. respectively below the costal margins, both were tender. There was moderate edema of the ankles. The calves were tender. Homans's sign was negative.

The temperature was 100.5°F., and the blood pressure 136 systolic, 88 diastolic.

Examination of the blood disclosed a hemoglobin of 15.5 gm. and a white-cell count of 16,700, with 88 per cent neutrophils. The urine had a specific gravity of 1.018 and gave a +++ test for albumin, the sediment contained numerous hyaline and granular casts. An electrocardiogram revealed auricular fibrillation, with a ventricular rate of 110 to 120. There was moderate right-axis deviation, the ST segment sagged in Leads 2 and 3. A blood culture was negative. Injection of penicillin was started on the first day. The superficial femoral veins were ligated on the second hospital day. No clot was found. Over the course of several days there was a steady increase in the severity of the patient's illness. He became more cyanotic, the heart rate increased despite continued digitalis, and the pulsations became weaker. On the third hospital day the nonprotein nitrogen was 52 mg. per 100 cc. The temperature returned to normal. Slight jaundice appeared. By the seventh hospital day he was weak and restless. The icterus increased. The nonprotein nitrogen was 106 mg. per 100 cc., and the carbon dioxide 13.1 milliequiv. per liter. During the last twenty-four hours there was no urine output. The radial pulse and the blood pressure were unobtainable. The patient died on the eighth hospital day after being in coma twenty-four hours.

nature of the acute terminal episode. It was not glomerulonephritis. The kidneys showed only relatively mild tubular degeneration which I think can be adequately explained as secondary to the other findings.

The surprise of the autopsy was provided by the lungs. Both lower lobes and the middle lobe of the right were very firm and heavy and cut with the consistency of leather. Even the two upper lobes were distinctly fibrotic. We were still further surprised when the microscopical sections came through. This photomicrograph (Fig 1) shows one of the medium-sized pulmonary arteries. The lumen is almost completely occluded by thrombus. The intima has been completely destroyed and appears as a black in the picture. Around the outside of the artery is an inflammatory infiltration consisting largely of lymphocytes. The small branches

FIGURE 1

of the artery show the same picture: complete necrosis of the media, periarterial inflammation and thrombosis. The second slide (Fig 2) is an example of the fibrotic pulmonary tissue and could have been taken from any one of the three lobes. The lumens of the alveoli are lined with apparent epithelium. The alveolar walls are five to ten times as thick as normal, and the respiratory function must have been reduced by 75 per cent. The puzzling picture is that the pulmonary fibrosis

is old, whereas the arterial changes are for the most part quite recent. There are a certain number of vessels scattered throughout the lung that show arterial changes. None of them impressed me as being more than a few months' duration. In contrast, the diffuse fibrosis is apparently a process of several years' duration tracing back, I should think, to one of the episodes of pneumonia. I would inter-

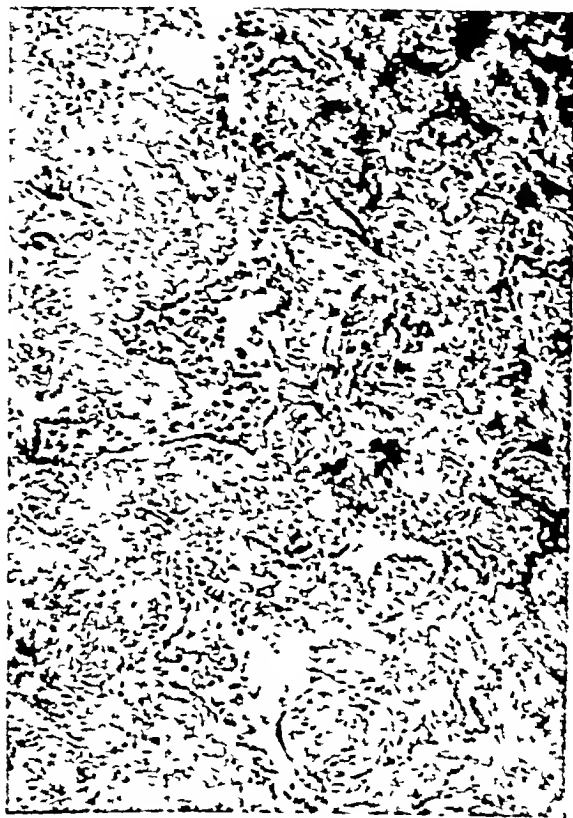

FIGURE 2.

pret them as organized pneumonia or pneumonitis. Another possibility is a healed interstitial pneumonia.

What are we going to call this? What are the arterial lesions? The histologic appearance of the individual lesion is essentially that seen in so-called periarteritis nodosa. On the other hand, many sections from all other organs in the body completely fail to show similar lesions. The vascular process was entirely restricted to the lung. The heart showed only completely healed endocarditis of the valves. There was no trace of activity in the myocardium. We have gradually become conscious in the last few years that periarteritis nodosa, so called, is not a specific disease but is simply a reaction pattern that can develop from a variety of etiologies. This case presents lesions anatomically entirely similar to periarthritis nodosa but limited to one

We have a great many things to explain on some other basis. What was the mechanism of the cardiac failure? Did he have sufficiently severe rheumatic heart disease to fail without any additional factor? We know that this occurs in adults. He had had failure off and on for eighteen years, so that I assume he had enough rheumatic heart disease to fail without very much in the way of active rheumatic fever. Also, I believe that he had kidney changes sufficient to cause some additional burden to the circulation. A good many patients with acute nephritis have heart failure, so that from the evidence it is possible that the nephritis had more effect on the terminal episode than actual rheumatic fever.

Did he have nephritis? He had retention of proteins. He also had jaundice. Do we have to make two diagnoses? Since rheumatic fever and glomerulonephritis can occur together and since they both have the same background of streptococcal infection, I am willing to believe that this man did have nephritis at the end, and that it played a definite role in his picture. I do not believe that bacterial endocarditis could be responsible for his nephritic picture. At least the patients that I have seen who died in uremia with bacterial endocarditis did so only after a long drawn-out illness.

We also have to explain the pulmonary picture. I suppose we should have looked at the x-ray films. We will come to them in a few minutes. I do not believe that we have to predicate the presence of thrombophlebitis in the legs to account for the pulmonary picture. Patients with failing rheumatic hearts often have pulmonary infarcts, but they can develop on the basis of disease in the pulmonary arteries rather than on the basis of embolism from the periphery of the body.

Did he have active rheumatic fever? Tooth extraction is known to stir up active rheumatic fever at times, and he did have a low-grade fever. He had an elevated white-cell count and had had at least two or three frank bouts of active rheumatic fever. If one exhaustively sectioned the heart muscle one might find Aschoff bodies or evidence of active rheumatic fever. However, it seems more likely that the additional nephritic burden, which I believe was present here, was sufficient to account for failure without an appreciable degree of active rheumatic fever. So I should like to guess that this man, who had severe rheumatic heart disease and mitral stenosis, also had glomerulonephritis, and that the severity of the rheumatic heart disease and the additional nephritic burden was sufficient to cause the entire syndrome that ended fatally.

Perhaps we should see the x-ray films.

DR JAMES R. LINGLEY: The heart shadow is grossly enlarged even though the film was taken with a portable apparatus at close distance. There is prominence to the right of the spine and marked prominence to the left in the region of the left

auricle. The pulmonary artery is enlarged, and there is some enlargement of the vessels throughout both lungs. In the left side there is a small quantity of fluid along the axillary border. On the right side there is a large, sharply defined shadow at the base, which in the lateral view is in the mid-chest, in the anterior portion of the lobe, and is consistent with infarct.

DR WALTER BAUER: Are we justified in making a diagnosis of glomerulonephritis without the presence of red cells in the urine?

DR JONES: We have only one analysis but he may have had red cells at another time.

DR BAUER: Jaundice occurs with pulmonary infarction, with congestive failure, perhaps the slight jaundice could be accounted for on that basis.

DR JONES: It has always been surprising to me that one does not get more jaundice in terminal rheumatic heart disease because the amount of liver change is tremendous.

DR BAUER: You would not be satisfied to say that the renal findings contributed by the laboratory studies could be adequately explained on the basis of congestive failure, phlebitis and pulmonary infarction.

DR JONES: I do not believe that as a rule the rheumatic patient develops uremia as a simple consequence of failure.

DR CHESTER M. JONES: In a few young persons we have seen definite jaundice without pulmonary infarction but with marked changes in the liver.

DR T. DUCKETT JONES: There have been three or four such cases. We have never been able to explain them other than on the basis of rheumatic fever causing liver change.

CLINICAL DIAGNOSES

Rheumatic heart disease, with mitral stenosis
Auricular fibrillation and congestive failure
Pulmonary infarction
Pneumonia

DR JONES'S DIAGNOSES

Rheumatic heart disease, with mitral stenosis
Glomerulonephritis
Pulmonary infarction

ANATOMICAL DIAGNOSES

Rheumatic heart disease, with mitral and aortic stenosis
Periarteritis nodosa of lungs
Organized pneumonitis
Hepatic cirrhosis

PATHOLOGICAL DISCUSSION

DR TRACY B. MALLORY: Autopsy showed, as Dr Jones predicted, very severe rheumatic heart disease. The mitral valve was reduced to a narrow slit, and the aortic valve was markedly stenotic. As he pointed out, the real question in the case was the

Examination of the urine was negative. The white-cell count was 23,850, with 87 per cent neutrophils, 3 per cent lymphocytes, 2 per cent monocytes, 1 per cent basophils and 7 per cent young forms. The granulocytes showed a shift to the right. The red-cell count was 8,260,000, and the hemoglobin was 18.5 gm per 100 cc, with a hematocrit of 76 per cent. The red cells demonstrated considerable variation in size and shape with some achromia, many cells showing polychromatophilia. The reticulocyte count was 7 per cent, with occasional normoblasts. The platelets were diminished. The sedimentation rate was 0. The bleeding time was 1.5 minutes and the clotting time 11 minutes. The prothrombin time was 5 per cent of normal. The plasma fibrinogen was 0.25 gm per 100 cc. A stool was soft brown and guaiac negative. The nonprotein nitrogen was 34 mg, and the total protein 6.2 gm per 100 cc, with an albumin-globulin ratio of 2.5, the serum calcium was 8 mg, the phosphorus 3.5 mg, and the alkaline phosphatase 5.9 units per 100 cc. The serum chloride was 102 milliequiv per liter. The van den Bergh reaction was 1.0 mg per 100 cc direct and 1.4 mg indirect. The cephalin-flocculation test was 1+ in forty-eight hours. The thymol flocculation test was negative. The thymol turbidity was 4.0 units. The bromsulfalein test showed 3 per cent retention of the dye in forty-five minutes. An electrocardiogram was defined as a normal tracing. The basal metabolic rates on two occasions were +69 and +59 per cent.

X-ray examination of the chest revealed some prominence of the cardiac shadow in the region of the left ventricle, with an elongated tortuous and partially calcified aorta. The lung fields were bright, with generalized prominence of the pulmonary markings. A plain film of the abdomen showed generalized decalcification of long structures, with collapse of a number of the ureteral segments. A large soft-tissue mass filled the left side of the abdomen and pelvis, with several flecked areas of calcification in the left pelvis. A dense linear streak of calcification in the left pelvis was thought to represent a calcified thrombus in the left iliac and femoral veins. Excretory urograms showed moderate embarrassment to drainage bilaterally but demonstrated no definite relation between the upper urinary tract and the abdominal mass. A barium enema revealed downward displacement of the major part of the colon by an extrinsic mass, but no intrinsic lesion was seen.

The patient was afebrile throughout the course of study in the hospital. On the seventh hospital day a sternal-bone-marrow aspiration was performed and reported as showing a myeloid-erythroid ratio of 9:1, with a marked shift of myeloid maturation to the right. No blast forms were seen, and there were rare promyelocytes. Megakaryocytes were plentiful. No plasma cells were seen. On the

fourteenth day a sternal-marrow biopsy was performed and marrow imprints were reported to show a myeloid-erythroid ratio of 6:1, with normal cells and increased megakaryocytes. On the following day the patient developed a painful subpectoral hematoma in the region of the biopsy site. Subsequently she complained of mild perspiration and chill sensations, with pleuritic pain over the right lower chest posterolaterally. There was no cough or hemoptysis, but there was slight tenderness in the left calf and thigh. On the seventeenth hospital day while elevating her arms for an x-ray examination of the chest, she experienced sudden pain in the left anterior chest and subsequently noticed rather rapid increase in size of the hematoma with extension over the chest and posteriorly. Subsequently she developed rather severe hypertension and a feeble pulse, with a radial rate of 130. Intravenous injection of protamine and intramuscular administration of vitamin K were given in addition to fluids intravenously and sedation. On the following day, the subpectoral hematoma was evacuated under local anesthesia. Postoperatively she had a pulse rate of 150, but the blood pressure was not obtainable. She was drowsy but responsive and coherent. There was no cyanosis.

On the nineteenth hospital day she developed dyspnea of progressive severity and abdominal distention with ileus and died quietly and abruptly the same evening.

DIFFERENTIAL DIAGNOSIS

DR. JOSEPH C. AUB: The description of the mass is important because the description of a tumor low in the abdomen suggests a tumor in the ovary, but there was no history of recent vaginal bleeding.

The chest findings mean nothing but congestion of the lungs, they do not imply fluid.

There are only three reasons for the slowed prothrombin time: a vitamin K deficiency, liver damage or the eating of red clover. There is no history of the eating of red clover, which is used as a treatment for cancer by traditional American folklore. Perhaps the patient was taking red-clover tea. The albumin-globulin ratio showed a relatively reduced globulin. The liver was large. The phosphatase was a little high. All this is hard to interpret but suggests diminished liver function.

It is interesting, but not exciting, that the basal metabolic rate was elevated because it may be quite high in both leukemia and polycythemia.

So far, I should say that this patient had polycythemia vera, because the white cells were mature. Why the platelets were diminished is not clear.

It will be very interesting to see if the x-ray films show a great deal of emphysema. This might account partially for the polycythemia, and I would like to find some reason for anoxia. It is interesting that in polycythemia, one gets decalcification of

organ in the body. It could be considered evidence of acute rheumatic infection, but we have no confirmation.

There was one additional finding of some interest. The liver showed a very well developed cirrhosis such as can occur in chronic rheumatic heart disease, but it seemed to me more marked than that ordinarily seen in this degree of mitral stenosis. The right ventricle was also unusually thick. It measured 1 cm. in thickness compared with a left ventricle of only 1 1/4 cm. I think that without much doubt the pulmonary lesion considerably increased the strain on the right ventricle, beyond what could be explained by the mitral involvement.

DR JONES: Would you think the pulmonary lesions, the acute ones, were comparable to Rich's² sulfonamide cases?

DR MALLORY: Yes, they are perfectly consistent with that.

DR JONES: I do not know whether this patient had sulfonamide prophylaxis at the time of death.

A PHYSICIAN: He did not develop signs of consolidation in the right lower lobe until two days before coming to the hospital.

DR MALLORY: We found nothing to explain that. All the lesions there are of years' duration.

DR JONES: Would you agree that these changes — if they are to be considered as evidence of active rheumatic fever — would call for a complete re-evaluation of what we term active rheumatic fever, on the basis of the findings that we see in the younger person? One does not find this pattern very often.

DR MALLORY: No, there are occasional cases of active rheumatic fever with arteritis so severe that one begins to think of calling it periarteritis nodosa, but these cases are the exception.

DR BAUER: Would the roentgenologist be able to read this chest plate differently now?

DR LINGLEY: I am afraid not. I do not understand what the shadow in the right lower lobe could be.

DR BAUER: Are you wholly satisfied with the explanation of the pulmonary changes?

DR MALLORY: As a healed pneumonitis?

DR BAUER: Yes.

DR MALLORY: I think there are two alternatives, either healed pneumonitis or the scars of long successions of pulmonary infarction. I am rather sure that one can rule out the latter.

CASE 35252

PRESENTATION OF CASE

A sixty-nine-year-old divorced woman was admitted with the complaint of an abdominal mass that had been increasing in size over a period of seven years.

When first detected it was said to have been the size of a walnut, located in the left lower quadrant and without associated symptoms. About three years before admission the mass had increased markedly in size and the patient began to notice increasing urinary frequency, nocturia and anorexia. At the same time she began to notice a tendency to bruise easily. She had some discomfort when erect, and difficulty in sleeping required medication from her physician. As the mass increased in size she developed moderate dyspnea and some palpitation on exertion, for which she was given daily green pills. At the time of admission, almost the entire abdominal cavity had become filled with the mass. She had lost 30 pounds during the previous three years but denied nausea, vomiting or change in bowel habits. There apparently had been no vaginal bleeding since the menopause at the age of fifty-three.

Twenty-nine years before admission she had an episode of post-partum phlebitis in the left leg and had recurring ulcerations about the left ankle. About twenty-five years before entry she had an episode of severe hemorrhage following multiple tooth extractions.

Physical examination revealed an emaciated, elderly woman with bronze pigmentation of exposed skin areas and multiple ecchymotic spots over the arms and upper trunk. Her color was high but not violaceous. A few telangiectases were present over both cheeks and the right ear. The heart was somewhat enlarged to percussion. There were frequent extrasystoles occurring irregularly and a Grade I, precordial systolic murmur. The aortic second sound was greater than the pulmonic. There was some dullness to percussion, and decreased breath sounds with fine crepitant rales at both lung bases. A large, smooth, hard mass filled almost the entire abdomen except for a portion of the right upper quadrant. It was not easily movable but was not attached to the abdominal wall. A definite notch was palpable on its right border below the level of the umbilicus. It was not palpable rectally, and the pelvic examination was within normal limits. The liver edge was palpable about four fingerbreadths beneath the costal margin in the right flank. A few small soft and nontender lymph nodes were palpable in the inguinal and cervical regions bilaterally. There was some distention of superficial veins in the neck and left leg. Slight edema, skin pigmentation and old scar formation were present about the left ankle.

The blood pressure was 148 systolic, 90 diastolic.

DIFFERENTIAL DIAGNOSIS

DR JOSEPH C. AUB: The description of the mass is important because the description of a tumor low in the abdomen suggests a tumor in the ovary, but there was no history of recent vaginal bleeding.

The chest findings mean nothing but congestion of the lungs, they do not imply fluid.

There are only three reasons for the slowed prothrombin time: a vitamin K deficiency, liver damage or the eating of red clover. There is no history of the eating of red clover, which is used as a treatment for cancer by traditional American folklore. Perhaps the patient was taking red-clover tea. The albumin-globulin ratio showed a relatively reduced globulin. The liver was large. The phosphatase was a little high. All this is hard to interpret but suggests diminished liver function.

It is interesting, but not exciting, that the basal metabolic rate was elevated because it may be quite high in both leukemia and polycythemia.

So far, I should say that this patient had polycythemia vera, because the white cells were mature. Why the platelets were diminished is not clear.

It will be very interesting to see if the x-ray films show a great deal of emphysema. This might account partially for the polycythemia, and I would like to find some reason for anoxia. It is interesting that in polycythemia, one gets decalcification of

the vertebrae, where a great deal of blood is made, and where the bone is composed largely of trabeculae that may become so thin that vertebral collapse may result.

The x-ray findings establish the fact that this mass was the spleen and not the kidney. If it were kidney or a retroperitoneal mass, the large bowel would be pushed over and not pushed down by it. It is only the spleen that pushes the large bowel ahead of it.

The bone marrow contained an enormous number of white cells. Dr. Jacobson says the normal ratio is 4:1 to 8:1. Certainly, with polycythemia vera there should be many more red cells than white cells. This is a high number of white cells for polycythemia but does not rule it out. There were very few platelets in the circulating blood, and yet many megakaryocytes were present in the bone marrow. No plasma cells were seen. We must think of multiple myeloma, in spite of this fact and the normal total protein and low globulin in her blood, but it is unlikely.

The first part of this case is, I think, easy. The second part is very baffling. I do not know just where her pain started, whether this was a pulmonary infarct, or whether it was bleeding with irritation of the pleura. She had tenderness in the calf and thigh, and, I suppose, an embolus was liberated from the phlebitis of the leg.

There is little description of the x-ray examination done at this time — whether it showed evidence of bleeding in the pleura or in the pericardium.

Well, there it is. The mass was the spleen. The diagnosis is polycythemia vera. There are a good many questions in relation to that. Why did she have so few platelets? The blood of polycythemia ought to have many platelets. She had a great many megakaryocytes in the bone marrow but very few platelets in the blood stream. I do not know why. She bled, which is common in polycythemia, and I think she died of bleeding. She had a high white-cell count, 23,800, and all the cells were mature, with no abnormal cells, this is also common in polycythemia. In fact, I recently saw a patient with straight polycythemia who had almost 100,000 mature polymorphonuclear cells. About 10 per cent of patients with polycythemia have leukemia as they progress. But I do not believe that this patient had leukemia.

I see no good evidence for the diagnosis of agnogenic myeloid metaplasia. Incidentally, this disease interests me very much as a preneoplastic lesion. This disease is a beautiful example of an enormous, increased production of red cells. Why it causes an increased production of normal adult red cells and then ends up with a neoplasm is fascinating, there is no explanation for it that I know of, and it remains an interesting opportunity for the study of preneoplastic lesions.

I want to see the x-ray films.

DR. JOSEPH HANELIN: I believe she has an emphysematous chest. The anteroposterior chest diameter is increased, and the sternum bulges forward.

The first set of chest films, taken on the second hospital day, shows findings in the chest essentially as described. The heart is somewhat enlarged, and the left ventricular salient is prominent. There is calcification of the aorta. In the lateral film of the chest multiple vertebral fractures involving the lower thoracic and upper lumbar segments are visible. There also appears to be a rib fracture on the right. The left costophrenic sulcus is blunted. One wonders whether this might be due to underlying infarct or whether it is possibly of longer duration, owing to some thickening of the pleura.

On the sixteenth hospital day, the chest findings have changed slightly — at least, to demonstrate very nicely the large subcutaneous hematoma, which is now visible anterior to the sternum. I rather suspect that the density noted overlying the left portion of the thorax is also due to subcutaneous blood accumulation. There is a small amount of fluid in the right costophrenic sulcus, possibly related to the rib fracture.

The plain abdominal film confirms Dr. Aub's impression that he was dealing with an enlarged spleen. There is a large mass in the left abdomen of ovoid configuration. The normal splenic shadow cannot be seen. I assume this is an enlarged spleen. In addition, the lower edge of the liver is situated below its normal location and extends slightly below the iliac crest. Pyelograms show slight embarrassment to drainage on the right and a slightly hydronephrotic renal pelvis on this side. Renal function may be impaired somewhat bilaterally. In the abdominal film there is a calcified streak following the course of the left iliac and femoral vein, which probably represents a calcified thrombus. In the anteroposterior view, we can also note the fracture of the lumbar segments. All the bones are decalcified, but in a woman of this age, the degree of osteoporosis is not unusual.

DR. AUB: The emphysema does not help me because it is not sufficiently marked. I do not think this patient had kala-azar, or myeloid metaplasia. She had polycythemia, as I said before, and I think polycythemia vera. So far, I am sure that I am on firm ground. From here on, I am on less firm ground because I do not know whether the hemorrhage killed her, or an infarction. Patients with polycythemia have hemorrhages, — this patient had had hemorrhages for a long time, — and they bleed very heavily, just as patients with leukemia do. This patient also had few platelets and a slow prothrombin time. Also, in polycythemia thrombi develop, and they may get loose. This woman died in shock, and she died while she was bleeding. Therefore, it seems to me, she died of either hemorrhage or infarction. The sternal biopsy may have gone

through into the upper mediastinum, and may have extended into the pleura, and hemorrhage may have occurred in the pericardium with subsequent cardiac tamponade. I have not enough evidence to say whether these occurred. She had some suggestion of phlebitis in her leg. There is evidence of old phlebitis. She had a sudden sharp pain in the chest, though she did not cough or spit up blood. She may well have had a pulmonary infarct, sufficiently great to cause anoxia, shock and death. She may possibly have had a cardiac infarct.

I have not enough evidence to make a differential diagnosis. I have some evidence that she was bleeding and some evidence that she had cause for having a large pulmonary infarct, no evidence is given that she had a cardiac infarct. I know she was bleeding about the sternal biopsy, and these people do go into shock from hemorrhage, and I believe that she kept on bleeding, with extension into some cavity, either pleural or pericardial. I rather guess that she had a large pulmonary infarct from which she went into shock and died. Therefore, I should be surprised if she did not have polycythemia vera, and I do not expect myeloid metaplasia or neoplasm in the bones. Her thin bones were due to the fact that they were full of actively regenerating blood and that the trabeculae had been hollowed out by this long, slow disease. I think her large spleen was due to polycythemia. Then it is to be expected that the liver has areas of regeneration of red and polymorphonuclear cells, with some hemosiderin in her liver, and probably in her spleen.

DR BERNARD M JACOBSON: Is there any record of the red-cell count and the hemoglobin in the last few days of life?

DR DAVID G FREIMAN: Do you know, Dr Milam?

DR DANIEL F MILAM, JR: She had severe hemorrhage, on the following day the hemoglobin was 17.8 gm.

DR FRANCIS T HUNTER: I saw the patient for about two minutes before she was transferred to the surgical department for biopsy. I never saw her again. There was evidence at that time that she had an enormous spleen. Because of the immature white cells in the smear, I thought she might belong to the small group we have seen in the clinic that we cannot make up our minds whether to call polycythemia vera or leukemia with polycythemia. Those with enormous spleens have a relatively benign course, provided they are left alone. Some that we have treated have done very badly. The usual case has a white-cell count of 50,000 to 100,000, with myelocytes and myeloblasts and so forth in the smear. Speaking of polycythemia becoming leukemia, I know of one case of typical polycythemia vera that was treated with "spray" radiation and did well. But after ten years she entered the Baker Memorial with a white-cell count of 150,-

000, all myeloblasts, and promptly died. Another point that suggests that this case may have been more leukemic than polycythemic — although I admit that I cannot tell where one begins and one ends, or whether they are not one and the same disease — is that the basal metabolic rate was high. In polycythemia the basal metabolic rate is about +25 or +35 per cent, in leukemia it is +70 or 80 per cent. We must remember that this patient had a long history, and, having had no treatment, she could have developed this enormous spleen with polycythemia vera alone. One thing missing in the history is that there is no mention of how long she had the ruddy complexion. Had she been that way all her life?

In regard to the basal metabolic rate, a few days ago I had quite a surprise. At autopsy the patient's spleen was not enlarged but the liver was, and the peripheral blood showed many nucleated red cells and myelocytes. It was my opinion that the high basal metabolic rate (+40 per cent) was in favor of leukemia. Because he was going downhill so rapidly, he was given no x-ray treatment and died soon thereafter. Post-mortem examination showed complete replacement of all the organs with cancer of the prostate. I had not seen such a high metabolism from cancer before, and this was explained by the rapidly growing tumor cells.

As to death from hemorrhages in this case, there is one cavity not mentioned. How about the peritoneal cavity? Could she have had a ruptured spleen?

DR AUB: The basal metabolic rate varies with the number of young cells, and in this disease may be due to the high, specific dynamic action of protein. The red cells discard their nuclei, and the uric acid excretion is high, and so there is a high protein breakdown from this disease. Besides, the white cells that were present in this bone marrow could account for some of the high metabolic rate on the basis of rapid regeneration of cells. As far as having bled into the abdominal cavity is concerned, that is possible. I do not know where the hemorrhage gravitated to.

DR HUNTER: I mentioned that because there was a case of leukemia on the medical ward a good many years ago, the patient squeezed his abdomen hard, went into shock and died. He had ruptured his spleen just by pressing on it.

DR AUB: It is not unusual to have the white-cell count as high as this with polycythemia.

DR HUNTER: That is true.

DR JACOBSON: I recall asking the patient how long she had had a ruddy complexion. She did not recognize that she had any abnormal high color, and she did not know the answer to that question. The protocol gives no adequate picture of what she looked like. She was one of the most emaciated women that I have ever seen. In addition to the ruddy complexion, she presented a peculiar pigmentation that in the minds of some observers raised

the question of Addison's disease or similar rare conditions. If there is any diagnostic information to be obtained at all from the bone marrow, certainly, in her case, it was not leukemia. The shift was to the right. The white-cell elements were more mature than normal, not less mature, and that is what influenced me mostly in thinking that she was not leukemic, at least, not at that time. It is interesting that on the surgical service she was given intravenous protamine to stop the hemorrhage, with the idea that she had had heparin-like bodies circulating and causing hemorrhage. As I recall, in looking at one of the initial smears, I was not impressed with the diminution in platelets. I do not believe the bleeding was due to thrombocytopenia. I think that anyone who saw her in her fragile, emaciated condition would have been loath to do anything major in the line of surgery on her without some type of treatment directed toward the blood-forming organs.

CLINICAL DIAGNOSES

Polycythemia vera
Splenomegaly
Subpectoral hemorrhage

DR AUB'S DIAGNOSES

Polycythemia vera
Hematopoiesis of liver and spleen
Pulmonary infarct

ANATOMICAL DIAGNOSES

Polycythemia vera
Hematoma, massive, subpectoral and subcutaneous
Hematoma, slight, mediastinal
Splenomegaly, marked
Myeloid metaplasia, spleen and lymph nodes
Erythropoiesis, focal, liver and adrenal glands
Pyelonephritis, chronic
Thrombosis, left iliac and femoral veins

PATHOLOGICAL DISCUSSION

DR FREIMAN. At autopsy this patient was an emaciated woman with extensive ecchymosis over the anterior thorax, especially on the left, extending up over both shoulders into the neck, and down over the left flank and abdomen. A hematoma was

present over the sternum at the site of the sternal biopsy, and a stab wound was present in the anterior axillary line, where a massive subpectoral hematoma had been drained surgically. The subpectoral area contained a large hematoma. The body cavities contained no blood. Our approach was limited to an abdominal incision. When the peritoneal cavity was opened, a large spleen presented, extending to about the brim of the pelvis in the midline. It weighed 3050 gm. The liver was moderately enlarged, weighing 2300 gm. Microscopically, the spleen showed very active myeloid metaplasia, with excellent maturation of all elements and many mature forms. The sinusoids of the liver also revealed hematopoiesis, chiefly of erythroid elements. The sections of bone marrow that were examined showed intense hyperplasia replacing all the fat, here, too, there was excellent maturation in all series. Large numbers of megakaryocytes were present in the marrow and spleen. The lungs demonstrated some atelectasis and emphysema, but there was no evidence of embolism or infarction. The left kidney weighed about 100 and the right 170 gm., both kidneys showed fine granularity that was due to chronic pyelonephritis. In the pyramids of the kidneys there were white streaks, which proved on microscopical examination to be urates in the collecting tubules. This may be related to the fact, as Dr Aub pointed out, that patients with polycythemia excrete considerable amounts of uric acid, probably owing to excessive nucleoprotein breakdown in the course of active erythropoiesis. As a matter of fact, cases of gout or gouty exacerbations have been described in association with polycythemia. There was an old thrombosis extending into the left iliac and left femoral vein as far as we could reach — the residue of the old phlebitis.

DR AUB. Why did she go into shock?

DR FREIMAN. As far as we could tell, it was due to the massive bleeding into the subpectoral area. The only internal evidence of bleeding was a small hemorrhage in the posterior mediastinum.

DR AUB. It does not take much there.

DR FREIMAN. Perhaps, but it did not seem to be producing any occlusion or compression.

MEDICAL CARE AND INDIVIDUAL INITIATIVE

ELSEWHERE in this issue of the *Journal* Drs McKittrick and Allen discuss the question whether the good of the American people demands compulsory health insurance. The opinions given and the conclusions drawn represent the physicians' answer to those who advocate Government supervision and direction of medical practice. Interest in these papers is heightened by the fact that they were delivered before a lay audience.

Dr McKittrick takes up in detail the arguments invariably advanced by the proponents of federal health insurance, presenting in rebuttal the facts as they appear to the majority of doctors. He considers the comments on the state of the nation's health—so often interpreted and misinterpreted as to offer obfuscation rather than enlightenment—in terms of whether they prove that the Govern-

ment's program is the only means of achieving the desideratum of the best possible medical care for the American patient. Thus, he finds no evidence that compulsory health insurance will improve the health of the nation, that it is necessary if medical services are to be furnished the 70,000,000 people who have difficulty in providing adequate minimal care for themselves and their families," or that it would meet the requirements of a good national program. He points out the danger that the proposed federal system would eliminate any possibility of experimentation outside the structure of the compulsory, centrally controlled plan" and he offers the opinion that such a program would eventually lower the quality of care received. Finally, he states that the history of medical progress gives promise that the problem can be solved without sacrifice of the initiative and freedom that have raised American medicine to its present eminent standard.

Dr Allen discusses the plan for better medical care in relation to what the profession has accomplished without the fetters and annoyances of federal dictation. He traces the progress in medical education, hospital standards and research that has made possible the present status of American health. He emphasizes the value of the system of free enterprise" that has helped progress in medicine and other fields. In forthright terms, he recommends a program that will provide medical care for those who cannot afford to pay for voluntary health insurance: community co-operation among local taxpayers, the state and philanthropy, with federal taxation to meet the deficit.

The proposals advanced in these papers appear to have merits that compulsory health insurance lacks. The argument in favor of Government medicine concentrates on the needs of people who cannot afford to pay for voluntary health insurance but ignores the contribution of private philanthropy and voluntary community and state agencies to the care of the medically indigent. It makes much of doing away with a means test (accepted with apparent unconcern by those who benefited from the WPA and work relief but now somehow intolerable to the free American, or to those who pretend to speak for him) in a way that, absurdly enough,

would provide free care for the wealthy ne'er-do-well along with his less fortunate fellows, the burden, presumably, would fall on the man with a job, the inevitable scapegoat in ill considered programs

The authors of the papers referred to are to be congratulated for their dispassionate but cogent presentation of the physician's side of the case. It should be evident to lay and medical readers alike that the physician's side is none other than that of the patient — the end in view is the good of the patient. It is high time the medical profession made its voice heard, not by its confreres but by the public, which in the final analysis will be the judge of what plan to accept or reject and what kind of medicine, Government or private, is best suited to its needs. The papers discussed offer assurance that the future health services of Americans can best be planned by those who provide the service

DAMAGED GOODS

THE careful study by Ingalls and Prindle of 107 cases of esophageal atresia with tracheoesophageal fistula, reported elsewhere in this issue of the *Journal*, suggests many still unexplored possibilities in the etiology and prevention of congenital defects. Most spectacular among recent revelations of applied embryology has been the incontestable sequence of events between maternal rubella and certain well known anomalies occurring in the fetus. Equally challenging are such anatomic variations as those of the trachea and esophagus, nonfamilial and obviously not hereditary, yet occurring with a degree of regularity that has made such an investigation imperative.

Studies on human embryos have shown that these specific defects are present long before birth—as early, in fact, as the second month of fetal life. The broad pattern of tracheoesophageal fistula, which indicates a departure from normal sequences of development occurring at about the fifth or sixth week, is apparently similar to that of seventh-week or eighth-week origin previously described for monogolism. This similarity suggests that these particular defects in the embryo may be caused by any of a number of possible mishaps, in themselves unrelated but exerting the same kind of effect on the

differentiating tissues. The anatomic structures involved are those that take shape at approximately the above-mentioned embryonic age.

The agents to be tested as causes of the anomalies are grouped in three categories. These are infectious agents such as rubella and syphilis, chemical agents such as nutritional deficiencies and toxic and metabolic disturbances, and such physical agents as mechanical trauma and structural disease of the uterus. In no case did the tracheoesophageal defect appear in successive generations or recur in the same generation of a family. Suggesting the diversity of the defects resulting from rubella were the associations also observed with anomalies of the cardiovascular, gastrointestinal, genitourinary, respiratory and skeletal systems.

The observation that illegitimacy was associated in an unusually large percentage of the cases studied suggests the possibility of an occasional connection with attempted abortion by mechanical or chemical agents. Instead of the abortion being accomplished, the fetus was possibly rendered defective.

The hypothesis that has been developed is that certain commonly grouped defects representing deviations from normal development during the second month of embryonic life are caused by agents acting through the mother and placenta. This hypothesis must be further tested, for "the question at issue not only is one of specific etiology but also involves principles underlying the larger phenomenon of acquired congenital malformations." Such testing can only be done effectively by a team, the members of which possess collectively more skills and training than any one man can usually master in a lifetime. The authors have availed themselves of the lifetime experience of Dr. Frederick T. Lewis in the field of embryology. The 18 1-mm embryo featured was considered as "probably normal" for thirty-eight to forty days in C. S. Minot's *Textbook on Embryology*, published in 1910. Its sections, one of which is reproduced for the first time in this issue of the *Journal*, provided perhaps the first recorded case of tracheoesophageal fistula in a small embryo.

EMETINE IN ALCOHOLISM

THE publication, elsewhere in this issue of the *Journal*, of a fatal case following the use of emetine hydrochloride in the conditioned reflex treatment of chronic alcoholism sounds a timely warning. Emetine is a drug that may on occasion be toxic to the myocardium, presumably in proportion to the patient's sensitivity to it, and certainly in proportion to the dose administered.

Toxic manifestations of the severity reported by Dr Kattwinkel are fortunately rare. Patients should, nevertheless, be subjected to the most rigid regime when on this treatment.

Dangerous reactions to the drug may be avoided, as suggested by the author and other authorities, by careful preliminary examination of the patient, including an electrocardiogram, in order to eliminate obviously poor risks, by his absolute rest in bed during the course of treatment and for the following four weeks, by careful observation for the signs or symptoms of diarrhea, fatigue, dyspnea on exertion, muscular tremors or weakness and dizziness, and by repetition of the electrocardiogram after the fifth grain of emetine has been administered, at the completion of the course of treatment, and two or three weeks later.

These precautions make the treatment reasonably safe as demonstrated by the large series of patients treated at the Washington Hospital in Boston and at the Shadel Sanitarium in Seattle, Washington. Observations at the Washington Hospital indicate that even in the rare cases in which cardiovascular and other manifestations have occurred, adequate measures, when instituted early enough, have led to complete recovery of the patient from the toxic reaction.

THE SHORTAGE OF NURSES

THE April and June, 1949, issues of the *Harvard Medical Alumni Bulletin* contain a remarkable essay entitled "The Shortage of Nurses." It is that part of the reminiscences of Harvard's oldest alumnus which is pertinent to this aspect of medical care. This is no new issue, but one with which the medical profession and the community have contended, with varying success and much failure, over a long

period. Here an eminent physician whose experience spans an eighty-year period, and whose memory in his nineties is remarkably lucid, tells of his effort and that of others to establish what the doctors of this century have come to accept as a standard institution—the training school for nurses.

One may not conclude that Dr Worcester altogether approved of developments as they took place. It is well known that the emphasis placed upon hospital schools for hospital purposes met with his vigorous warning, and he has long believed that with few exceptions the needs of the community were being neglected. Although it is true that the hospital has tended to neglect the needs of sickness in the home, it has on the other hand taken upon itself the responsibility of caring for many disorders formerly confined to home care.

In many communities this tendency has created a new paragraph in the minimum standard of living. Particularly in the urban areas, the people have come to consider that hospital care is an essential and inevitable service, to a much greater extent than it used to be and, perhaps, than it actually needs to be. The coming of the Blue Cross and the propaganda for "free medical service" is bringing to the minds of vast numbers of people a realization that hospitals are expensive places in which to live. The training of nurses in hospitals was once considered an economic stratagem, but it is no longer so. The training of nurses has become so expensive that many hospital schools are now silently folding their tents.

Dr Worcester's reminiscences have a peculiar historical and practical significance at this time. They indicate a primary responsibility on the part of the medical profession that his generation recognized and carried. Is nursing still fundamental to the care of the sick? It is true that times have changed, and there are different problems to contend with, but somewhere the same zeal, the same burning desire to find a better way, if not a solution, to the present shortage is needed. For fifty years the medical profession has moved in the direction of raising educational standards for the training of nurses, at the same time resisting most serious attempts to produce another, less highly trained,

attendant type of nurse. Should it not consider moving now in the other direction?

The *Journal* salutes Alfred Worcester for his long life of usefulness to others, for the enthusiasm with which he has met the challenges of the profession and for the clarity with which he has retained his interest in its problems.

CORRESPONDENCE

STATEMENT FROM MR. BARUCH

To the Editor: The statement has frequently been made that Mr. Bernard M. Baruch is in favor of compulsory health insurance. In view of this, will you be kind enough to publish the accompanying letter?

Dr. Madge C. L. McGuinness,
51 East 87th Street,
New York, N. Y.

My dear Dr. McGuinness:

What I don't understand in all this talk about medicine is that everybody wants to go to the Government, even our own friends, to get aid. Yet they expect that the Government is not going to call the tune as long as it pays the piper. I certainly do not want to see what is generally known as socialized medicine. As I said at the time of my address, I would oppose it with all my might. I said, as you may remember, that the doctors have to get a move on themselves to meet the needs of the situation, and I stand on my speech. I know that men like Dr. Rawls are doing all they can to meet the needs of the situation without destroying the benefit the world derives from the great service the medical profession has always rendered.

Yours very truly,
(Signed) BERNARD M. BARUCH

MADGE C. L. MCGUINNESS, M.D.

Medical Society of the County of New York

THE NATIONAL HEALTH PROGRAM

To the Editor: Some months ago I received a letter from Dr. Channing Frothingham criticizing my inaugural address and threatening to go to the medical and lay press if I did not make retractions. This letter I did not believe it worth while to answer.

Dr. Frothingham states that compulsory health insurance will take care of the medically indigent. Mr. F. Donald Kingsley, acting Federal Security Administrator, according to the *New York Times*, made the following statement: "Those unable to work or dependent on public assistance could have their insurance premiums paid by various public or private agencies. Later we hope to find the means of achieving a complete one hundred per cent coverage of the population." Dr. Frothingham and his cohorts should get together.

Perhaps Dr. Frothingham considers the statements of his co-workers more authentic than the findings of the Brookings Institution. I don't. Regarding compulsory health insurance or socialized medicine, or both, Dr. Ernest E. Irons, former president of the American College of Physicians and president-elect of the American Medical Association has said:

To assert that the proposed program, as implemented in the Wagner-Murray-Dingell Bill, is not socialized medicine is no compliment to American intelligence. We are confronted with an attempt to impose socialized medicine on a people who do not want it. It is a fight that is much more than the fight for the freedom of American medicine. It is a fight for the preservation of American democracy and the American way of life.

Dr. Frothingham criticizes me for not finishing a quotation I made from Mr. Baruch's speech. The amusing part is that the Committee for the Nation's Health (Dr. Frothingham, chairman) has unfinisshed quotes on its pamphlet with Mr. Baruch's picture. For example: "The public is demanding better and more medical service through some action—political or otherwise." (Addendum: "We must look for what can be done and do it. The great question is how. I do not want to seem to say, I know the answers.") "It can be devised, adequately safeguarded, without involving what has been termed 'socialized medicine.'" (Addendum: "The means can be met as in other fields, without the government taking over medicine—something I would fiercely oppose.") Dr. Frothingham states that Mr. Baruch proposed compulsory health insurance. That is not true. He did not advocate a compulsory health insurance scheme as envisaged by Dr. Frothingham or the Wagner-Murray-Dingell Bill. Mr. Baruch stated: "For those who cannot afford voluntary insurance, some form of insurance partly financed by the government covering people in by-law, I would call this compulsory health insurance, if that term's proper meaning had not been lost." What troubles me most are the needs of that sizable segment of society which does not earn enough to pay for voluntary insurance.

Dr. Frothingham gives a list of what he terms prominent people who are in favor of compulsory health insurance. Two of these were listed as sponsors of the recent cultural peace conference held in New York. Three doctors listed as sponsors of the conference are also listed as directors of the Committee for the Nation's Health. The papers during the conference were sufficiently explanatory, and nothing I might add would be more informative than the statements of the State Department, the press and the placards of the pickets.

In view of the happenings of recent months, does anyone question that employees of the Social Security Board are agitating for compulsory health insurance? Are employees of the Government paid to agitate or lobby for anything that is not a law of this country?

Concerning the Tokyo Mission, Mr. Harness quoted a letter from Mr. Wandel, which said in part, "We now think that our need is for someone who is primarily not so much an economic analyst as one versed in health insurance. Health insurance is the major field of social security in Japan. permanent revision requires amalgamating National Health Insurance with Health Insurance on a compulsory basis." Do we need more?

The Committee for the Nation's Health is a lobby and employs paid lobbyists. My purpose was to publicize this fact. I have accomplished my purpose.

I could refute all Dr. Frothingham's statements, but they are so utterly without foundation that to do so would be a waste of my time and of valuable space in your journal. Suffice it to say that my inaugural address has served to awaken the medical profession in New York. Dr. Frothingham and his cohorts are disturbed over my address because it gives facts that they cannot refute. We know and understand their tactics and are not afraid to meet them anywhere, any time, any place. We have them on the run, and all their unfounded claims are comparable to an animal in its death throes that lashes out in all directions. But let me warn those who would destroy the freedom of medicine and eventually all freedom in this country that we haven't yet begun to fight.

WILLIAM BRYANT RAWLS, M.D.

Medical Society of the County of New York
2 East 103rd Street
New York 29, New York

NOTICES

ANNOUNCEMENTS

Dr. Franklin P. Lowry announces the removal of his office from 313 Washington Street, Newton, to 62 Walnut Park, Newton, on July 1.

Dr. James G. Simmons announces that Dr. Fred W. Benton is now associated with him in the general practice of medicine at 30 Myrtle Avenue, Fitchburg.

MIGRATING THROMBOPHLEBITIS ASSOCIATED WITH CARCINOMA*

EDWARD A. EDWARDS, M.D.[†]

BOSTON

AN apparently idiopathic thrombophlebitis may be associated with visceral carcinoma. In most cases the thrombosis is secondary to direct invasion by the tumor. There are other apparently rare cases in which multiple segments of vein are attacked at a distance from the tumor or its metastases. In these circumstances, the venous disorder takes on a particular form, unique for the great number of veins involved, the tendency for migration of the process from one segment to another, its persistence and its tendency to recrudescence. The affected veins show no invasion by tumor, and little reaction of any type. Some change in the blood favoring thrombosis has been assumed, but not demonstrated. The term "migrating thrombophlebitis associated with carcinoma" is suggested to designate the syndrome. Six cases personally observed are described below. One of these has been previously reported.¹

The first description of the disease is attributed to the most writers to Trousseau.² It is probable that Trousseau was emphasizing the association of carcinoma with other and more usual varieties of thrombophlebitis. This matter has been discussed in a previous paper,¹ but may be mentioned again to place the condition in sharper focus. The presence of carcinoma materially increases the incidence of ordinary postoperative and postinfectious thrombophlebitis. Secondly, a vein surrounded or infiltrated by tumor usually undergoes thrombosis. Such a process is commonly observed in the iliac or subclavian veins, when the pelvis or thoracic inlet is the site of metastatic carcinoma. Thirdly, "migrating thrombosis" may occur in the large veins and even in the cardiac chambers, as an expression of terminal debility in patients dying of neoplasm.

The earliest clear description of the form under discussion was presented in 1900 by Osler and McCrae,³ who cited a previous report by Gouget.⁴ Further reports did not appear for many years.^{1, 2, 11}

In 1938 Sproul,¹⁵ by an analysis of 4258 autopsies on patients with cancers of varied origin, found that multiple venous thrombosis was present in 31 per cent of the cases of carcinoma of the body or tail of the pancreas, 10 per cent when the lesion was in the head of the pancreas, 25 per cent when it was in the lung, and 13 per cent when it was in the stomach. In Sproul's series, no other variety of tumor was associated with thrombosis in more than one vein. Kenney¹¹ has recently reviewed a smaller series of autopsied cases and reached similar conclusions.

The reports of 23 cases,^{1, 2, 11} which may be classified as migrating phlebitis associated with carcinoma observed during life, in addition to the 6 cases here reported, have been reviewed. In the total of 29 cases, the primary site of the cancer was in the tail or body of the pancreas in 16, the stomach in 4, the lung in 4, the gall bladder in 2 and undetermined sites in 3.

CASE REPORTS

CASE 1.† C. W., a 54-year-old farmer, suffered from pain in the epigastrium and chest, gaseous distress after meals, nausea, weakness and weight loss. Four months after the start of the symptoms, multiple, migrating phlebitis, lasting 5 weeks at each site, developed. In 3 months, he had three attacks in each leg, two in each arm and one in the left external jugular vein.

Physical examination disclosed emaciation, acute and subsiding thrombophlebitis in several areas and an enlarged lymph node in the left posterior cervical triangle. Anemia was present. X-ray study revealed calculi in the left kidney and ureter, with some hydronephrosis. The urine diastase was greatly increased (495 units).

Biopsy of the cervical lymph node showed a well differentiated mucus-secreting adenocarcinoma, interpreted as metastatic from a carcinoma of the body or tail of the pancreas.

A thrombophlebitis occurred in the right iliac vein. The patient gradually grew weaker and developed jaundice. He died suddenly, 10 months after the onset of symptoms attributable to the tumor and 6 months after the beginning of the phlebitis. No autopsy was performed.

CASE 2.‡ B. A., a 49-year-old physician, complained of severe pain in the interscapular region. Three months later, he began to suffer severe abdominal cramps and diarrhea. He abandoned his practice and drifted into semi-invalidism. Thrombophlebitis, which first occurred 7 1/2 months after the onset of the illness, involved the superficial and deep veins of one

*Previously reported.¹

†In the latter part of his course this patient was under the care of Dr. Regina H. Smithwick, who kindly made his records available.

*From the Department of Surgery, Tufts College Medical School. Aided by a grant from the Chariton Research Fund, Tufts College Medical School.

†Instructor in surgery, Tufts College Medical School; clinical assistant in anatomy, Harvard Medical School; consultant in peripheral vascular diseases, Joseph H. Pratt Diagnostic Hospital and hospital of the Massachusetts Soldiers' Home; surgeon-in-charge, Vascular Clinic, Boston Dispensary.

attendant type of nurse Should it not consider moving now in the other direction?

Concerning the Tokyo Mission, Mr Harness quoted a letter from Mr Wandel, which said in part, "We now think that our need is for someone who is primarily not so much an economic analyst as one versed in health insurance Health insurance is the major field of social security in Japan permanent revision requires amalgamating National Health Insurance with Health Insurance on a compulsory basis" Do we need more?

The Committee for the Nation's Health is a lobby and employs paid lobbyists My purpose was to publicize this fact I have accomplished my purpose

I could refute all Dr Frothingham's statements, but they are so utterly without foundation that to do so would be a waste of my time and of valuable space in your journal Suffice it to say that my inaugural address has served to awaken the medical profession in New York Dr Frothingham and his cohorts are disturbed over my address because it gives facts that they cannot refute We know and understand their tactics and are not afraid to meet them anywhere, any time, any place We have them on the run, and all their unfounded claims are comparable to an animal in its death throes that lashes out in all directions But let me warn those who would destroy the freedom of medicine and eventually all freedom in this country that we haven't yet begun to fight

NOTICES

ANNOUNCEMENTS

Dr Franklin P Lowry announces the removal of his office from 313 Washington Street, Newton, to 62 Walnut Park, Newton, on July 1

Dr James G Simmons announces that Dr Fred W Benton is now associated with him in the general practice of medicine at 30 Myrtle Avenue, Fitchburg
(Notices concluded on page xv)

From this time to death 7 months after the onset of the thrombophlebitis, the inflammation smoldered in the previously involved veins.

Autopsy, performed by Dr Michael MacKenzie, revealed that the adenocarcinoma had invaded the portal vein and extended into the branches of this vessel in the liver. The liver lymphatics were likewise invaded. The pancreas was not involved. There were multiple infarcts of the kidney and spleen dependent upon thrombosis of fine veins. The iliac veins and the vena cava to the level of the ligature showed an organizing thrombus. Nowhere except in the portal vein was there invasion of the veins by carcinoma. Inflammation was found only in limited zones in the walls of the veins. Here and there a few eosinophils were evident.

DISCUSSION

Clinical Features

Patients with this syndrome are of middle or old age, and of both sexes, men predominating. The patient may present himself because of the venous disease while the carcinoma is unsuspected.

Inflammation of the superficial veins of the legs or forearms is the usual initial complaint, even though one may deduce from the pathological material that many deep veins may be involved early. Thrombophlebitis is apt to be present in the saphenous system at the ankles, extending somewhat onto the dorsa of the feet, a territory ordinarily affected only in the migrating phlebitis of thromboangitis obliterans. I have not seen the process extend to the distal portion of the foot or onto the toes, however, as it does in thromboangitis obliterans. Deep calf tenderness and edema suggest involvement of the deep veins of the leg, and pain over the sacral or hip regions suggests pelvic phlebitis.

The thrombophlebitis appears at one or more sites at the outset. The process then extends here and there, often for distances such as from the ankle to the groin, whereas the initial segment may become quiescent, or may show a continuous inflammation for days or weeks. A quiescent area is prone to become inflamed again at almost any time in the disease, and pathological examination indicates that this represents recurrent thrombosis. As in other forms of thrombophlebitis, there is great variation in both local and general signs of reaction. Temperatures up to 100.5°F are common, though the white-cell count is generally unchanged. In my experience, the fever is uninfluenced by penicillin, as in the usual nonseptic forms of thrombophlebitis.

Multiple pulmonary emboli are very common, though often small and unrecognized. In 1 case (Case 5), the disease was probably first announced by a small pulmonary embolus. This tendency to emboli should be kept in mind particularly in the postoperative state.

As time goes on, the thrombosis becomes more extensive, with involvement often of much of the portal system, of the inferior vena cava and many of its tributaries, and still more of the veins of the extremities. The thrombosis may thus hasten the death of the patient, through pulmonary embolism

and through serious injury of viscera, which are more sensitive to venous occlusion than the peripheral parts. The thrombosis in the peripheral veins was extensive enough, however, to cause gangrene of the foot and toes in 1 case (Case 3).

The lack of arterial thrombosis is noteworthy.

Is the patient always doomed once the thrombophlebitis is detected? The thrombophlebitis has already been defined as one in which carcinoma evidently does not invade the involved segments of veins. This may be concluded from the examinations, by biopsy or at autopsy, in the cases reported. Moreover, evidences of blood-borne metastases, outside the probable portal-vein dissemination, have not been disclosed in the affected patients. Therefore, so far as the venous lesion is concerned, it should be possible for the patient to recover if the carcinoma were removable. Yet the carcinoma proved to be inoperable, by the time its presence was recognized, in every case reported, and the patient died within some weeks or months of the onset of the thrombosis. This was true whether the patient's first symptoms were related to the venous process or to the visceral lesion. It remains to be seen whether future earlier recognition of the syndrome, with immediate surgical intervention, will mitigate or reverse the present unfavorable prognosis.

Thrombogenesis

The cause of the thrombosis is unknown. It has already been emphasized that there is no malignant infiltration of the vessel wall. Inflammation of the wall is likewise generally absent, though in some areas one may find foci of a few polymorphonuclear leukocytes, lymphocytes, plasma cells and fibroblasts. This corresponds to the picture seen in the ordinary bland thrombophlebitis of the recumbency state. Sproul¹⁶ suggests that a few cancer cells, which metastasize to the vein and initiate the thrombosis through their local secretory activity, may be overlooked. This appears unlikely in the face of the rarity of metastatic growths in the periphery. Slowing of the blood stream, generally considered important in thrombogenesis, is likewise lacking, except in the splenic vessels actually surrounded by tumor.

This leaves the possibility that the determining factor is some unusual change in the blood, owing possibly to a material generated by the tumor. So far, no changes in blood coagulation have been revealed in the cases reported, though the studies have admittedly been far from exhaustive. It has been pointed out that a characteristic common to the cells of the tumors responsible is that they are mucin secreting. The existence of mucin has not been determined in all the tumors reported, and yet it would not be unusual to find some mucin formation by tumors all entodermic in origin. Still,

leg. Within four weeks, the process advanced to new areas in the same leg and spread to the other leg and to both upper extremities.

Significant clinical findings consisted of an increased serum bilirubin, evidence of impaired liver function and the presence of occult blood in the stool. The urine diastase was normal until just before death. Exploratory laparotomy was refused.

The patient's course was characterized by another attack of thrombophlebitis in the superficial veins of one arm, a deepening jaundice and, finally, ascites. He died 13 months after the onset of symptoms of the tumor, and 5 1/2 months after the first attack of thrombophlebitis.

Autopsy, performed by Dr. Rudolph Osgood, showed an adenocarcinoma of the pancreas, with extension about the hilus of the liver, and metastases to that organ and to the celiac lymph nodes. There was thrombosis of the portal vein, and the right femoral and both common and external iliac veins. No carcinoma was demonstrable in the veins, except in those traversing the tumor.

CASE 3 A D, a 57-year-old photoengraver, complained of upper abdominal distress, bloating after meals and loss of appetite. Three months later, he began to experience severe abdominal pain occurring in bouts, especially at night. Constipation became marked. He lost 5 pounds in weight. Thrombophlebitis first appeared in the superficial veins of both forearms and in the left leg 6 months after the onset of the abdominal symptoms. Five weeks later, and while the initial thrombophlebitis was still active, he suffered an erysipelas-like attack in the right leg, seemingly as an allergic reaction to epidermophytosis of the foot. A second attack of phlebitis in the veins of this leg was noted in a few days. This was quickly followed by a third attack in the superficial veins of the left forearm. Biopsy of the latter lesion showed a bland thrombosis.

Significant findings relating to the tumor consisted of a palpable liver edge and evidence of impaired liver function. Neither diastase nor lipase was increased in the blood or urine. A diagnosis of carcinoma of the tail of the pancreas was made. Laparotomy was performed 8 months after the onset of tumor symptoms, and 2 months after the initial attack of thrombophlebitis. An inoperable adenocarcinoma of the tail of the pancreas was found, with metastases in the liver and peritoneum.

Postoperatively, the patient showed increasing emaciation, jaundice and swelling of the abdomen. There was evidence of thrombosis of the deep veins of the lower limbs to the iliac level. One week prior to death, he developed gangrene of the left foot. He died 9 months after the first appearance of abdominal symptoms, and 3 months after the initial attack of thrombophlebitis.

Autopsy, performed by Dr. Philip Le Compte, showed extension of the carcinoma from the tail of the pancreas to the celiac lymph nodes and nerve plexus. The metastases to the liver had broken through to the right perinephric tissues and diaphragm. There was invasion with thrombosis of the splenic artery and vein as they traversed the tumor.

Recent and old thrombosis, without tumor invasion, was widespread in both the portal and the inferior-vena-cava system. The lungs showed a number of old and recent emboli of the smaller arteries with multiple infarcts. Thrombosis was present in the tributaries of the splenic vein, with splenic infarcts. A fresh thrombosis was also present in the upper superior mesenteric, midcolic and upper jejunal veins. The upper 40 cm of the jejunum was gangrenous. The middle of the gastropiploic venous arcade and its tributaries showed fresh thrombosis. The process involved the inferior vena cava from just below the renal veins continuously down both common and the left internal iliac veins, both external iliac and femoral veins and the superficial and deep veins of the lower limbs. Though the main renal veins were spared, the smaller veins of both kidneys were extensively involved, with resultant infarcts. There was extensive thrombosis of the prostatic veins, with evidence of superposition of at least three attacks. The process in the legs was examined in detail. No arterial occlusion was found, and the gangrene of the left foot was therefore attributed to the extensive and repeated venous thrombosis in the limb.

Only where the splenic vessels traversed the tumor was there evidence that cancerous infiltration was responsible for the thrombosis. Otherwise, the thrombosed veins generally

showed an absence of reaction, with scattered zones of infiltration with polymorphonuclear leukocytes or lymphocytes. The recurrent nature of the thrombosis was indicated by the variation in the age of the process in different segments of the veins and, in some areas, by thrombosis in vessels recanalized from a previous episode. The tendency to thrombosis did not extend to the arteries. The involvement of the splenic artery was hardly an exception, since such a process within a tumor is commonplace.

CASE 4 E P, a 52-year-old machinist, complained of pain in the lower thoracic portion of the back with a feeling of pressure across the chest. His appetite had become poor and he lost 30 pounds of weight in 3 months. Two and a half months after the onset of his illness, a thrombophlebitis appeared in the deep and superficial veins of the right foot. Two weeks later, the process extended to the vessels of the upper right calf.

X-ray examination showed a lateral and anterior displacement of the cardia of the stomach. The blood and urine amylase and lipase were not increased. A diagnosis of carcinoma of the tail of the pancreas was made. At laparotomy, an inoperable adenocarcinoma was found in this location, with metastases in the liver.

At the time of this report, the patient is alive, 4 months after the onset of symptoms attributable to the tumor and 1 1/2 months after the onset of the thrombophlebitis.

CASE 5 W G, a 56-year-old machinist, suffered an attack of phlebitis in the left leg, lasting 1 week and associated with a small pulmonary embolism and infarction. Ten days after the initial attack quieted down, a similar process developed in the right calf, lasting 3 weeks. A month later, a third attack developed at the right ankle, migrating through the superficial and deep veins of the right leg. The patient was working and in good condition when seen. He denied any symptoms except those referable to the thrombophlebitis. Hospital study revealed only an anemia. Another attack of phlebitis, involving the superficial veins of the right calf and the left thigh, developed during the period of observation.

Exploratory laparotomy was performed 3 months after the onset of the thrombophlebitis. An inoperable carcinoma of the stomach was found, with metastases to the liver. The pancreas was not involved. Thrombophlebitis was evident postoperatively in the superficial veins of the right upper limb and later in the deep veins of the left leg and foot. In the last months of life, there was recurring inflammation in many veins previously involved.

The patient died 6 months after the first attack of thrombophlebitis. No autopsy was performed.

CASE 6* C C, a 38-year-old machinist, had suffered a thrombophlebitis in the superficial and deep veins of the left leg. He had been given penicillin in oil intramuscularly. After the third dose, a generalized, itching rash developed, and the medication was discontinued. The phlebitis quieted down after rest, but recurred on return to work. Two months after the onset of the illness, the veins of the right leg were involved. A month and a half later, he suffered a small infarction of each lung. The superficial and deep veins of the left upper limb and then the superficial veins of the right forearm became thrombosed. This was followed by a phlebitis of a vein in the left flank.

Biopsy of a vein from the left forearm showed an angitis with an exudate rich in eosinophils. The white-cell count was 10,400, with 12 per cent eosinophils. Periarteritis nodosa was suspected, the penicillin in oil being the possible etiologic agent. Examination revealed no findings to suggest visceral carcinoma. A single, large gallstone was seen on x-ray study.

A month later, thrombophlebitis developed in a supra pubic vein and then in a vein in the right thigh. At this time, jaundice was noted. The eosinophil count had fallen to 8 per cent. A third and larger pulmonary infarction occurred, and the inferior vena cava was ligated.

Ten days later, there were signs of a cholecystitis and a laparotomy was done, 4 months after the first attack of thrombophlebitis. An inoperable carcinoma of the gall bladder was encountered extending into the lesser omentum and to the hilus of the liver, with direct extension and metastases in that organ.

*Reported through the courtesy of Dr. Walter Garrey.

thrombosis in a patient with carcinoma, the thrombosis of a vein involved in the tumor or its metastases or a marantic thrombosis in a patient dying of neoplasm) The involved segments in the process show neither neoplastic infiltration nor any other characteristic finding The veins of both the upper and lower extremities are involved early, and the intra-abdominal veins at some time of the disease The latter may lead to visceral necrosis Once the process has started, new attacks, and recrudescence in previously involved segments, occur rapidly until the death of the patient The great extent and recurrent nature of the thrombosis were indicated in 1 case by the production of gangrene of the foot seemingly through the venous process alone Pulmonary embolism is a common complication

The initial lesion is most often a carcinoma of the pancreas — especially of the tail or body — or less often, carcinoma of some other viscus

The thrombophlebitis must be differentiated from the migrating phlebitis of thromboangitis obliterans, and the more common "idiopathic thrombophlebitis," in which no associated causal factor can be discovered The presence of an idiopathic thrombophlebitis with the apparent characteristics of the variety associated with carcinoma is an indication for intensive investigation to discover the neoplasm, including an exploratory laparotomy in some cases The question of whether or not the carcinoma is ever removable when the thrombophlebitis has already appeared is so far unanswered

I have recently seen a seventh case through the courtesy of Dr F S Homburger The patient was a seventy-two-year-old man The carcinoma was located in the head of the pancreas, with migrating phlebitis of both legs, beginning six months after exploration had revealed an inoperable tumor

A MEDICAL SURVEY OF THE ALEUTIAN ISLANDS (1948)*

FRED ALEXANDER, M D †

BOSTON

THE early health beliefs of the inhabitants of the Aleutian Islands, a territory of the United States stretching in a broken chain from the western end of the Alaskan Peninsula to Kamchatka off the eastern coast of Siberia for a distance of about 1200 miles, are described by Veniaminov as follows

The old men taught that whoever should talk badly about the sun, that for instance it heats too much, or hides itself too much, etc., will be blinded by it and not allowed to see its light The moon will slay its detractor with a stone And he who talks badly about the stars will be forced by these to count them, failing in which he will lose his mind

From many beliefs relating to health, long activity etc., I know only that the fathers and uncles endeavored to get the saliva of some old man, most famous by his undertakings and faultless life, as well as healthy and brave, and such saliva they gave to their children to swallow as a preventive from infections and epidemic diseases and as a means for strengthening the bodily powers Such old men at their death regaled their grandsons by some of their hair or a part of their garments or

the weapon which they carried in their encounters and commanded them to carry these on all occasions so as to prevent misfortune in every thing as well as health

Many of these one hundred larger and smaller islands are clearly remembered by those in the armed forces stationed in this mountainous, rough and inhospitable terrain, not only because of the almost continuous drizzle and fog, the temperature rarely below 0°F or above 70°F in the shade, and the winds of intensities well over 100 miles per hour but also for the beauty of an unharnessed nature Many of the islands are piled up around volcanic masses ranging from an unapproachable structure of gray-white, hard granite to a huge mountain peaked by a snow-capped cone resplendent in its halo of clouds and rare sunshine

Very little is known of the habits of these island people before the influx of Russian culture around 1741 Veniaminov, a Russian priest of great ability and esteem, spent ten years with the Aleuts (1824-1834) at a time when there had already been an eighty-year contact with the white men, so that

this merely emphasizes a category of tumors and does not explain the thrombosis

The production of digestive enzymes in the presence of tumors of the pancreas has received special attention. This subject is carefully reviewed by Sproul¹⁵. The tumors of the tail or body are apt to be associated with an overabundance of enzymes in the circulating blood, whereas those of the head, by obstructing the ducts, may cause a diminution in output. It is considered possible that an increased production of enzymes hastens blood coagulation, directly, or indirectly — by facilitating absorption of materials used in the process. Sproul suggests that in cancer of the stomach an achylia gastrica would provide a more favorable medium for the action of the normal pancreatic enzymes. It is my belief that an increased quantity of enzymes in the blood stream might damage the endothelium. This has not been brought out by the determination of lipase and amylase in the early stages of the cases described, but the proteases might be more significant. Unfortunately, no good tests are at present available for the measurement of these enzymes.

Diagnosis

The diagnosis of migrating thrombophlebitis associated with carcinoma is a problem first of ruling out known causes for thrombophlebitis, and then of differentiating various types of idiopathic thrombophlebitis. At the outset, one should carefully exclude usual and adequate causes of the venous disorder. Particular attention should be paid to the presence of varices, a point often difficult to decide when the varices are small. The history may suggest direct invasion of the iliac or subclavian veins by tumor, particularly if a gradually developing lymphatic edema has preceded evidence of venous thrombosis. A thorough physical examination may demonstrate a mass in the thorax or pelvis responsible for such a process. Laboratory studies will help in disclosing a neoplasm or blood dyscrasia.

In most patients in whom a usual cause is not readily found, no specific disease connection will ever be disclosed, and the diagnosis will finally be true "idiopathic thrombophlebitis," so called. But before this diagnosis can be established with reasonable certainty, thromboangitis obliterans and visceral carcinoma must be ruled out.

The *thrombophlebitis of thromboangitis obliterans* closely resembles that associated with carcinoma. The criteria for the diagnosis of the former variety have been emphasized in another paper¹⁶. The patient is generally a much younger person (in the twenties or thirties) who almost invariably uses tobacco. The phlebitis, which is migrating and recurrent, is evident in the same veins as those in the cases associated with carcinoma, *its progress from one area, or one vein to another, is not as rapid or as extensive*. The arteries may or may not have been involved at the time the patient is seen. Biopsy

of an inflamed vein often shows a characteristic intraluminal granuloma.

Patients with the thrombophlebitis associated with carcinoma are ordinarily in their late forties, or older. The diagnosis may be indicated by the multiple, migrating and recurrent nature of the process, and is established by the finding of a visceral carcinoma that has not demonstrably invaded the involved veins. The disorder may be suspected when but a single vein is thrombosed, but it is highly improbable if the process does not spread to other segments within a few weeks of the first attack. Furthermore, if months or years have elapsed between a previous attack and the present one, the case is probably one of truly idiopathic thrombophlebitis. Biopsy has so far given no characteristic picture, but may be helpful in ruling out thromboangitis obliterans.

Treatment

Treatment is of secondary importance to the search for the responsible neoplasm. It is evident that suspicion rests on several organs, especially the pancreas, stomach and lung. Diagnostic procedures should be vigorously prosecuted. It is my conviction that exploratory laparotomy should be performed if the presence of a carcinoma is not established otherwise.

SUMMARY

Six personally observed cases of a multiple, migrating and recurrent thrombophlebitis associated with visceral carcinoma are reported. Four of the patients showed carcinoma of the tail or body of the pancreas, 1 a carcinoma of the stomach, and 1 a carcinoma of the gall bladder. In 2 cases the thrombophlebitis was the initial complaint, in the others, it started two and a half to seven and a half months after the onset of the illness.

The thrombophlebitis was a late sign of the carcinoma. Laparotomy was performed in 4 cases and revealed an inoperable carcinoma, three and four months, respectively, after the onset of the thrombophlebitis, in the patients in whom that was the initial complaint, and one and a half and two months after the first attack of phlebitis, in the patients in whom the initial symptoms were referable to the tumor itself. One patient is now alive one and a half months after the onset of the thrombophlebitis — the others died three to seven months after their first attack.

Two patients showed disorders that were probably allergic in nature — 1 an erysipelas-like reaction with a fungous infection of the foot as the possible initiating agent, and the other a condition resembling periarteritis nodosa, with administered penicillin in oil as the likely causative factor.

The term "migrating thrombophlebitis associated with carcinoma" is suggested for the syndrome. (The term is not meant to include a recumbency

thrombosis in a patient with carcinoma, the thrombosis of a vein involved in the tumor or its metastases or a marantic thrombosis in a patient dying of neoplasm.) The involved segments in the process show neither neoplastic infiltration nor any other characteristic finding. The veins of both the upper and lower extremities are involved early, and the intra-abdominal veins at some time of the disease. The latter may lead to visceral necrosis. Once the process has started, new attacks, and recrudescence in previously involved segments, occur rapidly until the death of the patient. The great extent and recurrent nature of the thrombosis were indicated in 1 case by the production of gangrene of the foot seemingly through the venous process alone. Pulmonary embolism is a common complication.

The initial lesion is most often a carcinoma of the pancreas — especially of the tail or body — or less often, carcinoma of some other viscus.

The thrombophlebitis must be differentiated from the migrating phlebitis of thromboangitis obliterans, and the more common "idiopathic thrombophlebitis," in which no associated causal factor can be discovered. The presence of an idiopathic thrombophlebitis with the apparent characteristics of the variety associated with carcinoma is an indication for intensive investigation to discover the neoplasm, including an exploratory laparotomy in some cases. The question of whether or not the carcinoma is ever removable when the thrombophlebitis has already appeared is so far unanswered.

I have recently seen a seventh case through the courtesy of Dr. F. S. Homburger. The patient was a seventy-two-year-old man. The carcinoma was located in the head of the pancreas, with migrating phlebitis of both legs, beginning six months after exploration had revealed an inoperable tumor.

I am indebted to the United States Coast Guard, Navy, Army and Fish and Wildlife Service for their many courtesies. †Clinic and research fellow, Massachusetts General Hospital.

perhaps none of his Aleut informers could speak directly of the pre-Russian experiences and culture. Data concerning the appearance of various diseases among the islands with the coming of the Russians have been compiled by Veniaminov and others, including Blaschke, — the first Russian doctor to be sent to the Aleutians in 1835, — and such information has been quoted in this review.

Syphilis and other venereal disease, smallpox, consumption, measles, scurvy, influenza, pneumonia and possibly typhoid fever all made their appearance with the introduction of the new culture. Each newly arrived ship was a potential source of infection for some strange new disease. Because of his lack of immunity to these invasions, the Aleut served as excellent culture material. Diseases that were easily cared for among the white inhabitants reached immense proportions among the islanders. It was reported that in 1845 an epidemic of measles, assuming the "black form," caused near panic among the inhabitants of Kodiak Island and the contiguous mainland. The health of the villagers was entrusted both to the village priest, or shaman, and to a certain number of select people schooled in the art of healing by principles handed down from generation to generation. Usually, this knowledge was kept in one family group and passed on only to the most deserving.

Smallpox exacted a terrific toll of life in 1838, sweeping across the entire length of the Aleutian chain and actually accounting for the terrible death of half of the Alaskan population. Prior to this time explorers sailing along the coastline were surprised to find pox-marked Aleuts around 1786 and attributed this onset to a visit made by the Spaniards ten years earlier. With such menaces lurking in every direction Petroff was indeed surprised to find the rare Aleut who had reached the age of fifty. Such a discovery in any tribe gave proof to the fact that this person must have been one of rugged constitution in early life. Although freed of the major ills, very few people escaped the annoying complaints of eye disease and possibly rheumatic pains. The former was attributed to the smoke-filled huts, or *barabaras*, which gave rise to almost continuous eye irritation. Many of the women folk used their eyes incessantly for fine needlework and now world-famous basketry in a poor light, and thus visual acuity was greatly diminished early in life. The villagers successfully treated occasional nosebleeds by bending the distal phalanx of the small finger — on the side corresponding to that of the nares emitting blood — on itself and tying it in such a position.

Owing to the rocky terrain, many bare feet of the Aleuts were cut by sharp stones, and it was not unusual to see one man, using a bone needle and sinew, sewing up the wound of another while the patient sat complacently holding his foot in position. To exhibit no outward sign of pain was a mark of merit and strength. Severe cuts and burns were

usually treated with warm fish oil, warm fresh fox grease or some similar substance. Deep wounds were dusted with parched powdered teeth, the hole being covered with a fresh skin of a mouse. Fractured bones called for the use of splints made from animal bones or driftwood.

In the treatment of dangerous wounds or diseases the Aleut employed both patience and diet. Such conditions were supposedly aided by a complete fast — allowing not one drop of water or any food for two to four days in sequence. To one in such a state, it was believed that food and drink led inevitably to inflammation and death. The intimate knowledge of the use of herbs was essential in the treatment of some ills. For swellings and rheumatic pains various poultices and warm, baked roots were used locally. Fevers were "cured" with bitter concoctions, and diarrheas with astringent herbs. Sore throats and stomach aches were also amenable to similar brews. Warm roots were applied to the chest of one who had complained of pain therein. Some of the local village doctors went through the motions of attempting to sew the lung up inside by actually sewing with thread a small area of the chest overlying the pain. A form of cupping was also used, suction being applied by way of mouth.

Lancing came into practice for cure of chest ailments, and only the artful medicine man, whose skill was handed down from generation to generation, was permitted to do this. Stone points were used, and a thorough knowledge of where and how deep to cut was essential. Only critical conditions were treated in this manner. Even colic was said to have been beneficially aided by such a maneuver. At times a slight degree of lancing over any affected area or organ was of noted aid. Blood letting from both hands and feet was a common practice for tiredness, feebleness, loss of appetite and headache. Another form of treatment in common employment was "holding." Practiced by the older women doctors, this consisted of bringing into the proper anatomic order and laying into place all the apparently affected internal organs of a given illness. Such manipulations have not gone without praise even today. The doctor today utilizes his sense of touch to a commendable degree in the diagnosis of various ills. I have seen hypertension suspected because the pulse in a small temporal artery seemed much stronger than normal.

The treatment of kidney trouble is noteworthy. If a person could not urinate he was placed in a vat-like structure of warm water. The water was heated by a small fire under the tub-like apparatus and kept warm by a deposition of sand in the bottom. Another practice, which is still used, is the giving of a glassful of water previously strained through a cloth containing cracked glass. It is thought that this water contains small particles of the glass, which in turn will clean out the small tubes in the kidney itself. Such a belief gave a clue to the fact that the early Aleut had a knowledge of human anatomy.

gleaned, no doubt, from his experience in preparing mummies and his habit of examining the organs of rivals killed during battle. Lutke, in 1827, mentioned this detailed study and knowledge of the anatomy of the human structure. Whether or not the Aleut recognized the difference between an artery and vein before Harvey's time and the circulation of blood is a debatable and interesting point.

Pregnancies were guided to completion by some older woman or female relative. Usually, each village had a midwife schooled in her duties by an older woman. To have her baby resemble a certain person, the pregnant woman had to visualize this person every time she ate or drank. Now and then she underwent the "holding" routine in which everything was put into its proper place. As soon as the child was born the mother was made to assume the squatting position, not being allowed either to lie or to sit down. After the placenta was discharged with the help of abdominal manipulation, the mother's abdomen was tied with a belt or cloth. In turn, she was usually carried to another position and propped up by pads into a squatting position where she remained for four days. On the fifth day she was washed and permitted to lie or sit down but not to stretch her legs. For forty days she was considered unclean and was not allowed to touch anything edible except for her own food, nor could she see any men. If the baby did not resemble the father, family discord, maltreatment and divorce resulted.

At the beginning of menstruation usually at fourteen years of age, every girl was immediately segregated in a special corner of her *barabara* so constructed by the hanging of a curtain or a matting. Small pieces of string were tied around each joint, and she was not allowed out of her corner for any purpose. Usually, she was given plenty of twine or yarn to knit. Visits were made only by her mother or close female friends, and she could show herself to no man. For forty days she remained in the same condition, and was finally allowed to leave to bury her pads but was not permitted to look at the sun. For ten more days she spent her time alone cleaning the house from top to bottom. At this time she was usually taken to the side of a sick boy and thus was able to utilize the curative powers that she thought to manifest at that time. Finally she was freed. If such a tradition went unnoted, it is said that the young lady would eventually turn black as coal and become afflicted with various communicable diseases. Also, unfulfillment of such obligations would drive all living fish and animals away from that particular village, with subsequent starvation of the inhabitants.

EXPEDITION OF 1948

During the summer months of 1948 I had the privilege of accompanying a group of scientists from Harvard University's Peabody Museum into

this unique region. Such an opportunity was afforded me through the generosity and encouragement of Dr Paul D. White. The purpose of the over-all project was an anthropologic and archeologic evaluation of the existent Aleutian culture, and although the medical program dealt primarily with cardiovascular problems, an opportunity to observe the changing customs and trend of disease was afforded the observer.

Evaluation of the dental problems was made by an orthodontist, Dr Coenraad Moorrees, of the Forsyth Dental Infirmary in Boston, and I am indebted to him for any dental information presented.

The population of two villages was studied — people of Nicol'ski on the island of Umank, one of the Fox Island group, and of Atka, a village of the Andreanov Islands. The former included 51 persons, 31 males and 20 females. The average age of the males was twenty-six and one-tenth years, and that of the females twenty-seven and one-tenth, the average age for both sexes was twenty-six and six-tenths years. Of this group, 4 males and 7 females were ten years of age or below, whereas 3 males and 4 females were above fifty years, the average age for both sexes was twenty-five years. The trend of the present rate of reproduction can be seen here. The latter village, Atka, added 66 people to the survey — 33 males and 33 females. The average age was twenty-six and two-tenths years for the males and twenty-four years for the females. Nine males and 8 females were ten years or below, whereas 4 males and 2 females were fifty years or above. All the inhabitants of Nicol'ski were included in 9 family name groups, whereas 11 family names embraced all Atkans. Of these 9 family groups at Nicol'ski all had been visited by tuberculosis, 5 by venereal diseases, 6 by pneumonia, 1 by possible cardiac disorder, 1 by possible cerebral thrombosis, 1 by diphtheria, and 4 by tonsillitis within the past two decades. Tuberculosis claimed as many as 4 victims in 1 family within this period. At Atka of the 11 families 9 were afflicted by tuberculosis, 6 by venereal disease, 6 by pneumonia, 1 by possible renal disease, and 1 by possible heart disease. These diseases of the past were quoted from death records and old church records, together with verbal histories available at the time.

With such a background, physical examinations carried out were most revealing. Steller, a botanist who accompanied Behring on his memorable voyage in 1741-42 described the typical appearance of the average Aleut as follows:

He is of medium stature, strong and square built with muscular arms and legs. The neck is short and the shoulders broad. The complexion is a ruddy one. Theirs is mostly glossy black hair with only a scant beard or none at all on the chin. In this fact they are similar to the inhabitants of Kamchatka and to other East Siberian natives.

Physical examination revealed the average blood pressure at Nicol'ski to be 128 systolic, 74 diastolic, and that at Atka to be 119 systolic, 72 diastolic. At this point it may be interesting to note some blood pressures taken at typical Eskimo villages (Table 1) and made available to us through the generosity of Miss Heller, a member of the Territorial Department of Alaska. These data are of interest because the anthropologists now believe that the Eskimo is closely related to the Aleut. The average pulse rate among male Aleuts was 66 and that among the females 71. A survey of rampant diseases as evidenced by clinical findings

TABLE 1 Blood-Pressure Values of Eskimo Peoples in 6 Villages and 1 School*

*Total of 296 cases

disclosed that tuberculosis, venereal disease, scabies, refractive errors of the eyes, trachoma and dental caries were most prominent. Hypertension (blood pressure above 140 systolic, 90 diastolic, in a moderately young subject fifty years of age or below) was found in only 1 person at Nicol'ski, a forty-three-year-old man with a blood pressure of 204 systolic, 110 diastolic, in the upper extremities and 100 systolic, 72 diastolic, in the lower extremities. He was suspected of having a mild degree of coarctation, and although there was no x-ray apparatus to substantiate this diagnosis, the presence of intercostal pulsations, lack of femoral pulsations, an enlarged heart by percussion, a hypertensive electrocardiographic picture and a lifelong history of trouble with his health led one to suspect that disease. Another man, sixty-six years of age, had a blood pressure of 180 systolic, 100 diastolic, with no clinical signs or symptoms. Table 2 presents the relative percentages of diseases found at both villages. Other conditions included vitiligo, keloid formation, arcus senilis, folliculitis, alopecia, feeble-mindedness, varicosities, kyphoscoliosis, pterygia, a case of possible carcinoma of the stomach, a case of probable beriberi resultant from a long-term period of involuntary encampment in Japan during the war and a case of duodenal ulcer proved by x-ray study in an Army camp. Menstrual disorders were prominent. Cardiac and renal disorders, cirrhosis and multiple avitaminosis were also noted. The degree of dental caries was deplorable. The majority of people had mutilated teeth because of dental decay and subsequent extractions. Mandibular prognathism, with

resultant dental malocclusion, was present to a considerable degree. Gingival and periodontal disturbances and the presence of calculus were found only occasionally. It has been stated by the old native Aleuts that before the advent of sugar and starches the condition of the teeth was excellent and that caries per se was relatively unknown. Such a belief seems to be borne out by the discovery that the teeth found in the skulls of the early Aleuts were without caries as it is now known. Scabies was more pronounced in Atka. This infestation was traced back to the World War II, when the Atkan Aleuts were evacuated to southeastern Alaska. Since that time all attempts to control this problem have been unsuccessful. The general morale seemed to be at a low ebb in this village, possibly because of a shortage of food at the time of the survey and a high incidence of disease and inebriety.

Much more investigative work will have to be done on the dietary program as it exists in this region. At the present time suffice it to say that these people maintain the present degree of nutrition on a diet consisting chiefly of fish and seal meat, sea-lion meat, duck, geese, reindeer meat, blubber and very few vegetables and green foods. They have little if any fruit and very little milk, together with a rather sparse supply of sugar and flour. In a preliminary analysis this diet was relatively high in protein, low in carbohydrate and moderate in fat. Vitamins A, B and D were of a low normal value. Vitamin C was extremely low,

TABLE 2 Diseases among 117 Patients Examined

DISEASE	INCIDENCE AT NICOL'SKI	INCIDENCE AT ATKA
	%	%
Tuberculosis	17.0	22.0
Venereal disease	19.0	17.5
Scabies	0.5	20.0
Hypertension (blood pressure, 140/90)	1.9	0

Renal disorders	0	1.0
Cataract	3.9	1.0
Refractive error	23.5	16.0
Cirrhosis	0	3.1
Trachoma	0	6.3

and calcium and iron were both low. The average nutritional value as estimated at present is approximately 800 to 1400 calories per day. Under this regime the average Aleut cannot work hard without a loss of weight and energy, according to American standards. Luckily, at present he does not have to do much to survive in his communal system of living. Before any criteria of comparison are presented, it must be mentioned that results employing American standards would be subject to question because of the short extremities of the Aleuts, both children and adults. With this in mind one can state that the ratio of weight to height in children was high, the absolute weight averaging less than

one standard deviation below what would be expected for comparable normal white American children. The absolute stature, however, was about three standard deviations below average. In adult the ratio of weight to height seemed to fall within normal limits. Further dietary studies will be forthcoming in a subsequent report.

Various chemical studies were carried out on these fish-eating and meat-eating peoples. It was surprising that of 66 nonprotein nitrogen determinations carried out on the Atka people the average result was 59.5 mg per 100 cc; urinalyses were within normal limits. The total proteins in these same people averaged 7.02 gm per 100 cc. Cholesterol determinations were done on 51 Nicolai people and 66 Atkians. The average was 176 mg per 100 cc for the former and 197 mg per cent for the latter. Almost immediately after the blood had been taken the serum was separated by means of a hand-powered centrifuge, stored in the cold, and sent to the Massachusetts General Hospital within a week for analysis. Miss Rourke and her staff at the Chemical Laboratories of the hospital ran a series of controls on cholesterol determination after the samples had been standing one, two, three and four weeks and showed thereby that variations from the original result in this period were negligible, as suspected.

Determinations of basal metabolic rates were attempted but were highly unsatisfactory because of the marked prognathism and the fear of the Aleuts in the use of the apparatus. Furthermore, it was thought that this method would surely be a dangerous procedure in this region of active tuberculosis. Determinations on 17 adults ranged from -10 to +17 per cent, however.

Electrocardiograms were done on the entire group, three limb leads and three chest leads (CF₁, CF₂, and CF₃) being employed. One case of paroxysmal auricular fibrillation in a woman of fifty-one years with no apparent structural cardiac disorder was found and this reverted to normal rhythm under the use of 0.4 gm (6 gr) of quinidine every two hours for five doses. One case of right-bundle-branch block was found in a man of forty-eight with no signs or symptoms of organic cardiac damage. The forty-three-year-old man with suspected mild coarctation exhibited a moderate degree of left-axis deviation with a low upright T wave in Lead CF₃ in the electrocardiogram. All the remaining tracings fell within the realm of normal.

For some time it has been shown by the anthropologists that most peoples of the New World have blood type "O" whereas Asiatics generally exhibit blood type "B". Therefore, it would be of great interest to know the blood types of the Aleut peoples, to achieve this aim one of the group, Dr William Laughlin, of the Peabody Museum, typed everyone included in the series. Table 3 gives the results. Of note is the fact that the New World probably

was the point of origin of the Aleutian Islanders before migration. This is substantiated by the low value of the subgroup "n". Dr Laughlin has also been utilizing a method to determine the blood types of skeletal remnants on all specimens brought back to Harvard's Peabody Museum, although a report cannot be given now it will probably be ready soon.

At present the health of the native Aleuts concerns chiefly the jurisdiction of the Alaska Native Service. Each island is visited by the Government health boat, the *Hygieia*, about once every year or two, depending upon the weather and so forth. During this time as much medical and dental work as possible is crowded into the ten days or two weeks spent at each village. The medical personnel aboard Coast Guard boats give readily of their time and facilities at whatever village they may happen to visit during their course of duty. The time spent at various islands is so short, however, that their work is restricted to the emergency category. The

Army and Navy installations have also been most generous with their aid to any Aleut requiring attention, although it is not their explicit duty to provide such care. Lastly, each Government school-teacher has been instructed in the general principles of first aid and has on hand certain of the more useful medications to treat the ill. However, all these measures seem inadequate when the end result is studied. The Aleut has not fared well with the introduction of the white man's culture and needs help desperately not only in organizing a social structure that can cope with the new problems and demands but also in preparing the proper environmental soil in which such a social reformation will thrive. The Aleut, for the most part, is also a spiritually ill person who needs the active guidance of some social or religious organization, Russian Orthodox faith or other, that will renew in him the spark of hope and the time-tested tenets of a good life.

SUMMARY AND CONCLUSIONS

Data on the present health status of 117 Aleutian Islanders are presented. The findings will be analyzed in subsequent reports.

In some parts of the world there no doubt live groups of people who exhibit the exact basic criteria

for an excellent control in many of the experiments of crucial value in present-day researches, and much can be learned by spending some time among these people, living close to them and observing their habits and customs so that progress in all fields of endeavor can be made. Such a variation of organized analysis and investigation has not to the present been utilized to its best advantage.

The introduction of the white man's culture in an area not properly receptive to the change because of a social and economic structure inadequate to absorb the impact can be definitely detrimental

to the persons involved. This has been the situation in the Aleutian area, and it will need to be amended before progress along any line of endeavor can be expected.

§Attending surgeon, Marlborough Hospital, Marlborough, Massachusetts.

orrhagic suprarenal infarction, acute hemorrhagic adrenalitis, spontaneous suprarenal hemorrhage and suprarenal apoplexy have been suggested

Table 1, in which the pertinent data of the 19 cases of the literature (including the 1 presented below) are shown in comparison, reveals the condition to be twice as frequent in the male as in the female, without any apparent relation to age, the youngest patient being a girl of seventeen and the oldest a man aged seventy-four years. In 16 cases the site of the hemorrhage was the right adrenal gland, in 1 case the left and in 4 both adrenal glands were involved by the process. No information about the site of the lesion was given in the remaining cases. Considering that the right adrenal vein drains directly into the vena cava (the left goes to the left renal vein), it has been postulated that this is the reason for the more frequent involvement of the right adrenal gland.

As for the mechanisms underlying the process, in 6 of the 19 cases no cause was apparent. In 1 case the hemorrhage developed eleven days after a burn (Arnaud⁴). Trauma was obviously the factor in one of the 2 cases of Thorstad¹⁴ in which there

were cases of MacMillan,¹⁶ Edelman¹² and Michaux and Marsset.⁶ There was a history of questionable grippe in the case of Williams and Ellis.¹¹ A co-existent bronchiogenic carcinoma was present in the case of Altschule,¹⁰ but there was no evidence that the adrenal glands were the site of metastatic involvement. Pancreatitis was present in Lavenon's⁴ case, and the possibility cannot be ruled out that necrotic changes in the retroperitoneal fat had followed the development of this condition. In 5 cases, including the one presented below, the adrenal hemorrhage developed in the course of a pathologic pregnancy—a combination that makes one suspect something more than a mere coincidence.

CASE REPORT*

A 22-year-old primigravida was admitted to the Marlborough Hospital on October 19, 1947, because of pain in the right side of the abdomen, more accentuated at the right costovertebral angle.

The patient had first been seen by one of us (A.G.R.) 75 days previously, when she was 2 1/2 months pregnant. The blood pressure was 150/80, but except for slight intermediate morning nausea and some urinary frequency she had no complaints. She had had the usual childhood diseases without complications, and there was no history of previous hospital-

*Probably the first successful operation (1936) for adrenal hemorrhage in an adult although report published later (1946) than that of Edelman¹² (1945)

was coexistent renal tuberculosis. A condition of long-standing hypertension, arteriosclerosis and chronic nephritis undoubtedly played a role in the

ization, accidents or injuries of any sort. The family history was noncontributory. Urinalysis was negative for sugar and

*The study of this case was made possible by Dr. C. G. Tedeschi, Director, Department of Laboratories, Framingham Union Hospital, to whom we express our appreciation.

albumin, the specific gravity was 1.024, and the sediment failed to reveal casts or cells. Nineteen days before admission she was seen again for a dull, intermittent discomfort in the lower back, accentuated by prolonged standing or walking and almost completely relieved by lying down. The blood pressure was 158/70, the temperature was 99°F, and the pulse 114. Urinalysis was negative. On the morning of October 17, on awakening from sleep, she had experienced an increase in the severity of the backache, accompanied by moderate urinary frequency and urgency. She attempted to do some housework but was unable to do so. She returned to bed and remained there for 24 hours with almost complete relief of back discomfort. Six hours prior to hospitalization she began to note abdominal pain that was maximum at the level of and to the right of the umbilicus. This shortly was accompanied by pain in the right costovertebral angle. Hospitalization was deemed advisable.

Physical examination revealed a patient who appeared ill and asthenic, was in obvious distress and complained of pain in the right flank and right middle portion of the abdomen. The skin and the mucous membranes of the lips and of the oral cavity were moderately pale. The abdomen was distended and tender in the right middle quadrant and right flank, with moderate spasm and rigidity in these areas. The uterus was enlarged to the level of the umbilicus. The fetal heart could not be heard. There was no evidence of vaginal bleeding, and rectal examination was negative.

The temperature was 100.2°F, the pulse 120, and the respirations 25. The blood pressure was 160/70.

Examination of the blood disclosed a red-cell count of 4,200,000, with a hemoglobin of 76 per cent, and a white-cell count of 12,050, with 76 per cent neutrophils, 20 per cent lymphocytes, 2 per cent monocytes and 2 per cent eosinophils. Urinalysis was negative.

With the preoperative diagnosis of acute appendicitis, the abdomen was opened through a right-lower-quadrant, pararectus incision. A large amount of serosanguineous fluid flowed from the abdominal cavity. The uterus was enlarged to the size of a 5 months' pregnancy. The appendix, when delivered into the wound, was normal. There was free oozing of blood from the right ovary, in which a number of raised, reddish nodules, suggesting endometrial implants, were visible. The oviducts and the left ovary were normal. The upper abdomen could not be examined owing to the pregnant uterus and the small size of the incision. The appendix was removed, together with small pieces of tissue from the bleeding ovary, and the abdomen was closed in layers with no drainage.

Pathological examination of the specimens showed the appendix to be normal, formations suggesting endometrial implants were recognized in the pieces of ovarian tissue. The patient continued to complain of pain in the right flank, and the abdomen became tympanitic and moderately distended. Penicillin and corpus luteum extracts were given. The temperature, pulse and respirations were within normal limits. The blood pressure was 140/60. On the next day the situation was unchanged. Examination of the blood on the third day showed a drop in both the hemoglobin, which was 67 per cent, and the red-cell count, which was 3,150,000. The urine was normal. In the meantime the temperature had risen to 102°F. The pain in the costovertebral angle had become sharp.

On the 4th day the condition became progressively worse. The abdomen was markedly distended, but there was no nausea or vomiting. The blood pressure had dropped to 134/60, and the red-cell count was 1,950,000, with a hemoglobin of 39 per cent. The patient was still rational and alert.

With the possibility in mind of an intra-abdominal bleeding, the patient was again operated on. Under nitrous oxide, oxygen and ether anesthesia a midline subumbilical incision extending right to the level of the navel was made. A large amount of serosanguineous fluid was free in the abdominal cavity. The implants on the right ovary had shrunk and now appeared as pale gray, slightly raised, flabby nodules. The left ovary was normal, and no change was noticed in the broad ligaments, oviducts or uterus. The left kidney was palpated and found to be normal. The right kidney, however, was encompassed by a semisolid mass, which extended from its lower pole up to the diaphragm, displacing the liver anteromedially. At this time the patient began to breathe laboriously, the pulse became rapid and feeble, and the blood pressure started to drop until it became unperceivable. All possible

resuscitation measures were applied without result, and the patient died.

Post-mortem examination* 2 hours after death revealed the body of a well developed, well nourished, extremely pale young woman. Except for the two abdominal incisions no external injuries or lesions of any kind were seen. The abdominal cavity was filled with a serous, sanguineous fluid in which a few blood clots were floating. The peritoneal membranes were blood tinged but smooth and glistening. The intestinal loops were inflated but otherwise not remarkable. The pregnant uterus, oviducts and ovaries were normal. The right kidney was encased by a large, reddish-brown, fluctuating mass, 20 cm long and 10 cm thick, of partly clotted and partly fluid blood. Section through this mass revealed a large, swollen, hemorrhagic adrenal gland, 7 cm long and 2 cm thick. It was ruptured at one pole and covered by a thick clot of blood. On section, the limits between cortex and medulla could hardly be recognized owing to infiltration of blood. Small islands of golden-yellow tissue, the size of a pinhead or a little larger and suggesting chromaffin tissue, were found adjacent to the ruptured pole of the gland. The other adrenal gland was intact, and none of the other abdominal organs showed changes of significance. The kidneys together weighed 280 gm., and except for a marked pallor neither appeared to be unusual.

Examination of the brain and organs of the chest was not permitted.

Microscopical examination of the right adrenal gland showed both cortex and medulla to be widely infiltrated by well preserved red blood cells, with almost complete obliteration of any normal structure. Large collections of polymorphonuclear leukocytes were noticeable here and there, most numerous in the proximity of yellowish-brown granules of bematic pigment, either free or in large macrophages. A middle-sized vein, close to the hilus, was found almost completely occluded by a recent thrombotic mass, which consisted mainly of blood platelets and of cellular debris imbedded in a structureless eosinophilic material. The vessel wall was swollen by edema and displayed moderate perivascular infiltration by granulocytic cells. The left adrenal gland was intact, and no significant deviations from the normal were shown by the sections from the liver, spleen, kidneys or gastrointestinal tract. No endometrial implants were revealed in the ovaries. The placenta showed small hemorrhagic infarcts.

DISCUSSION

From the study of the vascular supply of the adrenal gland in nearly 400 bodies Anson and his associates¹³ concluded that far more than the usual three arteries depicted in the standard textbooks—often as many as fifty—are present in each gland, all draining into a single vein. If this is the case one wonders why vascular accidents, followed by infarction of the gland, do not occur more frequently. It seems that both increased blood pressure and venous occlusion by the thrombus may have played equally important roles in causing the fatal hemorrhage in the case reported above.

It is difficult to conceive any correlation between the endometriosis and the adrenal hemorrhage, other than a coincidence.

A bearable, persistent pain, made worse by motion, and localized hyperalgesia characterized the onset of the condition in the case described above. As in those reported by others, absence of purpura, which is constant in the Waterhouse-Friderichsen syndrome, is a point of interest.

With the increased oozing of blood into the tissues of the perirenal region the signs and symptoms proper to intra-abdominal hemorrhage made their appearance. At this stage, the pain, which was

*Performed by Dr. C. G. Tedschli.

mainly referred to the infarcted area, became sharp. Pallor and prostration and drop of blood pressure were signs of the impending collapse.

Inasmuch as adrenal hemorrhage, if left alone is fatal, the only choice is prompt recognition of the condition, followed by surgical intervention. If we had thought of this possibility and properly explored the adrenal regions at the time of the first operation, perhaps the patient's life could have been saved. This case strongly emphasizes the necessity of including adrenal hemorrhage in the differential diagnosis of any uncertain abdominal situation. If this will be kept in mind it is hoped that other reports of successful interventions will be added to the 2 cases so far reported in the literature.^{12, 15}

SUMMARY

A fatal case of intra-abdominal hemorrhage following infarction and rupture of the right adrenal gland in a twenty-two-year-old woman, in the fifth month of pregnancy, with a history of moderate hypertension, is reported. The death is explained by increased blood pressure, complicated by thrombotic occlusion of a relatively large venous branch of the gland. A condition of endometriosis in the

right ovary — a most extraordinary and misleading coincidence — was present. The 18 cases previously described in the literature are reviewed and analyzed.

PROPHYLAXIS AND TREATMENT OF HEAT-REACTION STATES

LOUIS FRIEDFELD, M.D.*

NEW YORK CITY

DURING a severe heat wave in the summer of 1937, 8 of the aged residents of the Home of Old Israel in New York City succumbed in a single day under circumstances that left no doubt that the high environmental temperature was the precipitating cause of death. During the much more severe heat wave in August, 1948, not a single death occurred in the same institution although the mortality rate for the city as a whole was higher than that in 1937. It is believed that the reason for the difference is that the unfortunate experience of 1937 had led to more systematic prophylaxis and treatment of heat-reaction states. This paper presents a discussion of the methods followed since 1938 that have resulted in the striking reduction in the mortality from these conditions in the eleven succeeding years.

MAGNITUDE OF THE PROBLEM

None of the eight deaths that occurred on the fourth day of the heat wave in 1937 could have been anticipated on the basis of previous medical status, although most of the fatal cases occurred

in patients convalescing from infectious or vascular disorders. In several cases the immediate cause of death was heat stroke with hyperpyrexia, in others, heat exhaustion initiated a rapid downhill course. At the same time, other institutions in the metropolitan area had comparable experiences, and there was a sharp rise in the general mortality rate for the city of New York. Similar findings were reported from other cities.¹

Again, in the latter part of August, 1948, there was a severe and prolonged heat wave that affected a large portion of the country and contributed to a serious rise in the general and infant mortality rates. Although this did not approach the situation in Peking in July, 1743, when 11,000 persons are said to have perished on the streets from the effects of the heat,² New York City reported twice as many deaths for the week ending September 3 as for the corresponding week in 1947, or the preceding week in August, 1948 (Fig. 1). Table I shows the temperatures and deaths in August, 1948.

The importance of this heat-related mortality increase was further emphasized when it was noted that the last time that the weekly death rate had exceeded the expected death rate by over 100 per

*Adjunct in medicine, Beth Israel Hospital; chief of medicine, Home of Old Israel.

cent was in February, 1920, when the third wave of the devastating influenza epidemic of 1918-1920 hit the city

Forty-one homes for the aged in New York City, with a total census of 6688, responded to a questionnaire on the effects of the heat wave that began on August 23, 1948. The total deaths for the control period of August 11 to 20 were 25, whereas the deaths from August 21 to 30 rose to 68, an increase of 172 per cent. In the latter group 82 per cent occurred in the four days beginning with August 27, during which all the 14 cases of heat stroke also occurred. In 22 cases deaths were reported from other causes,

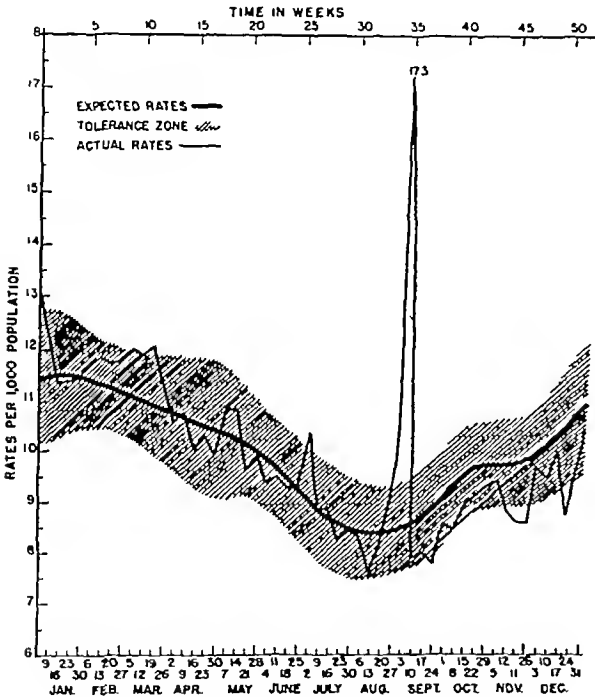

FIGURE 1 Deaths from All Causes City of New York, 1948 (Based on Data Supplied by Statistical Division, Bureau of Records and Statistics, Department of Health, New York City)

environmental heat effects contributing to the final outcome (Table 2)

After a study of the cases of heat reaction in 1937, a regimen was instituted at the Home of Old Israel for the prophylaxis and early treatment of these conditions. The results have been most gratifying, for there has been no recurrence of group deaths in the past eleven years, including the severe heat wave of 1948

TYPES

The symptom complexes that result from extreme summer heat are generally classified as heat cramps, heat exhaustion and heat stroke. In the condition known as "sunstroke," the clinical picture of either of the last two syndromes may appear. Heat ex-

haustion appears when peripheral circulatory failure due to vasomotor disturbance predominates, heat stroke results from the failure of the sweating mechanism through involvement of the hypothalamus, causing hyperpyrexia. Heat cramps do not terminate fatally, the mortality of heat reaction re-

sults from either heat exhaustion or heat stroke. The statistical breakdown between these two conditions seems almost impossible because of difficulties in diagnosis, the tendency to report pre-existing chronic conditions as the primary cause of death and the inclination to reject a diagnosis whose report would automatically result in a medical examiner's inspection.

Heat Cramps

Under normal conditions more than 95 per cent of salt is eliminated by the kidneys,³ but in heat cramps, the mildest of the heat-reaction states, there is a depletion of sodium chloride as the result

TABLE 2 Causes of Death for the Week Ending September 3, 1948, Compared to the Expected Average per Week for August, New York City*

*Based on data supplied by Statistical Division, Bureau of Records and Statistics, Department of Health, New York City.

of excessive perspiration. This is particularly common in an atmosphere of low humidity that facilitates the rapid evaporation of sweat.⁴ Excessive ingestion of water during periods of active perspiration may enhance this salt depletion by causing additional loss of salt in the urine. Low-salt diets,

diarrhea and diuresis also predispose to this condition. With acclimatization, the salt content of the sweat is reduced.⁵

In heat cramps there are painful contractions of the voluntary muscles of the extremities and the abdominal wall.⁶ Nausea and vertigo may be present. This condition can be prevented by the prophylactic ingestion of salt, or corrected readily by removal of the patient from the hot environment and administration of saline solution by the oral or intravenous route. There is no elevation of body temperature and no significant mortality.

Heat Exhaustion

During heat exhaustion, in addition to heat cramps, there may be peripheral circulatory collapse, nausea, vomiting, scanty urine, headache, giddiness and anorexia. Profuse sweating and sodium depletion are contributory factors. The skin may be cool, moist, pale or cyanotic.⁷ Body temperature may be normal, slightly elevated or slightly lowered. In previously normal persons there is generally no direct mortality, especially if the patient is removed from the excessive environmental heat. However, in the aged or those suffering from infections or chronic debilitating diseases, there may be a significant rise in the mortality rate that would commonly have been attributed to the pre-existing condition. This may account for the drop in the general death rate in the weeks following a heat wave (Fig 1). Many of the patients who succumbed during the period of excessive heat included those suffering from diseases that would ordinarily have been listed in subsequent death reports. Susceptibility to heat exhaustion varies with physical condition and the presence of alcoholism, but the aged are particularly vulnerable, especially those who suffer from debilitating diseases or circulatory impairments⁸ (Table 2).

Heat exhaustion may be prevented or controlled by limited exposure or exertion in high environmental temperatures, adequate hydration and an increased salt intake. The amount of salt depends upon the condition of the patient, the degree of excessive perspiration and the ability to restore an output of at least 30 ounces of urine. Although an increased daily ingestion of 5 gm of salt ordinarily suffices, in extreme cases the need may rise to 50 gm a day. In the active treatment of heat exhaustion, aside from removal of the patient to a cool place and administration of salt and water, specific treatment may be indicated to combat a state of shock.^{9, 10}

Heat Stroke

Heat stroke is an acute disease due to prolonged excessive environmental temperature causing a derangement of the heat-regulating center of the hypothalamus, and characterized clinically by the cessation of sweating, hyperpyrexia and central-

nervous-system disturbances. This is the most serious of the heat-reaction syndromes, and may be solely responsible for mortality directly caused by excessive environmental heat in previously normal persons. It is also known as heat hyperpyrexia. Watts¹¹ was among the first to note that the body temperature was elevated in major heat affections. Salt depletion is not an important factor in this condition, which is even more likely to appear when high humidity reduces the degree of body heat dissipation through lessened sweat evaporation. The sudden cessation of sweating is the important premonitory sign,¹² and the lesser heat syndromes need not coexist. The importance of the cessation of sweating is appreciated when it is recalled that this is the sole method of heat dissipation when the environmental temperature exceeds 95°F,^{13, 14} and that in the evaporation of 1 liter of sweat, 580 calories are absorbed.¹⁵ Conduction, convection and radiation, which perform 70 per cent of this function at ordinary temperatures, are no longer effective.^{16, 17}

After several days of extreme summer heat there is a sudden cessation of sweating — a premonitory sign that warrants emphasis. Although there may be increased urination, headache, weakness, nausea or faintness, the clinical condition may be precipitated with sudden collapse and coma. Unless shock is present, the skin is hot, dry and flushed. The body temperature rises sharply and may exceed 106°F. There may be convulsions, cyanosis, vomiting, incontinence, delirium or stupor. Although tachypnea is noted at first, Kussmaul breathing may supervene, and the Cheyne-Stokes type of respiration may be preterminal. Patients who remain ambulatory commonly have a staggering gait. There are difficulties in speech or swallowing, along with dryness of the mouth and excessive thirst. Lower-nephron nephrosis has been reported.^{18, 20} Persisting coma or delirium has grave prognostic significance.²¹

The mortality rate due to heat stroke is high, particularly among infants, the aged, those suffering from infections or chronic debilitating conditions,²² and those engaged in physical activity while exposed to excessive environmental heat. In a large series of patients admitted to a general hospital with heat stroke, the mortality was 44 per cent.²³ In the aged the rate is significantly higher. Most of the cases begin to appear about the third or fourth day of a heat wave. After the cessation of sweating and the onset of hyperpyrexia, over 70 per cent of patients die in less than twenty-four hours.⁶ Mortality figures for white people are many times higher in the North Central states than in Florida,²⁴ but this may be due to the effect of seasonal variations on acclimatization.²⁵ Although Negroes appear to be more vulnerable than white people, and males more often affected than females, occupational activities and outdoor exposure may account for these differ-

ences It is significant that half the deaths from this cause in the United States have occurred in persons over sixty years of age, whereas 45 per cent, the highest in any single year, occurred below one year of age The factor of individual susceptibility must also be considered

In the genesis of heat stroke, prolonged exposure is more important, to an extent, than the degree of elevation of environmental temperature This may be related to a suggested cause of heat stroke, such as exhaustion of the heat-regulating center of the hypothalamus^{12, 26, 27} After recovery from one attack of heat stroke an increased susceptibility to recurrences remains²¹

PROPHYLAXIS AND TREATMENT

During the 1937 period of extreme summer heat, the significance of the premonitory cessation of sweating in the development of heat stroke was apparent As a result, the early detection of this sign became an important part of the regimen that was instituted for the management of the aged Although some deaths still occurred among persons debilitated by severe infections or degenerative disorders, the frequency was greatly decreased, and deaths due to heat stroke among the physically well in the aged population were practically eliminated

Heat-Wave Regimen

In this heat-wave regimen, light, airy clothing is distributed, frequent bathing and proper skin hygiene are encouraged, physical exertion and prolonged outdoor exposure during midday are discouraged, rest periods in well ventilated rooms are arranged, a light diet with increased carbohydrate and decreased protein is prepared, salted foods are added to the diet and salt tablets distributed at regular intervals, plenty of drinking water and citrus-fruit juices are made available, supplementary vitamin preparations are furnished, and sweat rounds are conducted

Sweat rounds have been a significant feature of this program, even as the use of an oxygen tent has been most helpful in the treatment of these cases Several times each day the resident staff routinely inspects all the aged in hospital quarters, as well as those reported ill among the ambulatory This searching out of the characteristic premonitory sign has been helpful in permitting early therapy in heat stroke

When a dry skin is noted, even though the body temperature is normal and there are no associated symptoms, the patient is put to bed and clothing is removed Since air-conditioned rooms are not available at the institution, sponge baths are given frequently, and fans are used to maintain air circulation The increased drinking of water and ingestion of salt is encouraged When necessary, salt solutions are administered intravenously

If sweating does not return in a short while, or if fever is present, the patient is placed in an oxygen tent Here the air is cooled to below 50°F, air motion is maintained, and low humidity levels are obtained The increased oxygen tension also is helpful because of the marked rise in metabolism Generally, this treatment suffices However, if hyperpyrexia supervenes, the patient may be wrapped in cold wet sheets or sprayed from a water nozzle, and fans directed against the body surface¹ Iced tub baths may be used,²⁸ but shock and death have resulted from this drastic procedure In the latter method, the skin must be massaged while the patient is in the tub This friction maintains the skin hyperemia, otherwise the overheated blood would be driven to deeper areas⁹

The control of the central-nervous-system symptoms and the lowering of the temperature, along with the reappearance of sweating, are hopeful prognostic signs However, even after sweating is restored and the temperature returns to normal, relapses may occur¹² If sweating returns but fever continues, an intercurrent complication is to suspected

SUMMARY

Significant morbidity and mortality result from prolonged exposure to extreme environmental heat Heat cramps, heat exhaustion and heat stroke are described The differences in the therapy of heat exhaustion and heat stroke are considered The importance of sweat rounds is discussed in a regimen for the prophylaxis and treatment of the hyperpyrexia

It is pointed out that cessation of sweating is a highly characteristic premonitory indication of the onset of heat stroke During heat waves, careful observation of patients in a home for the aged for the early detection of this cessation of sweating and the immediate institution of appropriate therapy have enormously decreased the incidence of mortality due to heat stroke The benefits derived from the early use of an oxygen tent are described

MEDICAL PROGRESS

PREVENTIVE MEDICINE*

MIRIAM D MANNING, M D †

BOSTON

SEVENTEEN centuries ago Aretaeus¹ of Capadocia made the first mention in formal medical literature of the practice of isolation as a means of controlling disease, and until recently the control of communicable disease has been the prevailing and only concept of preventive medicine. If one studies the history of preventive medicine the reason for this concept is obvious, but if the new accomplishments in the field are to be placed in their proper perspective, the first realization must be that not the least of the recent advances has been recognition of the profound proportions and province of preventive medicine.

Simmons,² although recognizing Smillie's differentiation between public health and preventive medicine (namely, that preventive medicine is an individual responsibility and public health a community one), comes to the wise conclusion that these inevitably overlap and that the final responsibility rests with the medical and allied professions. He defines preventive medicine as "the sum total of all those services required to prevent disease and keep well people well." Armstrong³ has said "preventive medicine is not a specialty, but an attitude." Galdstone⁴ believes "the term preventive medicine is self-limiting in the adjective preventive." Smith and Evans⁵ give the following definition "the intervention of the physician or his technical allies in a limited range of situations in which specific diseases can be warded off or specific deterioration of the patient's condition can be forestalled." They take the broad view that preventive medicine has

a definite responsibility to prevent preventable disease, prevent the consequences of curable chronic diseases, and prevent or delay the consequences of nonpreventable, noncurable diseases.

Consideration of these definitions makes one believe with Stieglitz that preventive medicine is thus an integral part of the practice of medicine and has its function in all stages of the patient's existence, from the period of "preconception" to advanced age.

As a tribute to the oldest and still most active field in preventive medicine, advances in the control of communicable diseases are considered first.

COMMUNICABLE DISEASE

Significant increase in diphtheria morbidity in several states shows that immunization in childhood does not provide lifelong security, and that diphtheria is not a disease of infancy and childhood only. Eichelberger⁶ reports that 21 per cent of the cases reported in 1946 occurred in the age group ten to nineteen years. In a study of high-school groups in New York City he found that of previously immunized pupils, 20 per cent in junior high, and 18 per cent in senior high school were Schick positive.

Schick testing of American troops in Europe showed that 30 per cent of the persons under thirty-five years of age were Schick positive or combined reactors.⁷ (The reliability of the Schick test as a measure of immunity, although open to question, is at present the best means for mass determinations.) As a result of studies showing that diphtheria is becoming relatively more prevalent in the older age groups, and that childhood immunity does not

*The Prize Essay for 1949

†Formerly fourth year medical student Tufts College Medical School

last a lifetime, it is recommended that booster doses of 0.5 cc of diphtheria toxoid be given to Schick-positive reactors in the age group from ten to nineteen years. Whereas adults do not tolerate alum-precipitated toxoid well, persons in this age group showed no untoward reactions in the study made by Eichelberger.

The use of triple antigen as described by Sauer⁸ is one of the most recent contributions to childhood immunization. He obtained excellent levels of immunity to diphtheria, tetanus and pertussis by administering triple antigen — diphtheria and tetanus toxoids (refined) and pertussis vaccine (alum-precipitated) — after the sixth month of life. Alternate gluteal areas were used, and alum abscess almost completely eliminated when each deeply administered dose was terminated with 0.1 cc of air, and the site gently massaged.

The Chicago Pediatric Society⁹ recommends the schedules of active immunization shown in Table 1.

The Chicago Pediatric Society presents the following suggestion for passive immunization: diph-

theria poses every three or four years. The study demonstrated that this maintenance dose may be more important than the booster dose at time of injury since many deaths from tetanus occur within four days of date of injury.

Press¹¹ has expressed the following opinion in immunization against tetanus:

active immunization against tetanus as a practical public health measure is indicated. Until further information regarding the pathogenesis of the disease or a simple method of estimating the natural antitoxin level is available, it should be given routinely by private physicians, and should be included in health department programs for children.

The toxoid may be given with diphtheria toxoid, or pertussis vaccine, or combined with the two.

It is important that this routine immunization be done because as Press¹¹ points out, 50 per cent of the injuries leading to tetanus in the civilian population are either so inconsequential as to be entirely unknown or exceedingly trivial. Also, tetanus bacilli are widely distributed, more being found in human feces than that of horses, so that

TABLE 1 *Schedules of Active Immunization*

AGE OF CHILD	SCHEDULE A	SCHEDULE B	SCHEDULE C
3 mo	Triple antigen (slow absorbing)	Pertussis vaccine (slow absorbing)	
4 mo	Triple antigen (slow absorbing)	Pertussis vaccine (slow absorbing)	
5 mo	Triple antigen (slow absorbing)	Pertussis vaccine (slow absorbing)	
6 mo	Triple antigen (slow absorbing)	Pertussis vaccine (slow absorbing)	Triple antigens (fluid or slow absorbing)

8 mo		Diphtheria and tetanus antigens (fluid or slow absorbing)	Triple antigens (fluid or slow absorbing)
9 mo		Diphtheria and tetanus antigens (fluid or slow absorbing)	
10 to 12 mo		Smallpox vaccination	Smallpox vaccination
2 yr	Booster dose of triple antigen (fluid or slow absorbing)	Booster dose of triple antigen (fluid or slow absorbing)	Booster dose of triple antigen (fluid or slow absorbing)
3 yr	Booster dose of triple antigen (fluid or slow absorbing)		

theria, antitoxin (10,000 units) in known exposure of nonimmunized person, pertussis, human pertussis hyperimmune serum (20 cc) or hyperimmune globulin (2.5 cc) promptly when indicated, as in known exposure of nonimmunized infant or frail child (dosage as recommended by manufacturer), tetanus, antitoxin (5000 units), promptly administered in the nonimmunized after an injury that might lead to tetanus infection (subsequent immunization with tetanus toxoid is recommended), and measles, human serum globulin for modification or prevention when indicated, dosage recommended by manufacturer being used.

From a study by Banton and Miller,¹⁰ it appears that people should receive maintenance doses of tetanus toxoid as well as primary immunization and emergency injections when injury occurs. There is evidence that definite protection lasts for five years, but study of residual titers shows that periodic booster doses should be given for maintenance pur-

poses. The automobile age is no excuse for lessening our vigilance. Also, recognition of the undesirability of sensitizing people to horse serum that may be caused by the prophylactic use of tetanus antitoxin makes it more desirable to have a previous immunity that can be boosted by another dose of toxoid, which rarely has untoward reactions.

Mention of serum and globulin in immunization brings to mind the tremendous recent contributions made to preventive medicine by establishment of blood banks by hospitals, the American Red Cross and state departments of health. State and hospital services now provide for prenatal examination of blood for the Rh factor, the continued research and the development of facilities for the prevention of erythroblastosis fetalis due to this factor are a magnificent recent advance in preventive medicine.

The widespread use of blood and its derivatives has also presented problems that are now on the way to solution. Homologous serum jaundice and

infectious hepatitis have been recognized as two distinct diseases, varying in incubation period and mortality rate and possessing no cross immunity. Homologous serum jaundice is transmitted by blood and serum, and since there are no laboratory tests for detecting virus SH in plasma and serum, it is recommended that the practical and safe method of routine exposure to ultraviolet rays be made under properly standardized conditions. This causes no change in serum proteins except for a slight decrease in prothrombin and complement, and it inactivates the virus of serum hepatitis.¹² It is also a good idea to keep plasma pools as small as possible.

Since infectious hepatitis can be transmitted by yellow-fever vaccine and dehydrated, liquid and frozen plasma, as well as by flies, food, filth and contaminated water, the ordinary and well known hygienic precautions will prevent its spread. Also, gamma globulin, 300 mg per kilogram of body weight, will prevent an attack if given to an exposed person before the prodromal symptoms occur.

One of the most spectacular recent accomplishments in preventive medicine is immunization against tuberculosis with BCG. This vaccine has now begun to overcome the unfortunate publicity of the Lubec disaster, and is taking its rightful place, with isolation of open cases, as a major tool in the prevention of tuberculosis, which still ranks seventh in the causes of death, and is first cause in the young adult age group.

According to Birkhaug¹³ there are in the United States at the present time almost 180,000 cases of frank tuberculosis left at large to infect the healthy population.

Rosenthal and his co-workers¹⁴ in Chicago, after ten years' experience with BCG, confirmed the fact that vaccination with BCG (an avirulent and benign bovine tubercle bacillus, the bacillus of Calmette-Guérin) inhibits primary tuberculosis in a manner analogous to the specific resistance induced by spontaneous and clinically silent infection with virulent tubercle bacilli.

Hembeck¹⁵ states that in a group of student nurses working in the tuberculosis wards, victims of the disease were nearly always among the negative tuberculin reactors, and Madson,¹⁶ of Norway, believes that the primary tuberculosis complex produced in negative reactors by BCG vaccination is sufficient to protect against progression of a subsequently superimposed virulent infection. Norway, in 1947, made BCG vaccination compulsory for all persons under fifty years of age. The experience of Holm¹⁷ has been that morbidity and mortality among children in a tuberculous environment has been reduced, after vaccination, to almost zero. He believes BCG to give considerable if not absolute protection.

The BCG Advisory Committee of the State of New York made the statement that BCG

vaccination is the only known practical method of reducing mortality from tuberculosis.

It must be mentioned that the favorable comments on BCG are based on the premise that a positive tuberculin test offers more protection than a negative test — a fact still open to question among authorities. The present opinion of the medical profession is that until further work is done, BCG vaccination should be reserved for negative reactors who are constantly exposed to tuberculosis, such as doctors, nurses, attendants and students.

The development of BCG does not in any way lessen the necessity for diligently pursuing the course of case finding and isolation that has helped bring tuberculosis down from its place in 1900 as first in the leading causes of death.

As an aid in case finding, the detection of tubercle bacilli by fluorescent microscopy may shorten the time necessary to examine a slide, and may in time prove more accurate than the Ziehl-Neelsen staining method. It is valuable at present in screening tests, the standard Ziehl-Neelsen procedure being reserved for questionable fluorescent slides.¹⁹

Despite the enormous amount of publicity and immense sums of money spent in research, the problem of poliomyelitis remains unsolved at the present time. Recently, however, there has been a saner approach to its epidemiology. It is the consensus at present that it is not necessary to close churches, schools and movies, but places where children come in close contact with each other, such as swimming pools and playgrounds, should be closed. Activities leading to unusual fatigue should be avoided during epidemic time. Patients with poliomyelitis can be admitted to the wards of general hospitals if adequate precautions are carried out.²⁰ Control of flies is probably of value, but mass spraying of towns with DDT is not warranted in the light of present knowledge. The virus of poliomyelitis has been isolated in both the respiratory and gastrointestinal tracts of human beings, and close contact between human carriers plays an important part in transfer of the infection.²¹

The use of massive doses of penicillin in the treatment of syphilis and gonorrhea is well known and is making case finding an even more effective means of controlling these diseases. Another step forward is the prevention of congenital syphilis by treatment of the mother, early in pregnancy, with penicillin varying from 2,400,000 to 4,000,000 units and following the dosage with careful quantitative serologic titers.¹² Penicillin can be given as late as the seventh month with effect if the infant is viable at the time. Relatively small doses must be given at first, with careful follow-up study, if the Herxheimer reaction is to be avoided. If this is done there is little danger.

In the control of venereal disease considerable progress has been made in the field of education. The available clinics for treatment have been made

known to people, and at the same time the finger of scorn has been removed from those who come for help. The Army made a notable advance along this line when it recently removed the penalty involved when a soldier reported a case.²³

The morbidity and mortality rates of the armed forces for diseases endemic in war theaters represents an advance in preventive medicine so comprehensive as to be beyond the scope of this paper. However, a few accomplishments must be mentioned. One of these is sanitary control of environment by the use of DDT and its derivatives. It was discovered in Europe and the Pacific²¹ that in spite of being adequately vaccinated, men suffered from diseases diagnosed as typhoid and paratyphoid fever when sanitation broke down or when they ate raw vegetables from native fields heavily fertilized with human feces. This emphasizes the fact that preventive medicine is the dual responsibility of those who control the environment and those who seek to increase individual resistance and immunity.

The value of atabrine is now well known, but the important lesson to bear in mind is "that malaria can be controlled anywhere in the world, in any environment, when trained personnel are given the necessary supplies and authority."²⁵ Preventive medicine may sometimes evoke the same high pitch of enthusiasm that war does, and the combined efforts of research, education and action may bring about equally excellent results in the control of disease in civilian populations.

The streptococcal group of diseases has been the subject of considerable investigation. Lemon²⁶ has found that, "Chemotherapy with sulfadiazine (in the absence of resistant strains) or penicillin, newer techniques of environmental dust control with oil and air sanitation using germicidal vapors have been shown to have definite value in reducing possibilities for cross infection offered by nasal streptococcal dispersers."

The routine use of scarlet-fever immunization is not necessary, and it should be reserved for persons needing special protection, and for institutional precautions. Scarlet fever at present, for unknown reasons, is a mild disease, and preventive medicine is wisely engaged in seeking the relation of scarlet fever to possible sensitization with the hemolytic streptococcus.

Rheumatic fever is now being given the emphasis it deserves. Griffith²⁷ has recently pointed out that tuberculosis, syphilis and rheumatic fever remain the most important infectious problems in America. Whether one believes the disease to be infectious or allergic, or both, the fact is that rheumatic fever is still the leading cause of death (except for accidents) among persons five to nineteen years of age. It causes countless cardiac cripples in an age group in which inactivity is particularly

frustrating and economic insecurity especially depressing. So little is known concerning the disease that the only recent effective methods of control have been through organized community effort. Griffith²⁸ has suggested a pattern of study similar to the Framingham tuberculosis demonstration, in which objectives are outlined and public co-operation obtained for a specific program. He bases these ideas on the belief that rheumatic fever is a contact disease and that its epidemiology is the epidemiology of the Group A hemolytic streptococcus.

Experiments with groups of children suffering from rheumatic fever have shown fewer exacerbations of the disease in youngsters treated with prophylactic doses of sulfonamides the year around. The prophylactic use of penicillin preceding oral surgery in patients with rheumatic fever has prevented the occurrence of subacute bacterial endocarditis. The status of the sulfonamides, however, is not sufficiently established for prophylaxis to be made a routine procedure.

Some of the devastating effects of unknown heart disease in patients with mild unrecognized rheumatic fever, as well as those having congenital anomalies amenable to cardiac surgery, may be prevented if attention is paid to the results of mass x-ray study. In heart disease as well as in tuberculosis the development of technics for routine inexpensive mass x-ray examination of the population has made possible the detection of early lesions. Photofluorography has been a satisfactory means of suggesting cardiac abnormalities to be diagnosed by further clinical study. Berenson²⁹ states that these abnormalities should be looked for in all routine x-ray films, and his series suggests that the number of persons with demonstrable cardiac abnormalities on routine fluorograms is greater than that of patients with tuberculosis in a given population, and that incalculable gains can be made when unsuspected heart disease is diagnosed.

INDUSTRIAL MEDICINE

Industrial medicine, which has led in programs of preventive medicine for adults, has a particular responsibility and opportunity to carry on the health education of adults. The accomplishments in this early field of endeavor are well known, but recent recognition of the fact that chronic illness and impaired efficiency due to lack of optimum health of the employee are an important cause of low production and increased operating expense has led to increased emphasis upon attention to minor illnesses to prevent their becoming serious. "In general the frequency of impairment, as measured by reduced effectiveness, is in inverse proportion to the severity."³⁰ Though the incentive for industrial medicine has been largely a mercenary one, results have been excellent.

MATERNAL AND CHILD HYGIENE

In the field of maternal and child hygiene preventive medicine has made some of its greatest contributions to medical progress. The health and nutrition of the mother during pregnancy have been given considerable study.

Dietary deficiencies have been found to increase the incidence of miscarriages, premature births and stillbirths, and functionally immature infants may be produced by mothers with an inadequate diet during pregnancy.³¹ Wesselhoeft³² has shown that rubella during early pregnancy is a severe hazard to the unborn child and is a problem deserving national investigation and public support, as well as international research.

Early recognition and surgical correction of congenital defects, properly isolated and equipped facilities for the care of the premature infant, and more rigid control in the nursery all are factors in the continued decline in infant mortality.³³ Early ambulation of the mother has prevented many of the unfortunate sequelae of childbirth.

A specific virus has been found for five epidemics of diarrhea of the newborn, but a virus etiology cannot be assumed for a particular epidemic unless the diagnostic work has been carried out by experts. Regardless of the etiology, the fecal-oral route is the usual one causing outbreaks of infant diarrhea in nurseries, and at present the only method of prevention is scrupulous attention to the already well known nursery and formula-room technics. Strict aseptic technic may block the spread of virus as well as bacterial organisms, and the results in many hospitals have shown that by careful observance of rules epidemics can be prevented in spite of the personnel shortage and overcrowding.³⁴

Wise retreat may represent an advance. An example is the return to breast feeding, "demand" feeding and "rooming in"³⁵ that make the present-day baby luckier than his brother born ten years ago, when any resemblance to the normal mother-child relationship was purely coincidental.

Prophylaxis against allergy in children is possible according to Shulman.³⁶ He believes that a minor sensitization in a child can set off an extensive chain of symptoms, and that every precaution should be taken in infancy to defer upset of allergic balance in the potentially allergic person.

A program calls for no major deviation from generally accepted practice in infant care. All that is necessary is a knowledge of the infant's inherited allergic tendencies together with an awareness of the relative allergic potencies of each of the major foods and inhalants.

Two thirds of the cases of bronchiectasis develop in the first two decades of life, and much of the prevention lies in the hands of the pediatrician. Lobar and lobular atelectases lay the foundation for the development of bronchial dilatation by destruction of the bronchial wall. If bacterial pneumonias are

diagnosed early and adequate chemotherapy given, and if areas of atelectasis that follow pneumonias and acute respiratory infections are re-expanded promptly, especially in children, much bronchiectasis can be prevented. The immediate removal of foreign bodies and benign endobronchial tumors is another important preventive measure.³⁶

An outstanding contribution to preventive medicine for children has been made by the dental profession. The topical application of sodium fluoride to the teeth of children, when done under dental supervision, is effective in reducing dental caries. The United States Public Health Service has set up units all over the country to show the efficacy of this now proved remedy. The American Dental Association has given its approval with the statement "Fluoride therapy should be used routinely in private dental offices and in school and community health programs." The Dental Section of the American Public Health Association has gone on record as endorsing and encouraging the development of effective methods for making this service available.

GERIATRICS

From the enticing prospects of pediatric preventive medicine one must turn to the rapidly growing and newer field of geriatrics. Advances here have been concerned with the problem of preventing or delaying the consequences of the nonpreventable, noncurable diseases. These diseases — heart disease, cancer and nephritis — are the three leading causes of death and, together with cerebrovascular accidents, the fourth cause, represent the etiology of much of the disability of the aged and aging. At the present time one cannot do a great deal to prevent or cure these diseases, geriatrics is making most of its progress by teaching people how to live with, and within, their physical limitations. Arthritis, eye changes and mental hygiene have recently received the attention of the Indiana State Board of Health.³⁷ The New York State Department of Health gave up its entire June, 1948, issue of *Health News* to "Problems of the Aged." Massachusetts is devoting time and money to the problems of cancer, diabetes and other diseases of the aged. Recreation departments are beginning to realize that programs for persons over sixty-five are a part of their work, and many cities are establishing places of meeting and giving encouragement to clubs that will give happiness and contentment to those no longer in active work. The object of geriatric medicine is to add breadth and depth, rather than mere length, to life,³⁸ and most of its progress thus far has been in laying the unspectacular but necessary foundations.

One of the major tasks of preventive medicine is the maintenance of physiologic tone in the hope of delaying, mitigating or if possible preventing the degenerative and senescent changes that account for most diseases in later life. One of these diseases

is cancer, and an organized battle against this has begun on all fronts—epidemiologic, research and administrative. The adoption of the Papanicolaou technic for the cytologic diagnosis of cancer of the cervix, lung, prostate and stomach has decreased the mortality. The advantage of this technic is that it makes diagnosis possible in the early stage while surgery is still of use, stained smears often showing malignant cells before any symptoms are evident. The number of false-positive reactions is few, and the incidence of correct diagnoses ranges from about 85 per cent in cervical cancer³⁹ to 64 to 90 per cent in cancer of the lung⁴⁰. The Mayo Clinic has had some success with the identification of malignant cells in the urine by the use of the Papanicolaou method⁴¹. As yet, there are too few trained workers in this field, which is one of the newest and most promising in preventive medicine. State health departments are beginning to realize that the chronic diseases of middle age may be studied by epidemiologic methods, and until the etiology is known they will have to be attacked on the administrative rather than on the purely scientific front.

ACCIDENT PREVENTION

It does no good to save persons from death by disease, only to have them die from accidents. The National Office of Vital Statistics⁴² states, "Deaths from accidents among children five to nine years of age were three times as great in 1948 as the combined number of deaths from poliomyelitis, and pneumonia, perhaps the most feared of childhood diseases." Accidents now are fifth in the leading causes of death, and until they are removed from this position, must be considered a serious threat to the health of the nation. The medical profession through national, state and local associations has recently become aware of this problem, and is making a determined aid to effect accident-prevention programs. In the age group from ten to fourteen years accidents outranked diseases of the heart, the single greatest nonaccidental cause of death, nearly 5 to 1. Even among young persons in the group in which tuberculosis is the leading cause of death, with heart disease and pneumonia next in line, accidents accounted for nearly twice as many deaths as the three together.

NUTRITION

The relation between food and preventive medicine is an ancient one. The Laws of Moses and Aaron⁴³ recognized that food may be a source of infection. The British Navy, in 1795, included lime juice in its rations, for the prevention of scurvy. Advances in food sanitation and vitamin requirements are beyond the scope of this paper, but the work of Schneider⁴⁴ in nutrition and natural resistance to infectious disease must be mentioned. He has localized, but not isolated or identified, in the

germ of whole wheat, a new nutritional entity. This agent has been responsible for the increased survivorship in specific breeds (host-genotype) of mice exposed to varying virulences (pathogen-genotype) of typhoid. Dr. F. J. Stare has called this work the highlight of the 1948 Food and Nutrition Section meetings of the American Public Health Association.

The fact that good nutrition not only prevents disease but also is responsible for positive health has long been known. Positive health, not merely the absence of disease, is the most recent and highest objective of preventive medicine, and notable scientific achievements have been made in the field of optimum nutrition. One might reasonably expect, therefore, a population in positive nitrogen balance. Unfortunately this is not true. The gap between what is known and what is done is widened by educational and economic problems that are not so easily solved as the equations of biologic oxidation.

MENTAL HEALTH

Although preventive medicine has made remarkable progress in all lines of endeavor, its most significant advance in recent years has been the attention that it has given to mental health. Modern society demands that its members live under a tension that is overwhelming, and many have failed to keep the pace required. As standards of living have improved, the need for psychiatry has increased. This is especially true in the very early and very late years of life.

The need of the child for help in adjusting himself to disturbing family situations and the high speed of life in general is being met by the work of such organizations as the Judge Baker Foundation and the James Jackson Putnam Children's Center in Boston, The Philadelphia Child Guidance Clinic, The Langley-Porter School in San Francisco, the Orthogenic School in Chicago, and the Rochester Child Health Institute in Minnesota. These centers not only offer help to the unadjusted child, and thus prevent mental ill health in later life, but also provide training centers for professional personnel. Their aim is preventive psychiatric and "well child" service. Another outstanding advance in this field is the formation of the Association of Psychiatric Clinics for Children, with Dr. Frederick H. Allen as president. Much of the prophylaxis of mental sickness begins in childhood, and the value of child psychiatry in preventive medicine is just now being realized. Dr. Allen⁴⁵ says, "The future of this all-important field is full of promise."

There is also the inevitable relation between physical and mental health. Psychosomatic medicine may well be considered a recent advance in the field of mental hygiene. "Physiological tone is so intimately connected with emotional balance that dynamic psychiatry is an indispensable tool of preventive medicine."

EDUCATION

The recent scientific advances in preventive medicine have put an additional burden upon the doctor, for as Clark⁴⁶ says, "it is safe to say that at least three-fourths of the preventive work made possible by present day medical science must be carried by the practicing physician." Have there been advances in methods of helping the physician to meet this increased responsibility? I believe there have been. Preventive medicine has been recognized as a logical and important part of the medical-school curriculum. Smith and Evans⁵ have outlined the work of the department of preventive medicine as follows: to teach the medical student what he needs to know about available techniques for the prevention of communicable diseases, to give him understanding of epidemiology, and quantitative methods in medical science, to sensitize him to opportunities for arresting the development of noncommunicable disease, to make him aware of the patient as a person and thus to initiate him more fully into the art of medicine, and ultimately to show him how medicine can help to maintain or increase productive energy in both normal and handicapped persons.

These ideals of education will enable the physician to lessen the gap between what the scientist has discovered and what the people know and do. This is a difficult task. It is easier to vaccinate than to educate, but as surely as vaccination overcomes smallpox, education will overcome the ignorance that makes for misery. Long,⁴⁷ however, believes that in time preventive medicine will be taught entirely by the clinical approach, and that when it reaches this ideal a separate department will be unnecessary. This ideal represents an advance in the philosophy of preventive medicine that, when fully realized, will mean that the physician is truly educated to its possibilities.

* * *

The recent advances in preventive medicine have been as diverse as the subject itself. This paper has touched lightly upon a few of them. Perhaps the accomplishments most significant have not been mentioned, for these lie in the invisible realm of thought. Yesterday, on the threshold of bacteriologic science, Sir William Osler said, "preventive medicine is the medicine of the future," and today, on the threshold of the atomic era, one can say that without preventive medicine there will be no future.

CASE 35261

PRESENTATION OF CASE

A fifty-five-year-old businessman entered the hospital because of abdominal pain and vomiting.

One night six weeks before admission the patient awoke feeling nauseated, and vomited several times. There was no pain. Business and family worries had been plaguing him, and for several months he had felt tense and nervous. After this episode he remained in bed for four days, and then returned to work. Late at night following days on which financial problems had been particularly trying, spells of painless vomiting recurred. Two weeks before admission he left work. The nocturnal vomiting became more frequent and began to be accompanied by severe cramps starting in the back and radiating around to the midline in a viselike manner. He was given pills and put on a bland diet without relief. Two days before admission the frequency of vomiting increased to every two or three hours, no food or fluid was retained. The vomitus consisted of food, fluid and mucus without blood. The bowels had been moving only with laxatives or with enemas. The stool color was normal. During this illness there was a 25-pound weight loss.

During examination the patient was tense and uncomfortable, constantly shifting position in an effort to relax. When the activity reached a peak, he vomited. The speech was rambling, and he had difficulty recalling dates and time. The heart was normal. There was dullness over the left lower lobe posteriorly and in the left axilla, breath sounds and tactile fremitus being reduced in the same areas. The abdomen showed tenderness and spasm throughout the epigastrium. Peristalsis was active. There were no masses.

The temperature was 98.6°F, the pulse 88, and the respirations 20. The blood pressure was 135 systolic, 90 diastolic.

Examination of the blood revealed a hemoglobin of 14.6 gm per 100 cc and a white-cell count of 9600. The urine gave a + test for albumin, and the sediment contained rare casts. The icteric index was 13.

In the hospital the patient was tense and frequently nauseated but appeared to obtain considerable relief from hot baths so that he stopped vomiting and was able to drink water. On the third hospital day the skin and scleras were slightly jaundiced. A surgical consultant found a tender mass in the epigastrium extending to both sides of the midline, but slightly more to the left. The edges of the mass were indefinite, the whole mass was about 15 cm in diameter. Rectal examination was negative. On the same day the gastrointestinal series showed some thickening of the gastric folds, and there was evidence of pressure along the lesser curvature and the posterior wall. The duodenal loop was enlarged (Fig 1), the second portion was displaced to the right and showed evidence of somewhat lobulated compression from the region of the pancreas that also displaced the third portion of the duodenum downward. There were several diverticula in the colon. The spleen was enlarged. There was considerable fluid in the left pleural cavity. Linear areas of atelectasis showed in both lower lobes of the lungs, and the motion of both leaves of the diaphragm was slightly limited. On the following day the icteric index was 25, and the serum amylase was 78 units per 100 cc. Three hundred and fifty cc of opaque, amber fluid, which proved to be sterile, was removed from the left chest. The temperature remained normal.

An operation was performed on the fifth hospital day.

DIFFERENTIAL DIAGNOSIS

DR RICHARD WARREN. This case presents the problem of differential diagnosis of an epigastric mass, which caused considerable vomiting, slight jaundice and fluid in the left chest. I think we can assume at the outset that since most of the symptoms were localized in the epigastrium, the fluid in the left chest was a sympathetic effusion from infradiaphragmatic disease. Furthermore, it seems logical to suppose that this infradiaphragmatic disease was not necessarily of a suppurative nature. The normal white-cell count would not necessarily convince me of this, were it not also true that the pulse and the temperature were normal. Conditions, therefore, that might lead to the more conventional type of subhepatic and left subdiaphragmatic abscess, such as perforated peptic ulcer and phlegmonous gastritis with abscess, I tend to put into the background. This decision is particularly forceful if one considers that the gastrointestinal series showed no evidence of either.

A perforated gall bladder is unlikely for the same reasons, in addition to the fact that the symptom of pain did not make itself evident until well along in the present illness.

There is so much evidence in this case pointing toward the pancreas—namely, the depression of the lesser curvature of the stomach, the displace-

ment laterally of the second portion of the duodenum, the pain in the back, the elevated serum amylase and the slight jaundice — that it is difficult to escape the conclusion that the lesion was in that organ.

The question regarding the nature of the disease then arises. I believe there are two major types to be considered. The first, and least likely, is apoplexy or rupture of some branch of the splenic artery that could cause a large mass in this region and simulate disease of the pancreatic parenchyma itself. Such ruptures, however, are usually catastrophic and run a more rapid course than this. Furthermore, a hemorrhage causing a mass of this size would have caused an anemia, which was not present. I would vote against apoplexy.

The second type of disease in this patient, and the one that I feel to be most likely, is acute pancreatitis with areas of pancreatic necrosis leading to formation of a so-called pseudocyst of the pancreas. Such a cyst very often occupies the whole lesser omental cavity extending to the diaphragm and causing sympathetic pleural effusion above. It generally contains a serous type of fluid with active pancreatic enzymes within it, although these enzymes often erode small blood vessels and cause rather massive bleeding within the cavity of the cyst. If the cyst is seen early it may contain broken down bits of pancreatic tissue and then is generally termed a pancreatic abscess. The jaundice is caused by inflammatory edema of the head of the pancreas — squeezing of the lower end of the common duct rather than encroachment on the common duct by the cyst. I am not prepared to say definitely what the contents of this cyst were but believe they were of such a nature as to put the mass on the borderline between pancreatic abscess and pancreatic cyst. My diagnosis, therefore, is a large inflammatory pseudocyst of the pancreas causing pleural effusion.

DR REGINALD LINGLEY To begin with, I think this would have to be a tumor of the pancreas. The duodenal loop is tremendously enlarged. There is pressure on the lesser curvature of the stomach so frequently associated with pancreatic tumor. The irregular mucosa in the second portion of the duodenum and the presence of what looks like small nodules are very much against a cyst. A cyst of the pancreas is sharply defined and smoothly rounded. Although it can produce a pressure defect on the fundus of the stomach and enlargement of the duodenal loop, the enlargement is smooth and sharply defined whereas this is quite nodular. This is not a usual place for an aortic aneurysm. We usually see it on the left side. This extends to the right and corresponds exactly to the head of the pancreas. In addition to the abdominal findings we have fluid in the chest on the left and areas of atelectasis.

DR CLAUDE E. WELCH This was an interesting problem in differential diagnosis. The rapid appearance of the epigastric mass, with jaundice and left pleural effusion combined with severe prostration, made me believe that we were probably dealing with a subacute pancreatitis and a large pseudocyst of the pancreas. Carcinoma of the pancreas was considered as an alternative possibility.

The patient's rapid decline made it clear that unless some dramatic relief could be obtained rapidly by operation he would die. Accordingly he was explored with little delay. At operation he was

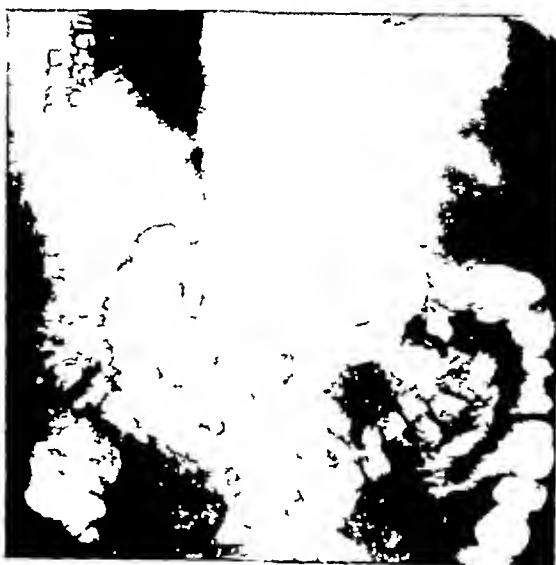

FIGURE 1

found to have a great deal of bloody fluid throughout the abdomen, with small nodules that were grossly typical of fat necrosis. There was a large hard mass involving the entire pancreas and posterior wall of the stomach. Several of the nodules were removed for biopsy, and a jejunostomy was performed.

CLINICAL DIAGNOSIS

Acute pancreatitis

DR WARREN'S DIAGNOSIS

Inflammatory pseudocyst of pancreas

ANATOMICAL DIAGNOSES

Adenocarcinoma of pancreas, with retroperitoneal and splenic extension, and with microscopic metastases to lungs and kidney

Hydrothorax, bilateral

Atelectasis, left lung

Adenoma of islets of Langerhans, microscopic

DR TRACY B MALLORY The biopsy specimen removed by Dr Welch showed a tumor that we thought was epithelial in origin and consistent with primary cancer of the pancreas. The patient went rapidly downhill after operation and died. At post-mortem examination we found the pancreas almost totally replaced by tumor. The same tumor had grown into the hilus of the spleen and occupied two thirds of the spleen. There were metastatic extensions along the retroperitoneal lymph nodes, no metastases in the liver and microscopic metastases to the lung. The sections confirmed the original impression that this was a primary carcinoma of the pancreas. The fact that it had involved the spleen so extensively would suggest that it started near the tail of the pancreas and only secondarily reached the head.

CASE 35262

PRESENTATION OF CASE

A seventy-two-year-old widow was admitted to the hospital because of pain in the right knee.

Thirty to forty years before admission the patient first noted pain, swelling and stiffness of her knees. Multiple tooth extractions and a tonsillectomy and adenoidectomy were done. She was told that she had "tapioca in the knees," and this was aspirated. An infection developed in her left knee following this procedure and drained for a long time. Both knees were ankylosed. Subsequently she had gradual involvement of all joints, with progressive ankylosis and deformity. Twenty-seven years before admission she was treated with a two-month course of radium water, with no relief. Ten years before admission when the right ankle became ankylosed in inversion, the patient received treatments to stretch the ligaments. During this procedure the right tibia and fibula were fractured. The patient became progressively more crippled, with discomfort and stiffness of the joints. There was no real pain until a year before admission, when, while being lifted, she felt her right knee crack. Since then she had constant pain in the right knee, which became swollen. There was no increased heat or redness. An x-ray film showed a pathological fracture with rarefaction of the medial portion of the end of the femur. There were no constitutional symptoms, and in general she felt well.

Six years before admission a uric acid stone was removed from the left kidney.

On physical examination the temperature, pulse and respirations were normal. The blood pressure was 140 systolic, 80 diastolic.

There was limited motion and deformity of all joints. The right knee was swollen and tender, most marked medially. There was no motion of either knee.

The specific gravity of the urine was 1.020, and there was a + test for albumin. The hemoglobin was 13.2 gm and the white-cell count was 8000, with a normal differential. The sedimentation rate was 1.33 mm per minute, and the hematocrit was 40 per cent. The blood serum calcium was 9.3 mg, and the phosphorus 4.2 mg per 100 cc, and the phosphatase was 3.4 units.

An x-ray examination of the right knee showed a markedly narrowed joint, and the adjacent bones were extensively osteoporotic, consistent with old rheumatoid arthritis. Occupying the medial distal extremity of the femur was a large area of bone rarefaction measuring 10 cm in length by 8 cm in width (Fig 1). There was a thin cortical shell medially and posteriorly, while in places there appeared to be loss of continuity of the cortex without, however, frank extension of the mass into the adjacent soft tissues. The lesion had definitely grown in size in comparison with the films taken elsewhere, three months before admission. The femoral shaft above the lesion appeared dense, and its trabeculae somewhat wider than in the left knee, which showed extensive changes of old rheumatoid arthritis.

On the eighth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR THOMAS ANGLEM* We might start by looking at the x-ray films.

DR STANLEY M WYMAN This is the original film taken elsewhere, and here is a film taken in comparable projection three months later. The area of bone rarefaction is well demonstrated in the distal femur occupying the femoral condyles. There is an unusual accumulation of amorphous, very dense calcification seen in the lateral aspect of the lesion, with a few small less definite areas of calcification in this region. This is present on both films, and

*Assistant professor of surgery, Boston University School of Medicine surgeon, Massachusetts Memorial Hospitals

is seen on other projections to lie definitely in the lesion. The increase in size in the mass is quite apparent compared to the films in similar projection, and one can make out tiny slivers of what I take to be cortical bone remaining, with, in a few places, loss of continuity of the bone. The shaft of the right femur is denser than the left, but the findings are not typical of Paget's disease. Changes, which are quite typical of old, long-standing rheumatoid arthritis, are seen in both knee joints, and osteoporosis is also well demonstrated.

DR. ANGLE: There are many significant points in this history. The patient had pain in the knee for one year. It seems clear that she had an unmistakable rheumatoid arthritis, which however I do not believe had any bearing on the real issue in this case. Twenty-seven years before admission she had a course of treatment with radium water. This may be a red herring, but on the other hand it may have played a definite part in the etiology of this lesion. Ten years before entry she sustained a fracture of the right tibia and fibula in the course of manipulation of the foot for inversion, which suggests that the bone was unusually friable and this may perhaps be classed as a pathological fracture. In the course of her present illness she sustained another pathological fracture of the right knee while being lifted. Six years before admission she is reported as having had a uric acid stone of the kidney. Another point that seems of some significance is that she was said to have felt well otherwise. Her only complaint was with reference to the pain in the knee.

On examination the knee showed swelling and tenderness. Her laboratory findings showed nothing of particular significance. The urine gave a + test for albumin. The blood was virtually within normal limits, with a normal calcium, phosphorus and phosphatase, and the sedimentation rate was within normal limits.

The diagnosis, I believe, will rest chiefly on the interpretation of the x-ray films. I think the first thing one has to decide about this lesion is whether it was a benign bone cyst of some kind or a tumor — if a tumor, whether it was benign or malignant, primary in bone or metastatic.

Regarding bone cyst, I am certain that this was not a solitary bone cyst, which usually occurs in the shaft of long bones and is extremely uncommon at this age. The cysts occur almost entirely in childhood or adolescence and are very rare after

twenty-one years of age. I believe that we can dismiss bone cyst.

The possibility of cystic change in the bone secondary to parathyroid adenoma is suggested, at least superficially, by the history in this case. The x-ray films are reported as showing some osteoporosis

FIGURE 1

of the adjacent bone. She is also reported as having had a kidney stone in the past, and there is a history of pathological fracture on two occasions, so that one has to consider this possibility. On the other hand we have no support in the laboratory findings to warrant such a diagnosis. The blood calcium, phosphorus and phosphatase were normal, and although it is possible for parathyroid adenoma to exist with findings within normal range, I do not believe that such a situation existed here. The old

DR TRACY B MALLORY The biopsy specimen removed by Dr Welch showed a tumor that we thought was epithelial in origin and consistent with primary cancer of the pancreas. The patient went rapidly downhill after operation and died. At post-mortem examination we found the pancreas almost totally replaced by tumor. The same tumor had grown into the hilus of the spleen and occupied two thirds of the spleen. On examination the knee showed swelling and tenderness. Her laboratory findings showed nothing of particular significance. The urine gave a + test for albumin. The blood was virtually within normal limits, with a normal calcium, phosphorus and phosphatase, and the sedimentation rate was within normal limits.

The diagnosis, I believe, will rest chiefly on the interpretation of the x-ray films. I think the first thing one has to decide about this lesion is whether it was a benign bone cyst of some kind or a tumor — if a tumor, whether it was benign or malignant, primary in bone or metastatic.

Regarding bone cyst, I am certain that this was not a solitary bone cyst, which usually occurs in the shaft of long bones and is extremely uncommon at this age. The cysts occur almost entirely in childhood or ad

twenty-one years of age. I believe that we can dismiss bone cyst.

The possibility of cystic change in the bone secondary to parathyroid adenoma is suggested, at least superficially, by the history in this case. The x-ray films are reported as showing some osteoporosis

FIGURE 1

of the adjacent bone. She is also reported as having had a kidney stone in the past, and there is a history of pathological fracture on two occasions, so that one has to consider this possibility. On the other hand we have no support in the laboratory findings to warrant such a diagnosis. The blood calcium, phosphorus and phosphatase were normal, and although it is possible for parathyroid adenoma to exist with findings within normal range, I do not believe that such a situation existed here. The old

renal calculus was a uric acid and not a calcium stone. I think that we can dismiss benign cystic disease of bone and consider the tumors.

Was this a benign tumor? The only benign tumor that is suggested to me is benign giant-cell tumor. There are features that suggest it rather markedly. The position of the lesion — at least the involvement of the epiphysis — is characteristic of benign giant-cell tumor, and the general contour of the lesion is similar to what one sees in benign giant-cell tumor in this area. On the other hand the degree of extension up the shaft of the bone is unusual, and the areas of density described are not commonly seen in benign giant-cell tumor. The so-called aggressive type of giant-cell tumor, which is undergoing malignant change, must be considered. I believe that this was a malignant tumor, and whether or not it was primary or secondary must still be considered.

Another primary tumor that one has to consider in patients of this age is solitary myeloma. It occurs frequently in old people, although it is not a common disease. Opposed to this diagnosis we have the fact that the patient felt well otherwise, which is not usually the case with myeloma. The patient with myeloma usually has some degree of general malaise, weakness and a greater degree of anemia than this patient showed. There is no report of Bence-Jones protein in the urine, and while its absence is not particularly significant, it would be of significance if present. The serum protein is not reported, it is usually elevated with myeloma. The sedimentation rate is also usually elevated. The x-ray appearance of the lesion does not suggest myeloma.

Reticulum-cell sarcoma must be considered although it is not common at this advanced age. It occurs generally, however, in the shaft of the bone, and the osteolytic lesions produced by this disease do not resemble the x-ray picture that we see in this case. I do not believe that we are dealing with reticulum-cell sarcoma.

Of the primary tumors of bone the diagnosis that I am most strongly attracted to as an explanation of this patient's difficulty is osteolytic osteogenic sarcoma. There may or may not have been a relation between this patient's history of ingestion of radium water twenty-seven years previously, and the lesion in question. During the past twenty-five to thirty years there have been a

quack remedies on the market purporting to contain radium. Many did not, but on the other hand there were some that actually did contain radioactive material. If the so-called radium water actually contained radioactive substance it may have been responsible for this lesion. One point that is a bit further suggestive of this possibility is the reported appearance of osteitis in the shaft of the femur above this lesion. Osteogenic sarcoma when it occurs as the result of radioactive material occurs on the basis of pre-existing osteitis, which is caused by the radioactive material in the bone. We have some evidence here of a pre-existing osteitis that may have been of significance in the development of this degenerative lesion.

One has to consider metastatic lesions in this case. And, of course, the strongest point against metastasis is the complete absence of anything in the history or physical examination suggestive of a primary lesion elsewhere. Of the types of malignant tumors of soft tissue or other parts of the body capable of producing osteolytic bone lesions, the most common are breast, thyroid, kidney and adrenal gland, and of these the breast is by all odds the commonest. On the other hand it is very unusual for breast cancer to produce metastases without the breast lesion itself being easily discoverable clinically. It is not mentioned in this history. Carcinoma of the thyroid gland, adrenal gland and kidney may produce metastatic lesions of bone, and they may make their appearance some time before the primary disease is discovered. These possibilities have to be considered, but they do not as a general rule occur in the end of long bones.

On a purely statistical basis, a lesion such as this, even a solitary lesion, occurring at this age is several times more likely to be metastatic than a primary tumor of bone. On the other hand the definite history of ingestion of radium water and the appearance of the lesion on x-ray examination tempt me to make a diagnosis of osteolytic osteogenic sarcoma secondary to radiation osteitis from the ingestion of so-called radium water.

DR. WYMAN: There is one point to add to Dr. Anglem's excellent discussion. We did not have the history of the ingestion of radium water at the time the films were interpreted, and we tended to a diagnosis of osteogenic sarcoma based on possible Paget's disease. However, this is by no means the picture we usually see in Paget's disease, and I

her favor Dr Anglem's diagnosis, knowing about the radium now

CLINICAL DIAGNOSIS

Osteogenic sarcoma

DR ANGLEM'S DIAGNOSIS

Osteolytic osteogenic sarcoma secondary to ingestion of "radium water"

ANATOMICAL DIAGNOSIS

Fibrosarcoma of femur, invading knee joint, possibly related to ingestion of "radium water"

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY About a dozen years ago we had a patient in this hospital who was likewise an arthritic and had taken so-called radium water for treatment. She kept it up for a long period, several years, and samples were tested and proved actually to contain radioactive substances. In the case under discussion we have not that positive evidence. The other patient developed a tumor of the knee in exactly the same location as this patient, and the lesion turned out on pathological examination to be a fibrosarcoma, which rapidly metastasized and caused her death.

It is a rather striking coincidence that in the case under discussion the tumor was also in the knee region, involving both the femur and the knee joint, and was also a fibrosarcoma rather than an osteogenic sarcoma. We were not able to demonstrate any radioactivity of tumor or bones. Examination with a Geiger counter was negative, whereas in the preceding case it was definitely positive. But I have a rather strong suspicion that the radioactive material may have had something to do with the development of the tumor but cannot prove it.

DR WYMAN What were the changes found in the bone proximal to the lesion?

DR MALLORY Not very striking — mild osteoporosis was all we found. In the earlier case the changes were much more extensive, and there was a marked hematopoietic reaction in the bone marrow of the femur, it almost suggested the picture of pernicious anemia.

The lesion occupies the lower end of the shaft of the femur. It extends up beyond what was the epiphyseal line into the diaphysis. The knee joint is completely fused by the old arthritic and septic process. With the specimen in one's hand one can see that the tumor has extended across the slight remnants of the joint space and involved the posterior surface of the patella.

LICENSURE OF FOREIGN GRADUATES

THE Council on Medical Education and Hospitals of the American Medical Association, taking cognizance of the number of foreign physicians who are entering this country with the hope of establishing themselves here has sponsored an unofficial committee on foreign medical credentials. The membership of this committee is made up of representatives of a number of organizations, including several state licensing boards. Its function is to investigate the entire matter of the licensing of foreign medical graduates and to make recommendations for the solution of the problems involved.

The difficulties that have arisen concerning these physicians, many of them inadequately trained as a result of thirty years of unsettled conditions abroad, have been recognized for some time, and the manner in which they have been met has already been discussed in these columns.*

The migration to the United States of foreign schools began about 1926, and of this and conditions brought about War II, many states have raised their requirements for licensure. The New York Board of Medicine, for instance, no longer admits to the state licensing examination graduates of European medical schools who matriculated since January 1, 1914, with the possible exception of graduates of universities of Cambridge, of London, of Dublin, and of Ireland. This drastic step has been taken for due cause, in the last twenty years 66 per cent of the foreign physicians taking the examination have failed to pass. In Massachusetts no graduate of any foreign medical school who matriculated later than January 1, 1941, have been permitted to register, except those from Canada.

These matters require serious study in order that foreign schools may as soon as possible be evaluated as are those in the United States and Canada. Reasonable justice in licensure cannot be attained until the quality of the training of applicants can be appraised.

ANNALS OF WORLD HEALTH

THREE years ago the first steps were taken to organize an international health conference. The conference prepared a constitution for the proposed World Health Organization, which became an official specialized agency of the United Nations in April 1948, after 26 member nations had signified their acceptance of the constitution. By January of 1949, 58 nations had become members of WHO.

WHO now publishes in English, French, Spanish, Russian and Chinese each month the *Chronique* which contains general information concerning the trend of its work and summaries of its most technical publications, the *Bulletin*, which presents signed articles on subjects under consideration by the organization such as the control, prophylaxis and treatment of malaria, tuberculosis, venereal and epidemic diseases, a weekly epidemiologic record, epidemiologic and vital-statistics reports and fifteen volumes of official records. These publications are obtainable at moderate cost from the sales section of WHO, Palais des Nations, Geneva.

*Editorial "Of thee I sing" *New Eng J Med* 239:152, 1948

expressed aim of the World Health Organization—the improvement of the physical, mental and health of all peoples. Such improvement is badly needed. It was thought that progress is actually being achieved in this direction before it is a generation of cataclysmic disintegration. No one is skeptical of the capacity of the human mind for any sort of co-operative effort. WHO offers the few remaining opportunities to demonstrate that such skepticism is not justified. If science, the humanities and religion can get out of politics, there is still hope. May this noble organization be able to point to considerable growth and achievement three years hence!

DR. BERRY AT HARVARD

Dr. George Packer Berry, dean for Harvard Medical School has been selected and will take office on July 1, 1949. Dr. C. S. Burwell who has held the administrative position for nearly thirteen years and who announced earlier in the academic year his intention of returning to teaching and research, is to be succeeded by Dr. George Packer Berry at present professor of bacteriology and associate dean of the School of Medicine and Dentistry at the University of Rochester.

In addition to his deanship Dr. Berry, whose previous investigative work has been in the fields of immunology and virology, will hold an appointment as professor of bacteriology. A native of Troy, New York, Dr. Berry graduated from Princeton University in 1921 and from the Johns Hopkins University School of Medicine in 1925. After resident services in the Connecticut State Hospital for the Insane, in Bellevue Hospital in New York and in the Johns Hopkins Hospital, he became an assistant and later instructor in medicine in Johns Hopkins University School of Medicine. From 1929 to 1932 he was assistant resident physician in the Hospital of the Rockefeller Institute for Medical Research and an associate of the Institute. He became professor and head of the Department of Bacteriology and associate professor of medicine at Rochester in 1932, and in 1947 became associate dean. In 1946 Dr. Berry, as an officer

of the Naval Reserve on active duty, took part in the atomic-bomb tests at Bikini Atoll.

Dr. Berry is a diplomate of the American Board of Internal Medicine and a fellow of the American Association for the Advancement of Science, the American Public Health Association and the American

GEORGE P. BERRY, M.D.

of the American Medical Association. A former president of the American Association of Immunologists, he has also served as vice-president of the Association of American Medical Colleges.

The *Journal*, in welcoming Dr. Berry to New England, at the same time congratulates Harvard on his acquisition, wishing them both a mutually profitable and extended relationship.

A GOOD INSECTICIDE, NOT A POISON

A STATEMENT was recently issued by the Department of Agriculture and the Federal Security Agency calling attention to the proved value of DDT as an insecticide. Some public alarm has been caused by misleading comments concerning possible haz-

ards connected with the use of this chemical. It is pointed out that DDT has contributed materially to the welfare of the world, and should not be brought into disrepute through overemphasis of the well recognized fact that it has toxic properties, especially if improperly used. The ingestion of a tube of toothpaste, or a cake of soap or a bottle of cleaning fluid might be injurious or fatal, and yet they are harmless and useful substances if properly employed.

The fact that DDT, like other insecticides, is a poison, has been given full consideration in the formulation of recommendations for its use. "There is no evidence that the use of DDT in accordance with the recommendations of the various Federal agencies has ever caused human sickness due to the DDT itself despite the fact that thousands of tons have been used annually for the past four or five years, in the home and for crop and animal protection." As a precautionary measure modifications of recommendations have recently been made by the Department of Agriculture for the use of DDT on dairy cattle. There is, however, no justification for any public alarm about the safety of the milk supply from the standpoint of possible DDT contamination. This has been agreed upon by the Department of Agriculture, the Army and the Navy, the Pan-American Sanitary Bureau and the Federal Security Agency.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

COFFIN — Susan M. Coffin, M.D., of Boston, died on June 1. She was in her sixty-ninth year.
Dr. Coffin received her degree from Boston University School of Medicine in 1910.
A nephew survives.

CONDRIK — James F. Condrick, M.D., of Quincy, died on May 27. He was in his sixty-fourth year.
Dr. Condrick received his degree from Tufts College Medical School in 1919.
His widow survives.

GIDDINGS — Harold G. Giddings, M.D., of Newton, died on May 28. He was in his seventieth year.
Dr. Giddings received his degree from Harvard Medical School in 1907. He was a member of the staff of the Newton-Wellesley Hospital and of the Board of Consultation of the Massachusetts General Hospital and was formerly chief of surgery of the Whidden Memorial Hospital in Everett. He was a former president of the Middlesex South District Medical Society and chairman of the Committee on Arrangements of the Massachusetts Medical Society, for many years he had been a councilor of the Society. He was also a fellow of the American College of Surgeons.
His widow, two sons and a sister survive.

McCORMICK — William A. McCormick, M.D., of New Bedford, died on February 21. He was in his fifty-eight year.

Dr. McCormick received his degree from Tufts College Medical School in 1914.

His widow, a daughter, a brother and three sisters survive.

MULHERN — Joseph P. Mulhern, M.D., of Worcester, died on March 6. He was in his fifty-eighth year.

Dr. Mulhern received his degree from Tufts College Medical School in 1918. He was a visiting surgeon, orthopedic service, St. Vincent Hospital, member of the courtesy staff in orthopedics, Hahnemann Hospital, and consulting surgeon in orthopedics and president of the board of trustees, Worcester City Hospital. He was a fellow of the American College of Surgeons and American Medical Association.

His widow, six daughters and two sons survive.

NEW HAMPSHIRE MEDICAL SOCIETY

DEATH

ABBOTT — Edson M. Abbott, M.D., of Rochester, died on May 14. He was in his eighty-first year.

Dr. Abbott received his degree from University of Vermont College of Medicine in 1898.

His widow survives.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS

The July schedule for Consultation Clinics for Crippled Children in Massachusetts under the provisions of the Social Security Act follows:

CLINIC	DATE	CLINIC CONSULTANT
Haverhill	July 6	William T. Green
Salem	July 11	Paul W. Hugenberger
Gardner	July 12	Carter R. Rowe
Springfield	July 12	Garry deN. Hough, Jr.
Brockton	July 14	George W. Van Gorder
Worcester	July 15	John W. O'Meara
Pittsfield	July 20	Frank A. Slowick
Fall River	July 20	David S. Grice
Hyannis	July 28	Paul L. Norton

Physicians referring new patients to clinics should get in touch with the district health officer to make appointments. Patients are seen by appointment only.

COMMUNICABLE DISEASES IN MASSACHUSETTS FOR APRIL, 1949

DISEASE	RÉSUMÉ		
	APRIL 1949	APRIL 1948	SEVEN YEAR MEDIAN
Chancroid	5	0	2*
Chicken pox	2485	1973	1973
Diphtheria	42	18	18

Whooping cough			

*Five year median

COMMENT

Diseases whose incidence was above the seven-year median were chicken pox, diphtheria, German measles and typhoid fever

Diseases whose incidence was below the seven-year median were bacillary dysentery, measles, mumps, salmonellosis, scarlet fever and whooping cough

Diphtheria was at the highest level for the month of April since 1934

The seasonal peak for measles was reached in March this year, and that for scarlet fever in February

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Diphtheria was reported from Arlington, 1, Ayer, 1, Billerica, 1, Boston, 30, Cambridge, 4, Malden, 2, Quincy, 2, Somerville, 1, total, 42

Dysentery, amebic, was reported from Brookline, 1, total, 1

Dysentery, bacillary, was reported from Brockton, 1, Wrentham, 1, total, 2

Encephalitis, infectious, was reported from Marshfield, 1, Needham, 1, Watertown, 1, Worcester, 1, total, 4

Infectious hepatitis was reported from Newton, 1, Norwood, 1, Wrentham, 6, total, 8

Lymphocytic choriomeningitis was reported from Fitchburg, 1, Framingham, 1, Somerville, 1, total, 3

Malaria was reported from Lynn, 1, total, 1

Meningitis, meningococcal, was reported from Newton, 1, Worcester, 1, total, 2

Meningitis, Pfeiffer-bacillus, was reported from Brockton, 1, Gardner, 1, Haverhill, 1, Hull, 1, Milton, 1, Salem, 1, Westfield, 1, West Springfield, 1, total, 8

Meningitis, pneumococcal, was reported from Fall River, 1, Worcester, 1, total, 2

Meningitis, undetermined, was reported from Braintree, 1, Fall River, 1, Taunton, 1, Wakefield, 1, total, 4

Poliovirus was reported from Springfield, 1, total, 1

Salmonellosis was reported from Greenfield, 1, Newton, 1, total, 2

Septic sore throat was reported from Boston, 6, Cambridge, 1, Lynn, 2, Templeton, 1, total, 10

Tetanus was reported from Milford, 1, total, 1

Trichinosis was reported from Cambridge, 1, total, 1

Typhoid fever was reported from Boston, 1, Cambridge, 1, Fairhaven, 1, Lakeville, 1, Randolph, 1, total, 5

Undulant fever was reported from Dartmouth, 1, Ware, 1, total, 2

DISCONTINUANCE OF PAPANICOLAOU SMEAR SERVICE

Because of the large number of smears, and as a result of curtailment of federal funds allocated to the Department of Public Health, it has become necessary for the Massachusetts State Tumor Diagnosis Service to discontinue its service of Papanicolaou smear diagnosis to the cancer clinics of the Commonwealth for the time being

CORRESPONDENCE

DR FROTHINGHAM IN REBUTTAL

To the Editor I appreciate your giving me an opportunity to reply to Dr Rawls's letter published a week ago in the *Journal*. May I also take this opportunity to commend your attitude of offering all sides an opportunity to present their viewpoint on this controversial subject of the development of a national health program

If one will read the inaugural address of Dr Rawls mentioned in his letter and my letter in the February 17 issue of the *Journal* I believe it will be evident that Dr Rawls's letter adds nothing to the clarification of my claim that in his inaugural address there were misstatements of fact and misleading innuendoes. Therefore it seems to me that no useful purpose will be served in discussing the various statements in his letter

I should like, however, to say that the Committee for the Nation's Health has never tried to hide the fact that it endeavors to influence legislation in a proper manner, and in accordance with law has always registered as lobbyists members of the group who are paid for this service. In addition to this activity the Committee devotes much more of its time in endeavoring to unite throughout the country the millions of citizens who are interested in the development of a national health program to be financed in part by compulsory health insurance and in educating all the people in the value of such a program

CHANNING FROTHINGHAM, M.D.

Chairman, Committee for the Nation's Health
101 Bay State Road
Boston 15, Mass

DRAMAMINE IN MENIÈRE'S DISEASE

To the Editor For the past thirteen years, I have suffered from Ménière's disease, with only temporary relief from any form of treatment that has been tried

In March, 1949, having read about the effect of dramamine on motion sickness, as used by Dr Leslie N. Gay and Dr P. E. Carliner at the Johns Hopkins Hospital in Baltimore, I communicated with a representative of G. D. Searle and Company, and Dr Lee D. van Antwerp, about the effect of dramamine on Ménière's disease. I received the following reply from Dr van Antwerp:

At the present time there is no information available concerning the usefulness of dramamine in Ménière's disease, but we readily recognize a causal relation between the pathology of that condition and the presumed disturbed physiology of motion sickness. It is my understanding that Dr Leslie N. Gay, of Johns Hopkins, is currently conducting a study of the usefulness of dramamine in Ménière's disease, although his information is not yet complete

I then communicated with Dr Carliner and asked him if they had had any experience with the use of dramamine in Ménière's disease. Dr Carliner replied that they had 30 people on dramamine in their investigative work, and I asked to be added to the list. I have been on dramamine since March 15, 1949, with a dramatic and immediate cessation of all vertigo and a 75 per cent improvement in tinnitus and some improvement in hearing in my left ear

In April, 1949, I asked Dr Henry L. Haines, of New London, Connecticut, to try dramamine on patients who had Ménière's disease. He now informs me that he has put 3 patients on the drug with immediate and dramatic improvement

It is hoped that further experience with the use of dramamine in the treatment of Ménière's disease may be obtained so that its benefits can be accurately determined

WILLIAM V. WENER, M.D.

Norwich, Connecticut

BOOK REVIEWS

Peripheral Vascular Diseases: Diagnosis and treatment. By David W. Kramer, M.D. With a foreword by Edward L. Bortz, M.D. 8^{vo}, cloth, 620 pp., with 157 illustrations. Philadelphia: F. A. Davis Company, 1948. \$8.00

This vascular-conscious period welcomes a treatise based on practical experience and aimed at correlating the accelerated contributions to this ever-expanding field. With this view in mind, Dr Kramer has succeeded in presenting a readable, lucid, orderly discourse, supplemented with excellent illustrations and tabular differential diagnoses, on peripheral vascular diseases that should constitute a reliable *cadre mecum* for the student, general practitioner and internist.

The subject is treated comprehensively in five parts, as follows: symptoms, signs and tests, occlusive arterial disorders, vasomotor disturbances, gangrene and ulcers, and veins, anticoagulants, antibiotics and lymphedema. In the first section on history, symptoms, signs and tests, it is pleasing to see the term "claudication" unmasked and called

by its synonymous term "cramps" — whether of the intermittent or rest type. In the reviewer's teaching and clinical experience, the term "intermittent claudication" always seemed to connote to the uninitiated a symptom pathognomonic only of thromboangitis obliterans. In the same section the author misses an opportunity, however, to stress the value of inquiring into the history of ingestion of various drugs causing peripheral vascular disease, notably ergot. He does, it is true, devote a later discussion on ergotism under the heading of gangrene and ulcers. In neither the former section under color, as a sign, nor in the latter, does the author refer to the frequently observed, tell-tale, coxcomb color, which characterizes this type of lividity. There is an excellent, illustrated discussion on focal gangrene in diabetes in this section. The chapter on tests is a specific and well illustrated presentation, with a final evaluation. The new tropidore method for reflex vasodilatation carries no reference, it might be the author's own technic, of course. In actual performance, it appears that the author favors the histamine test for capillary appraisal, the sphygmomanograph or recording oscilometer for arterial trunk evaluation, and dermatohemic, skin-temperature determinations, before and during general anesthesia by gas, gas ether or cyclopropane, rather than paravertebral block, for vasomotor response. The skin-temperature charts, though simple and adequate, might be labeled more clearly or revised for the purpose of more precise exposition.

In the second section, on occlusive vascular disorders, there is an excellent discussion of acute arteritis, periarteritis nodosa and endarteritis obliterans, as well as the more common conditions. Apropos of the statement under thromboangitis obliterans that failure of increase in skin temperature after vasomotor tests constitutes a contraindication to ganglionectomy, the reviewer's experience to the contrary does not permit him to subscribe to this only partly correct view. Likewise, issue might be taken with Dr Kramer's statements that ganglionectomy is attended by an objectionable "mortality rate" (not specified) and that it is a "formidable" procedure. Regarding embolic occlusion, no reference is made to the limb-saving procedure of radical decompressing fascial incisions in popliteal-artery embolism or acute thrombosis.

In the section on vasospasm the author presents a clear picture of the various and obscure conditions mediated by neuroendocrine dysfunction. This clarification of Raynaud's disease, scleroderma, scalenus anticus syndrome, pneumatic hammer disease, erythromelalgia and so forth is a valuable contribution to understanding of the etiology and clinical characteristics of this perplexing group of conditions. Under Raynaud's disease the author does not stress the currently accepted doctrine of preganglionic section. In the treatment of the acute phase of traumatic arteriospasm, paravertebral ganglionic block, repeated if necessary, is not mentioned.

A good résumé of the entire field of peripheral vascular disease from the obverse side is afforded in the fourth section on gangrene and chronic leg ulcers with, however, several surgical shortcomings, such as failure to mention femoral-vein ligation, lumbar ganglionectomy and the Linton operation in the treatment of chronic varicose and post-phlebotic ulcers.

The last section is devoted to veins, antibiotics and lymphedema with, again, characteristic excellent clinical descriptions. The ubiquitous problem of varicose veins is discussed fully, and in its development, the discussion contains a desirable and complete review of the various tests employed in the study of this condition. From the surgical point of view there is room for disagreement with the author's preference for high saphenous ligation and retrograde sclerosing injection in the light of the modern trend toward stripping, total or segmental, or multiple ligation, or both.

To the reviewer Dr Kramer's book is obviously an internist's treatise, lacking in the highly important details of surgical treatment. In the light of this criticism it cannot be accepted that the author fulfilled his aim, as stated in the preface, of "the value of explicitness" in the treatment of these disorders. The author might have warned the reader of his legitimate limitation of discussion of surgical techniques to general terms. This treatise does, however, "lead the reader through the basic subjects into diagnosis and treatment" with clarity, ease of style and a wealth of bibliographic information.

Premature Infants. A manual for physicians. By Ethel Dunham, M.D. 8°, paper, 401 pp., with 31 illustrations and frontispiece. Washington, D.C.: United States Government Printing Office, 1948. \$1.25. Children's Bureau Publication No. 325, 1948.

It may be said that this so-called manual constitutes an up-to-date treatise on prematurity and the general care of the premature infant. The subject is important, and it is estimated that 5 per cent of all births in the United States fall into this class, and that the single greatest cause of infant mortality in the first month of life is premature birth, which accounts for half of all infant deaths in this period. The text is divided into two main parts: "General Considerations," analyzing the incidence, causes, and prevention of immaturity, and the growth and development of premature infants, and "Clinical Considerations," dealing with physical problems and clinical care, including the neonatal period, resuscitation, incubator care, nutritional congenital malformations and birth injuries, infectious abnormal blood conditions, metabolic and nutritional disturbances and other conditions. Dr Dunham is well qualified to write this comprehensive guide. She received her degree from Johns Hopkins University School of Medicine and taught in the Pediatric Department of the Yale University School of Medicine before joining the Children's Bureau in 1927. She is a member of the American Pediatric Society and a fellow of the American Academy of Pediatrics. The material is well organized, and the text well written. An extensive bibliography is appended to each part, and there is a good index. The type and printing are excellent. The book is worth a number of times its low price and should be in all medical libraries and in the collections of all obstetricians and pediatricians.

Report of the Sanitary Commission of Massachusetts 1851. By Lemuel Shattuck and others. With a foreword by Charles Edward Winslow. 8°, cloth, 321 pp. Cambridge: Harvard University Press, 1948. \$4.50.

This reprint of a classic on public health is only partial for it does not contain the appendix of 218 pages and the index. The original report comprised 544 pages and was issued in a heavy, paper cover. This appendix is important since it contains many of the factual data upon which the report of the Commission was written. The Commission consisted of Lemuel Shattuck, Nathaniel P. Banks, Jr., and Jehie Abbott. Although the report is attributed to the Commission, the actual author was Lemuel Shattuck, of Boston. The partial reprint is preceded by a foreword by C. E. A. Winslow, a noted expert on the subject, in which he states:

Surely this is an outstanding document for the year 1850 and it has its message for us in 1948. Johann Peter Frank, Cbadwick, Simon, Sedgwick, Cbapin, have written classics in the science of public health, but I know of no single document in the history of that science quite so remarkable in its clarity and completeness and its vision of the future.

The original report was a state document, and two thousand copies were printed — a large number for the period. Despite this comparatively large number of copies the report is very rare and commands a high price. The reprint is well published and even in its abbreviated form should be in all medical libraries and public-health collections.

Economic Man. In relation to his natural environment. By C. Reinold Noyes. In two volumes. 8°, cloth. Vol. I, 692 pp.; Vol. II, 751 pp. New York: Columbia University Press, 1948. \$15.00 for the set.

This treatise is an important medical reference work. The first six chapters, and their appendixes, of nearly five hundred pages, constitute a mass of new material in the biological sciences, including physiology and especially neurophysiology, classified under the heading of "wants," present and future. In formulating his synthesis Mr. Noyes has consulted a great number of scattered research articles and reports. Likewise, the most recent research on the brain has been utilized. The work has been in progress for seventeen years. Mr. Noyes, although an economist, has an excellent background for the biologic aspects of his subject. He is a graduate of Yale University, and pursued

special studies at Johns Hopkins University in the Department of Psychology and in the Medical School. Additional extensive research was done in the libraries of the New York Academy of Medicine, Columbia University and Dartmouth College. A bibliography of 450 titles is appended to the text. There is a good index. The treatise should be in all biologic libraries and in the reference collections of medical school and regional medical libraries.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return or the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The Thyroid and its Diseases. By J. H. Means, M.D., Jackson Professor of Clinical Medicine, Harvard Medical School, and chief of the medical services, Massachusetts General Hospital. With chapters on *Pathology*, and on *Tumors of the Thyroid*, by R. W. Rawson, M.D., assistant professor of medicine, Harvard Medical School, and associate physician, Massachusetts General Hospital, and on *Surgery of the Thyroid*, by Oliver Cope, M.D., assistant professor of surgery, Harvard Medical School, and visiting surgeon, Massachusetts General Hospital. 8°, cloth, 571 pp., with illustrations. Second edition. Philadelphia: J. B. Lippincott Company, 1948. \$12.00.

This standard treatise has been thoroughly revised and brought up to date since the publication of the first edition in 1937. It reflects the work carried on in the Thyroid Clinic of the Massachusetts General Hospital. Special chapters on surgery of the thyroid gland by Oliver Cope, M.D., and on pathology and on tumors by R. W. Rawson, M.D., have been added. Lists of references are appended to the various chapters, and there is a good index. The volume is a good example of excellent publishing. It is essential for all medical libraries and to all persons interested in the thyroid gland.

The Hygiene of the Breasts. By Clifford F. Dowkontt, M.D. 12°, cloth, 222 pp., with illustrations. New York: Emerson Books, Incorporated, 1948. \$2.50.

This popular manual is written by a surgeon who specializes in plastic surgery of the breasts. It is hoped that it will encourage women to take better care of their breasts. There is a special chapter on corsets. The text is concluded with a glossary of terms and an index.

Manual of Urology. By R. M. LeComte, M.D. Fourth edition. 8°, cloth, 311 pp., with 58 illustrations. Baltimore: Williams and Wilkins Company, 1948. \$4.00.

This manual was first published in 1933. Four years have elapsed since the printing of the third edition. The text has been revised and brought up to date, and the use of penicillin and streptomycin has been included. The volume is intended for the student of urology. The material is well arranged, and there is a good bibliography and an index of subjects. The book is well published.

Neurosurgical Pathology. By I. Mark Scheinker, M.D., assistant professor of neuropathology and assistant professor of medicine (neurology), University of Cincinnati College of Medicine and neuropathologist and attending neurologist, Cincinnati General Hospital. 8°, cloth, 370 pp., with 238 illustrations. Springfield, Illinois: Charles C. Thomas, 1948. \$3.75.

This book is well published. The price is reasonable for this type of publication. The volume should be in the reference collection of all medical libraries and available to all neurosurgeons.

Bronchiogenic Carcinoma and Adenoma. With a chapter on mediastinal tumors. By B. M. Fried, M.D., associate attending physician, Montefiore Hospital for Chronic Diseases,

New York. 8°, cloth, 306 pp., with 118 illustrations. Baltimore: Williams and Wilkins Company, 1948. \$6.00.

In this monograph Dr. Fried discusses the anatomic and physiologic aspects, clinical manifestations, laboratory diagnosis and treatment of bronchiogenic carcinoma and adenoma, and mediastinal tumors. The work is based on a large clinical experience and the study of post-mortem material. Lists of selected references are appended to the different chapters. A good index concludes the text. The volume should be in all medical libraries and should prove of value to all physicians interested in the subject.

Methods in Medical Research. Volume I. Van R. Potter, editor-in-chief. 8°, cloth, 372 pp., with illustrations. Chicago: Year Book Publishers, Incorporated, 1948. \$8.00.

This volume forms the first of a projected series and is the joint work of forty-nine contributors. The text is divided into four sections: assay of antibiotics, circulation and blood-flow measurement, selected methods in gastroenterologic research, and cellular respiration. The various articles present the latest methods, techniques and apparatus pertaining to the special subjects under discussion. Lists of selected references are appended to the more important articles. The work is well published. It is an essential reference book for all medical libraries and clinical laboratories.

Deafness, Tinnitus, and Vertigo. By Samuel J. Kopetzky, M.D., director of the department and professor of otolaryngology, New York Polyclinic Medical School and Hospital. 8°, cloth, 314 pp., with 30 illustrations and 10 tables. New York: Thomas Nelson and Sons, 1948. \$7.50.

This monograph covers the whole field of deafness and allied conditions from anatomy to therapy. The tenth chapter discusses the pathological findings and criteria indicating rationally applied therapy in one hundred pages. Pertinent references are appended to the various divisions of the text. The volume is well published and should be in all medical reference collections and in the libraries of specialists on the subject.

Education for Professional Responsibility. A report of the proceedings of the inter-professions conference on education for professional responsibility held at Buck Hill Falls, Pennsylvania, April 12, 13, and 14, 1948. 8°, cloth, 207 pp. Pittsburgh: Carnegie Press, 1948. \$3.00.

This volume reports a conference participated in by eighteen leaders in the fields of education in divinity, medicine, law, engineering and business. The subject matter is divided into three parts on professional education: the objectives, content and method, and social and humanistic aspects. Medicine was represented on the panel by William W. Beckman, of Harvard, George P. Berry, of the University of Rochester, and Aura E. Severinghaus, of Columbia. A short bibliography concludes the text. The lack of an index detracts from the reference value of the book. The volume is well published and should prove valuable to persons interested in the subject.

Hemolysis and Related Phenomena. By Eric Ponder, The Nassau Hospital, Mineola, New York. 8°, cloth, 398 pp., with 69 illustrations. New York: Grune and Stratton, 1948. \$10.00.

This monograph constitutes a second edition of the author's *The Mammalian Red Cell and the Properties of Hemolytic Systems*, first published in 1934. The text has been amplified and is concluded with a bibliography and indexes of authors and subjects. The publishing is excellent. It is noted with pleasure that a light, soft, nonglare paper has been used for the volume, which should be found in all medical reference collections and should prove useful to specialists in its field.

A Brief History of The South Carolina Medical Association To which are added short historical sketches of various medical institutions and societies of South Carolina. 8°, cloth, 197 pp., with illustrations and frontispiece. Charleston: South Carolina Medical Association, 1948.

This brief history of the state society also includes the county societies, miscellaneous societies, special societies

and state institutions. The society was founded in 1848, and this volume is issued in commemoration of its centenary. In actuality it comprises a short history of medicine in South Carolina for the past hundred years. There is a special chapter on the ether controversy in which it is claimed that ether was first used for the purpose of producing insensibility by Dr. P. A. Wilhite, of Anderson, South Carolina, in 1841. The text is the joint work of twenty-five authors supervised by a special committee of the Society. A good index concludes the volume. The publishing is excellent.

Hungerkrankheit, Hungerödem, Hungertuberkulose. Historische, klinische, pathophysiologische und pathologisch-anatomische Studien und Beobachtungen an ehemaligen Insassen aus Konzentrationslagern. By A. Hottinger, O. Gsell, E. Uehlinger, C. Salzmann and A. Labhart. With a preface by Oberst K. Kistler, Zürich, director of the Militärsanitätsanstalt 4. 8°, cloth, 297 pp., with 171 Abbildungen. Basel: Benno Schwabe and Co., 1948. Ganzleinen Fr. 28.

This monograph is based on a study of 5000 severely wounded and sick soldiers hospitalized in Switzerland during 1944 and 1945. "Hungerkrankheit" may be freely translated as chronic illness due to insufficient food over a long period. The text is divided into five parts. The first constitutes a short, historical sketch, the second a clinical study of the cases of Hungerkrankheit and their treatment, the third and fourth the clinical aspects, pathogenesis and pathological anatomy of Hungerkrankheit and Hungerödem, and the fifth tuberculosis as a complication of hunger disease. The monograph is well published, but the lack of an index detracts from its value as a reference book. It should be in all the large medical libraries and in all collections on metabolism and tuberculosis.

Klinik und Therapie der Leptomeningitiden für Ärzte und Studierende. By Hermann Czickeli. 8°, paper, 95 pp. Vienna: Wilhelm Maudrich, 1948. \$2.00.

This monograph discusses the various types of meningitis. An appendix concerns the technic of lumbar puncture. Thirty-seven pages are devoted to epidemic cerebrospinal meningitis. There is a valuable table on the changes in the spinal fluid in various diseases of the central nervous system. The material is well organized. A short bibliography ends the volume. Unfortunately, there is not an index. The monograph should be available to all physicians interested in the subject.

The Rh Blood Groups and Their Clinical Effects. By P. L. Mollison, A. E. Mourant, and R. R. Race. 8°, paper, 74 pp. London: His Majesty's Stationery Office, 1948. 1s. 6d. net. Privy Council Medical Research Council Memorandum No. 19.

In this small pamphlet Dr. Mollison presents the latest information on the Rh blood groups. The text is divided into three parts: the Rh groups, clinical considerations, and Rh testing. Selected references are appended to each part.

Die vegetativen Anfälle des Herzens. By Kurt Polzer and Walter Schober. 8°, paper, 97 pp. Vienna: Wilhelm Maudrich, 1948. \$2.50.

In this monograph the heart conditions due to the action of the sympathetic nervous system are discussed. The material is well organized, proceeding from anatomy and physiology to treatment. There is a bibliography and an index. The pamphlet should be available to physicians interested in cardiology.

Erinnerungen, Erfahrungen und Methoden eines Praktikers. By Eduard von Hueber. 8°, paper, 72 pp. Vienna: Wilhelm Maudrich, 1948. \$1.00.

This small pamphlet is devoted to the achievements, ideas and methods of a general practitioner. Two thirds of the text deals with therapeutics, and the remainder with diagnosis.

Psychiatry in General Practice. By Melvin W. Thorner, M.D., D.Sc., assistant professor of neurology, The Graduate School

of Medicine, University of Pennsylvania. 8°, cloth, Philadelphia: W. B. Saunders Company, 1948. \$.

This new book on psychiatry has been written primarily for the general practitioner and the internist. The text is purposely simple and nontechnical, and the material is well organized. The text is divided into two main parts. The first discusses the various types of psychiatric problems. The second deals with examination, diagnosis and treatment. Two appendixes contain important material on the classification of mental disorders and on commitment procedures including an analysis of the law in the various States. References to the literature are appended to each chapter. A good index concludes the book. The publishing is excellent in every way. The volume should be in all medical libraries and should be available to all physicians.

The Surgery of Abdominal Hernia. By George B. Mair, M.D., F.R.F.P.S.G., F.R.C.S.E., surgeon, Law Junction Hospital, Lanarkshire. 8°, cloth, 408 pp., with 138 illustrations. Baltimore: Williams and Wilkins Company, 1948. \$7.00.

Dr. Mair, in this monograph, endeavors to clarify many points of etiology and treatment. He has been concerned with the high rate of recurrence and attributes it in part to faulty technique. The work is primarily intended for those who are especially interested in hernia, including anatomists, physiologists and sociologists. The text is well written, and lists of selected references are appended to the various chapters. There is a good index. The book is well published in every way. The illustrations are excellent. The monograph should be in all medical libraries and available to all surgeons.

Human Biochemistry. By Israel S. Kleiner, Ph.D., professor of biochemistry and director of the department of physiology and biochemistry, New York Medical College, Flower and Fifth Avenue Hospitals. Second edition. 8°, cloth, 649 pp., with 77 illustrations and 5 color plates. St. Louis: C. V. Mosby Company, 1948. \$7.00.

This textbook for students, first published in 1945, has been revised, and the material brought up to date. A new chapter has been added on chemical structure in relation to biologic phenomena. Lists of references are appended to the various chapters. There is a comprehensive index. The material is well organized. The publishing is excellent. The volume should prove useful to students and others interested in the subject.

Diseases of the Adrenals. By Louis J. Soffer, M.D., associate attending physician, The Mount Sinai Hospital, New York City, and assistant clinical professor of medicine, Columbia University College of Physicians and Surgeons, New York City. Second edition. 8°, cloth, 320 pp., with 45 illustrations and 3 color plates. Philadelphia: Lea and Febiger, 1948. \$6.50.

This second edition of a standard work has been thoroughly revised and brought up to date. The material is well arranged, and the book is well published. Bibliographies are attached to the different chapters, and there is an index. The volume should be in all medical libraries.

Crime and the Mind. An outline of psychiatric criminology. By Walter Bromberg, M.D. 8°, cloth, 219 pp. Philadelphia: J. B. Lippincott Company, 1948. \$4.50.

This special monograph was developed from the clinical study of hundreds of convicted criminals. The case material was derived from the Court of General Sessions, New York, and several United States Navy prisons. The text is divided into two parts. The first discusses the legal and social environment of the criminal. The second deals with the individual criminal, including the psychopathic personality, the neurotic offender and emotional immaturity and crime. The last chapter, entitled "Cure of Crime," stresses the value of psychotherapy. There is an extensive bibliography and a good index. The text is well printed with a good type on good paper. The book should be available to all psychiatrists and psychologists.
